In Figure 8-5, two experiments with bovine serum albumin under different conditions, with and without added electrolyte, are presented. As with the measurements shown in Figure 8-1, it can be seen that the virial coefficient, B , changes appreciably with changes in conditions; in this case it even inverts in sign because the protein is participating in a concentration-dependent oligomerization in the absence of electrolyte. Bovine serum albumin readily self-associates to form adventitious dimers, trimers, and higher oligomers.⁴⁰ The intercepts, however, again remain the same. It has been shown that under the same conditions with the same protein, the same values of the second **virial coefficient** are obtained by measurements of either osmotic pressure or light scattering.⁴¹ This result demonstrates that the virial coefficient is a property of the solution itself rather than the method of measurement, and it provides further evidence that these techniques are both measuring the same property of the solution. From the extrapolations in Figure 8-5, the molar mass of bovine serum albumin was estimated to be $70,200 \text{ g mol}^{-1}$, which is within 6% of the actual value of $66,430 \text{ g mol}^{-1}$.

From an examination of Equation 8-32, it is clear again that the units chosen for C_{prot} , the concentration of protein (units centimeter⁻³), determine the units (units mole⁻¹) of the parameter W . If the concentration of protein is known in grams centimeter⁻³, the units on W will be grams mole⁻¹, or molar mass. The determination of the molar mass, however, will only be as accurate as the measurement of the concentration of protein.

Electrospray mass spectrometry⁴² is widely used to

Figure 8-5: Light scattering by solutions of bovine serum albumin.³⁹ The Rayleigh ratio $R_{90,u}$ (centimeters⁻¹) was determined for each of a series of solutions of bovine serum albumin, each at a different concentration (γ_{prot} ; milligrams centimeter⁻³), by measuring the scattering of unpolarized light (u) at an angle θ of 90° . The quotient $\gamma_{\text{prot}}(R_{90,u})^{-1}$ was calculated for each measurement and plotted as a function of the concentration of protein (γ_{prot}). Measurements were made in 0.15 M sodium chloride (upper line) or in water (lower line) of solutions prepared by diluting an isoionic solution of albumin into the appropriate solutions. determine the molecular masses of proteins. Individual vaporized molecules of protein, each molecule with its own particular charge, are submitted to mass spectrometry (Figure 8-6).⁴³ From the envelope of individual peaks, precise estimates of the mass of the molecule of protein can be calculated. For example, it was possible to show that the molecular mass of the blue copper protein rusticyanin from *Thiobacillus ferrooxidans* was 16,552 Da, which is within 1 Da of the mass calculated from its amino acid sequence.⁴⁴

Major **applications** of mass spectrometry are the analysis of posttranslational modification, the verification of the integrity of a preparation of protein, and the assessment of the number of subunits in an oligomer. For example, in the case of rusticyanin the conclusion drawn from the mass spectrometric analysis was not that the molecular mass of the protein was 16,552 Da, which was already known, but that the protein lacked posttranslational modifications. In the case of the L1 metallo- β lactamase of *Stenotrophomonas maltophilia*, mass spectrometric analysis demonstrated that the normal posttranslational removal of the 21 amino-terminal amino acids had occurred,⁴⁵ and in the case of subunit V of ubiquinol-cytochrome-*c* reductase, mass spectrometric analysis demonstrated that the iron-sulfur cluster was

Figure 8-6: Mass spectrum of aldehyde dehydrogenase (NAD) from rat liver.⁴³ The purified protein was vaporized by electrospray, and the resulting gaseous ions were passed into a mass spectrometer. The relative abundance of each ion is plotted as a function of the ratio (m/z) of its molecular mass to its charge. Four ions of the single subunit (54.87 kDa), bearing charges of +15 (m/z = 3658 Da), +16 (m/z = 3430 Da), +17 (m/z = 3228 Da), and +18 (m/z = 3049 Da), are labeled M for monomeric. The six ions labeled T, bearing assigned charges of +29 (m/z = 7568 Da), +30 (m/z = 7316 Da), +31 (m/z = 7080 Da), +32 (m/z = 6859 Da), +33 (m/z = 6651 Da), and +34 (m/z = 6455 Da) were designated as molecular ions of a tetramer of four subunits (219.48 kDa) because the monomer could have produced only ions of +7 (m/z = 7839 Da), +8 (m/z = 6859 Da), and +9 (m/z = 6096 Da) in this range of masses. Because three peaks lie between each of these positions, the species producing all of these peaks must be ions of a tetramer.

present.⁴⁶ Electrospray mass spectrometry was used to verify that each member of a set of site-directed mutants of dethiobiotin synthase from *E. coli* contained the intended amino acid replacement.⁴⁷ Mass spectrometry can also discover errors in a sequence. For example, in the case of subunit I of bovine ubiquinol-cytochrome-*c* reductase, electrospray mass spectrometry indicated correctly that the published amino acid sequence of the protein was missing 27% of its amino acids.⁴⁶ Intact molecules of a protein containing several subunits (Figure 8-6) can be vaporized to obtain the molecular mass of the oligomer,⁴⁸ and membrane-bound proteins can be vaporized after the phospholipid in which they are normally dissolved has been removed from them.⁴⁹

Now that the sequences of so many proteins are known, as well as the stoichiometries of their subunits, precise values of molar mass can be calculated for a large array of proteins from their atomic compositions. These can be compared with values determined by osmotic pressure, sedimentation equilibrium, and light scattering before the actual molar masses were known (Table 8-1). By and large, the agreement between the actual values of molar mass and the measured values is quite close, and this in itself validates the methods.

The problem with molar mass, no matter how accurately it can be determined, is that it means very little to most people. Once it was clear that proteins were polymers of amino acids, sometimes posttranslationally modified, the reason behind all determinations of molar mass has been to estimate the **number of amino acids** that are contained in a given polypeptide and the number of polypeptides that are contained in a given protein. These are quantities that anyone can understand. Unfortunately, the results have seldom been presented in these terms even though they always could have been.

As it happens, the mean molar mass of an amino acid in most proteins is a reasonably constant number, $110 \pm 3 \text{ g mol}^{-1}$ (Table 8-2). When the **mean molar mass of an amino acid** is calculated from the amino acid composition of a set of proteins containing a total of 43,250 amino acids (Table 7-4),⁷² the value obtained is 109.3 g mol^{-1} . It follows that the number of amino acids in most proteins can be estimated by simply dividing an estimate of its molar mass by 110 g mol^{-1} , after glycosylation and other posttranslational modifications are accounted for.

It should not be imagined, however, that the molar mass is a more fundamental number while the number of amino acids in a protein is somehow an approximation. It has already been pointed out that expressing C_{prot} in the units of grams centimeter⁻³ during determinations of molar mass is an arbitrary choice. Were C_{prot} expressed in terms of moles of amino acids centimeter⁻³, each of the procedures would have necessarily provided as accurate a value of W in terms of moles of amino acids (mole of protein)⁻¹ rather than grams (mole of protein)⁻¹. The ability to determine molar masses by physical measure-

Table 8-1: Comparison of the Actual Molar Masses of Selected Proteins and the Molar Masses Determined by Light Scattering, Osmotic Pressure, and Sedimentation Equilibrium

protein	subunit stoichiometry	molar mass (kg mol ⁻¹)

mean molar mass of an amino acid = 110 ± 3

^aProteins composed of one or more polypeptides, the sequences of which were available in the Swissprot data bank, were chosen as examples. An attempt was made to include examples of all types of proteins, but extremely unusual proteins such as collagen were avoided. The constituent polypeptides the compositions of which were used are indicated. ^bThe lengths of the polypeptides chosen for analysis are presented in numbers of amino acids. ^cCalculated by dividing the molar mass of the protein portion of the polypeptide or polypeptides by the length or combined lengths, respectively.

ments has always relied ultimately upon the ability of the investigator to make an accurate **measurement of dry weight**. All values of molar mass can be traced back to such a determination. The difficulties involved in measurements of dry weight have been noted,¹⁸ and more than anything else, the accuracy of the values in Table 8-1 are a testimony to the careful measurements of this quantity. Accurate dry weight measurement, however, requires more protein than is usually available, and other measures of protein concentration have unfortunately but necessarily supplanted it. Ironically, when the amount of protein is in short supply, the most accurate method for assessing its concentration is quantitative amino acid analysis, which is a measure of moles of amino acids centimeter⁻³, and the use of A_{280} to follow protein in sedimentation equilibrium actually is a measure of the concentration of tyrosine and tryptophan in the solution.

One of the most peculiar manifestations of the abiding infatuation with molecular mass is the habit of naming proteins on the basis of estimates of the molecular mass performed by electrophoresis of their complexes with dodecyl sulfate. For example, protein p27 from simian retrovirus SRV-1 has an actual molecular mass of 24.73 kDa,⁷³ and protein p56 from murine lymphoma has an actual molecular mass of 57.82 kDa.⁷⁴ It is unclear what will be done when two-digit numbers run out.

Part of the description of a particular protein is an enumeration of the length of each of the polypeptides from which it is composed and the number of each subunit that it contains. At one time this information could be most conveniently learned by ascertaining both the molar mass of the entire protein and the molar mass of the isolated individual polypeptides. The history of this quest is interesting but beyond the scope of the present discussion. In two celebrated instances, that of aspartate carbamoyltransferase and that of fructose-bisphosphate aldolase,^{75,76} disagreements arose over the results from such measurements. These particular disagreements coincided with the development of the two techniques that have supplanted almost entirely the earlier methods of determining molar mass that were just described. These newer procedures are both based on the electrophoresis of complexes between polypeptides and dodecyl sulfate upon gels of polyacrylamide. In one procedure, sieving is used to display the different types of polypeptides in the protein and provide estimates of the length of each. In the other procedure, patterns of covalently cross-linked polypeptides separated by electrophoresis are used to count the number of each polypeptide present in the whole protein.

Problem 8-1: Calculate the molar mass of bovine ribonuclease from its sequence.

Problem 8-2: Calculate the molar masses of these proteins that have the following incremental osmotic pressures at 25 °C.

protein	$\lim_{\gamma_{\text{prot}} \rightarrow 0} \frac{\Pi}{\gamma_{\text{prot}}}$
L-lactate dehydrogenase ⁵³	173 dyne cm ⁻² (g of protein) ⁻¹ L
β -lactoglobulin ⁷⁷	0.722 cm of H ₂ O (g of protein) ⁻¹ *
bovine serum albumin ⁸	3.57 N cm (g of protein) ⁻¹

* These are the centimeters that the level of the solution containing the protein rose above the level of the solution lacking the protein as a result of the expansion of the former at the expense of the latter. This additional layer of solution exerts a pressure because of the force of gravity. The units of centimeters are converted into newtons centimeters⁻² by multiplying by the density of the solution lacking the protein (grams centimeter⁻³) and the gravitational acceleration (980.6 cm s⁻² at sea level, 45° latitude) felt by the excess fluid on top of the solution of protein. The density of the solution has already been converted into the density of water.

Problem 8-3: The isoelectric pH of bovine serum albumin in a solution of 0.15 M NaCl is 5.37.⁷⁸ From the data in Figure 8-1, calculate the mean net charge number \bar{Z}_{SA} on the serum albumin at pH 7.0 by assuming that the difference in slope between the two lines is due entirely to the Donnan effect.

Problem 8-4: The second virial coefficient, B , for the osmotic pressure of lysozyme from *Gallus gallus* in solutions of (NH₄)₄SO₄ varies as a function of pH and ionic strength, I_c .³

pH	I_c (M)	second virial coefficient (cm ³ μ mol g ⁻²)
4	1	-140 \pm 23
7	1	-198 \pm 15
8	1	-307 \pm 21
4	3	-396 \pm 19
7	3	-423 \pm 34
8	3	-446 \pm 26

- What causes the second virial coefficient to become less negative as the pH of the solution is lowered?
- Why is the effect of pH smaller at the higher ionic strength?

- (C) What limit do these measurements place on the isoelectric point of lysozyme?
- (D) What limit do these measurements place on the second virial coefficient at the isoelectric pH for lysozyme?
- (E) Why does the second virial coefficient have the sign that it has at the isoelectric pH of lysozyme?

Problem 8-5: Human hemoglobin is a protein formed from two α polypeptides, two β polypeptides, and four hemes for a total molar mass of $64,450 \text{ g mol}^{-1}$. It is referred to as an $(\alpha\beta)_2$ tetramer to indicate that it is a heterotetramer formed from two $\alpha\beta$ heterodimers. The osmotic pressure at 20°C of a solution of hemoglobin,⁷⁹ at a concentration of 3 g L^{-1} , that had been flushed exhaustively with N_2 gas was $1750 \text{ dyne cm}^{-2}$. When the solution was flushed with O_2 gas, the osmotic pressure increased to $2500 \text{ dyne cm}^{-2}$ even though the concentration of the hemoglobin was unchanged.

- (A) Assume ideal behavior and that the virial coefficients are 0 and calculate the average molar mass for each circumstance.
- (B) Explain the values that you obtain.

Problem 8-6: The enzyme glutamate–ammonia ligase, which catalyzes the ATP-dependent condensation of glutamate and ammonia, was isolated from *E. coli*. It was purified by $(\text{NH}_4)_2\text{SO}_4$ fractionation followed by ion-exchange chromatography. The final preparation of the enzyme was considered to be a pure protein because a single peak was obtained on repeated ion-exchange chromatography. The protein is a complex of 12 identical polypeptides each 468 amino acids in length. The length of its constituent polypeptides has been ascertained by sequencing its genomic DNA.

Glutamate–ammonia ligase was dissolved in 6 M guanidinium chloride, and the osmotic pressure of this solution was determined with a high-speed osmometer at 20°C . The following results were obtained

protein concentration (g L^{-1})	pressure (mmHg)
2	0.69
4	1.40
8	2.87
10	3.63
15	4.73
20	7.96

- (A) What is the molar mass of the protein in 6 M guanidinium chloride?
- (B) What has this salting-in solute done to the protein?

Problem 8-7: Calculate the molar mass of aspartate kinase I–homoserine dehydrogenase I from the data in this figure (adapted with permission from ref 80; copyright 1968 Springer-Verlag).

Sedimentation equilibrium of aspartate kinase I–homoserine dehydrogenase I from *E. coli*. The initial protein concentration was 0.6 mg mL^{-1} . Interference optics were used. In an interference scan, the logarithm of the distance in micrometers of the fringe displacement between blank corrected fringes at each point in the chamber and blank corrected fringes at zero level concentration is plotted against r^2 , the square of distance (centimeters²) from the center of the rotor to the point at which the measurement was made. It has been assumed that the concentration of the protein was zero at the top of the sample so that the fringe displacement (in micrometers) is directly proportional to the concentration of protein. Because the concentration of protein at the top of the sample is so small, the leftmost points are scattered.

Use the approximation of Equation 8-21, and assume $\rho_{\text{sol}} = \rho_{\text{H}_2\text{O}}$. The partial specific volume of the protein is $0.737 \text{ cm}^3 \text{ g}^{-1}$, the rotor was spinning at $11,272 \text{ revolutions min}^{-1}$ (1 revolution is 2π radians), and the temperature was 23°C .

Problem 8-8: The light scattering from a series of solutions of ovalbumin from *G. gallus* was measured at an angle θ of 90° .⁸¹ The apparatus sampled the light scattered from a volume of solution of 1.8 cm^3 with a photomultiplier tube at 10 cm from the center of the sample. The differences between the scattering of the buffer alone and the scattering of each solution were used to calculate the Rayleigh ratio, R_{90} , for each solution. The intensity of the incremental scattered light, i_θ , was less than 0.001% of the intensity of the incident light I_0 . The Rayleigh ratios for light of wavelength 436 nm in the vacuum were as follows:

$\gamma_{\text{prot}} (\text{g cm}^{-3})$	$R_{90} (\text{cm}^{-1})$
4.3×10^{-3}	1.13×10^{-4}
5.8×10^{-3}	1.52×10^{-4}
8.6×10^{-3}	2.22×10^{-4}
9.7×10^{-3}	2.54×10^{-4}
13.7×10^{-3}	3.66×10^{-4}

The refractive index \tilde{n}_0 of the solution without the protein was 1.333, the increment of the refractive index with concentration $[(\partial\tilde{n}/\partial\gamma_{\text{prot}})_{T,P,\mu}]$ for the protein at $\lambda_0 = 436 \text{ nm}$ was $0.1883 \text{ cm}^3 \text{ g}^{-1}$, and the temperature was 25°C .

- (A) Determine graphically the limit

$$\lim_{\gamma_{\text{prot}} \rightarrow 0} \frac{\gamma_{\text{prot}}}{R_{90}}$$

- (B) Assume that the Rayleigh ratio, R_θ , does not vary significantly with variation in θ for this small protein at this long wavelength and that

$$\lim_{\substack{\theta \rightarrow 0 \\ \gamma_{\text{prot}} \rightarrow 0}} \frac{\gamma_{\text{prot}}}{R_\theta} = \lim_{\gamma_{\text{prot}} \rightarrow 0} \frac{\gamma_{\text{prot}}}{R_{90}}$$

and use the value for this limit to estimate the molar mass of ovalbumin.

Problem 8–9: Calculate the mean molar mass of an amino acid from the amino acid composition of the set of proteins in Table 7–4.

Electrophoresis on Gels of Polyacrylamide Cast in Solutions of Dodecyl Sulfate

The sodium salt of dodecyl sulfate ($\text{H}_{25}\text{C}_{12}\text{OSO}_3^-$) is a detergent widely used commercially to dissolve nonpolar substances in water. It accomplishes this purpose by forming micelles. A **micelle of dodecyl sulfate** at moderate ionic strength (0.2 M) contains about 100 of the anions in an oblate ellipsoid that is 3 nm across at its minor axis.^{82,83} All of the anionic sulfonates are at the surface of the ellipsoid and the hydrocarbon is in the center. It is the hydrocarbon core of the micelle that dissolves individual molecules of a nonpolar substance, producing the detergent properties. Although dodecyl sulfate must be present at concentrations high enough to form micelles in order to interact with proteins, the complexes that result between the anions of dodecyl sulfate and polypeptides do not seem to involve discrete micelles.

When sodium dodecyl sulfate⁸⁴ is added to a solution of protein at a concentration greater than its critical micelle concentration* and at ratio greater than 2 g of dodecyl sulfate (g of protein)^{–1}, all of the polypeptides present in the solution are unfolded and separate from each other as they become coated with the dodecyl sulfate. The amount of dodecyl sulfate coating the **unfolded, separated polypeptides** at saturation is usually a function only of

their total length. Pitt-Rivers and Impiombato⁸⁵ observed that, within a series of globular, water-soluble proteins, each of the constituent polypeptides would bind 0.54 ± 0.01 molecule of dodecyl sulfate for every amino acid in its sequence. The important point, however, is not the numerical value of this ratio but the fact that it is constant (less than 2% variation) regardless of the protein examined, as long as it is of the usual water-soluble, globular variety and does not have significant segments of its sequence enriched in acidic amino acids and lacking basic amino acids.⁸⁶ This regularity in the binding of dodecyl sulfate, however, is observed only when all of the cystines in the proteins, if there were any, have been cleaved.⁸⁵ Usually this is done by disulfide interchange with a small thiol (Figure 3–20). The constant ratio between bound dodecyl sulfate and the number of amino acids presumably results from the fact that proteins displaying this behavior all have similar compositions of amino acids. Proteins with peculiar compositions,⁸⁷ an excess of charged side chains,⁸⁶ or an excess of hydrophobic side chains⁸⁸ behave anomalously.

The complexes that form between dodecyl sulfate and polypeptides are extended structures and have been variously described as cylindrical rods the length of which is directly proportional to the length of the polypeptide⁸⁹ or micellar pearls of dodecyl sulfate on a string of the flexible polypeptide.⁹⁰ No definitive description of their structure is available, but there is no evidence that the dodecyl sulfate in these complexes is present in discrete packets of 100 molecules of detergent, as would be expected if the micelles present in the absence of the protein were simply incorporated intact into a long string upon the unfolded polypeptide.

As with nucleic acids and presumably for the same reasons, the complexes between dodecyl sulfate and those polypeptides that bind a constant ratio of this strongly anionic detergent all display the same **free electrophoretic mobility**, $(-2.62 \pm 0.04) \times 10^{-4} \text{ cm}^2 \text{ s}^{-1} \text{ V}^{-1}$, regardless of the length of the polypeptide.⁹⁰ In the case of nucleic acids, the invariance of the free electrophoretic mobility with length results from the uniform distribution of negative charge along the regular polymer, and presumably this is also a necessary condition met by the complexes between dodecyl sulfate and polypeptides. With nucleic acids, however, this is a covalently conferred, intrinsic property of the phosphodiester of the backbone rather than the fortuitous and less reliable inclination of the polymer to bind a charge-conferring species uniformly along its length. As such, any polypeptide that binds dodecyl sulfate abnormally should have a different free electrophoretic mobility. When the amount of dodecyl sulfate bound to a series of polypeptides was purposely decreased, the magnitudes of their free electrophoretic mobilities also decreased.⁹⁰

As is the case with nucleic acids,⁹¹ native proteins (Figure 1–17), and other macromolecules submitted to electrophoresis on gels of polyacrylamide or other poly-

* The critical micelle concentration is the minimum concentration at which the detergent forms micelles.

meric supports, the electrophoretic mobilities of complexes between dodecyl sulfate and polypeptides (Figure 8-7)⁹² follow the relationship

$$u_i = u_i^\circ \exp(-K_{r,i} T_a) \quad (8-34)$$

where T_a is the concentration of acrylamide (in percent) from which the gel was cast and the **retardation coefficient**, $K_{r,i}$ is a constant unique to the particular polypeptide i . Because u_i° is the free electrophoretic mobility of the complex between dodecyl sulfate and polypeptide i and u° is the same for all complexes between dodecyl sulfate and well-behaved polypeptides, this relationship predicts that the lines in Figure 8-7 should intersect at the axis of the ordinate when T_a is equal to 0, which is almost the case. Because each complex has a unique retardation coefficient, electrophoresis on gels of polyacrylamide can be used to separate these complexes one from the other (Figure 8-8).⁹³

Systems for **stacking** complexes between dodecyl sulfate and polypeptides have been developed to improve the resolution of the separation. One system

Figure 8-7: Relative electrophoretic mobilities, R_f , of complexes of polypeptides and dodecyl sulfate as a function of the concentration of acrylamide, T_a , used to cast the gel.⁹² Various proteins—myoglobin (my; 153 aa), chymotrypsinogen (ch; 245 aa), L-lactate dehydrogenase (ld; 331 aa), ovalbumin (ov; 385 aa), glutamate dehydrogenase (gd; 501 aa), bovine serum albumin (sa; 583 aa), and phosphorylase (ph; 842 aa)—were dissolved separately in a solution containing a concentration of dodecyl sulfate sufficient to saturate the polypeptides. Each was then submitted to electrophoresis on gels of polyacrylamide cast in a solution of 1% sodium dodecyl sulfate. A series of gels was used for each protein that differed in the percent acrylamide (T_a) from which they were cast. The gels were stained for protein, and the distance migrated by the protein was divided by the distance migrated by a dye, Pyronine-Y, of low molecular weight to obtain the relative electrophoretic mobility (R_f) of each polypeptide at each percent acrylamide. The assumption made was that the mobility of the Pyronine-Y would be unaffected by the percent acrylamide. Reprinted with permission from ref 92. Copyright 1972 *Journal of Biological Chemistry*.

releases the complexes from the descending boundary in which they are stacked by using an ascending boundary that increases the concentration of the neutral conjugate base of the cationic acid that is common to all of the solutions.⁹⁴⁻⁹⁶ The other releases them by using an ascending boundary that delivers the neutral conjugate base of a different cationic acid of much higher pK_a to jump the pH after the complexes have stacked.⁹⁷ The latter system is more effective at releasing the smaller polypeptides from the descending boundary than is the former. The former relies heavily on the increase in the concentration of polyacrylamide at the top of the running gel to accomplish the release and fails to do so when the concentration of polyacrylamide in the running gel is decreased below a certain level.

As with nucleic acids, the electrophoretic mobilities of complexes between dodecyl sulfate and polypeptides on gels of polyacrylamide are a regular function of the

Figure 8-8: Separation of polypeptides by electrophoresis on gels of polyacrylamide cast in a solution of 0.2% sodium dodecyl sulfate.⁹³ Proteins containing the polypeptides were dissolved in solutions of sodium dodecyl sulfate sufficient to saturate them. They were submitted to electrophoresis on cylindrical gels (0.6 cm × 10 cm) cast from 10% acrylamide in 0.1% sodium dodecyl sulfate and 0.1 M sodium phosphate, pH 7.0. Following electrophoresis, the gels were stained for protein. The polypeptides that were run on gel A were those composing bovine catalase ($n_{aa} = 506$), the mitochondrial isoform of porcine fumarate hydratase ($n_{aa} = 466$), isoform A of fructose-bisphosphate aldolase from muscle of *Oryctolagus cuniculus* ($n_{aa} = 361$), glyceraldehyde-3-phosphate dehydrogenase from muscle of *O. cuniculus* ($n_{aa} = 332$), human carbonate dehydratase I ($n_{aa} = 260$), and equine cardiac myoglobin ($n_{aa} = 153$). The polypeptides run on gel B were the same as those run on gel A, but the myoglobin was omitted. The polypeptides run on gel C were catalase, fumarate hydratase, the E isoform of alcohol dehydrogenase from equine liver ($n_{aa} = 374$), glyceraldehyde-3-phosphate dehydrogenase, carbonate dehydratase, and myoglobin. length of the polypeptides, as long as they have a normal composition of amino acids⁸⁷ and bind the proper amount of dodecyl sulfate. To understand this property of the electrophoretic separations, the process known as sieving must be understood.

Sieving

Sieving of macromolecules, for example, native proteins, nucleic acids, or complexes between dodecyl sulfate and polypeptides, occurs during both chromatography by molecular exclusion and electrophoresis on polymeric supports. **Sieving** is the discrimination between macromolecules on the basis of size that is accomplished by a random network of linear polymers. In chromatography by molecular exclusion, the network of polymer forms the beads among which the mobile phase percolates and is the sieve within the beads through which the macromolecule diffuses when it is inside of the stationary phase. In electrophoresis, the network of polymer forms an obstacle course through which the macromolecule must pass as it moves in the direction of the electric field.

Consider a geometric solid of any shape within a network of lines thrown at random through a volume of space completely containing the solid. An equation⁹⁸ for the probability that none of these lines intersects the solid, $P(\text{ni})$, was derived during the solution of an unrelated topological problem,⁹⁹ and

$$P(\text{ni}) = \exp(-lS/4) \quad (8-35)$$

where l is the density of the lines (centimeters centimeter⁻³) and S is the surface area of the solid (centimeters²). Assume that a macromolecule is a geometric solid and a network of chemical polymers is a network of lines. When a molecule of protein is submitted to **chromatography by molecular exclusion**, the fraction of the total volume available to macromolecule i , $K_{\text{av},i}$ (Equation 1-21), in the stationary phase of randomly arranged linear polymers should be that fraction of the total volume the occupation of which by the macromolecule does not cause any polymer to intersect the macromolecule. In this case,

$$K_{\text{av},i} = \exp(-bT_p S_{\text{app},i}) \quad (8-36)$$

where T_p is the concentration of polymer in percent [grams (100 cubic centimeters)⁻¹], b is a constant of proportionality to convert, among its other roles, the con-

centration of polymer [grams (100 cubic centimeters)⁻¹] into its linear density (centimeters centimeter⁻³), and $S_{\text{app},i}$ is the apparent surface area (centimeters²) of the macromolecule i .

Because the polymers are not lines but solids themselves, the **apparent surface area** of the macromolecule is not its real surface area. The apparent surface of macromolecule i , $S_{\text{app},i}$, lies outside its actual surface by a distance equal to the sum of the widths of any tight shells of hydration around either the macromolecule or the polymer and the width of the polymer itself. All of the dimensions that cause the polymer not to be a line and the macromolecule not to be a dry smooth solid object are incorporated into the dimensions of an apparent macromolecule that is larger than the actual macromolecule. When the actual macromolecule collides with the actual polymer, the apparent macromolecule collides with a line in the center of the polymer.

This model predicts that if a series of beaded stationary phases of increasing concentration of polymer is used to separate the same set of standard macromolecules by molecular exclusion chromatography, then

$$K_{\text{av},i} = \exp(-K_{r,i} T_p) \quad (8-37)$$

If this is so, then $\ln K_{\text{av},i}$ should be a linear function of T_p . It has been demonstrated that the relationship of Equation 8-37 describes the behavior of both proteins^{98,100,101} and polysaccharides¹⁰¹ during chromatography by molecular exclusion on gels of both polyacrylamide (Figure 8-9)^{98,100,102} and linear dextrans.¹⁰¹

If Equation 8-36 describes behavior during chromatography by molecular exclusion, then when T_p is fixed, $-\ln K_{\text{av},i}$ should be directly proportional to $S_{\text{app},i}$. Computer programs exist for calculating the accessible surface area of a molecule of a protein (6-12) by rolling a spherical probe over the surface of its crystallographic molecular model.¹⁰³ The accessible surface area is the surface area traced by the center of the probe. Unfortunately, there is no computer program that performs such a calculation for a cylindrical probe, which would not detect the smaller irregularities of the surface so readily as does a spherical probe (Figure 6-20). One can choose, however, a radius for the spherical probe that is large enough to include the radius of the polymer and the layers of hydration on the polymer and the protein as well as being large enough that the smaller irregularities of the surface of the protein that would not be detected by a cylinder are also not detected by the sphere. When a sphere of the appropriate radius is used as the probe, the values of $-\ln K_{\text{av},i}$ for a series of standard proteins that have been submitted to chromatography by molecular exclusion¹⁰⁴ upon cross-linked dextran are found to be directly proportional to the accessible surface areas¹⁰³ calculated from crystallographic molecular models of those same proteins (Figure 8-10A).

Figure 8-9: Distribution coefficients for a series of globular proteins submitted to chromatography by molecular exclusion on polyacrylamide gels of varying composition.^{98,100} A series of gels cast from different concentrations of acrylamide, T_a (percent), were separately fragmented to form suspensions of polyacrylamide granules of different porosities. Columns were made from these chromatographic media, and a set of standard globular proteins were submitted to chromatography by molecular exclusion on these columns and their respective elution volumes were used to calculate the respective distribution coefficients, K_D (Equation 1-22). The distribution coefficient K_D is directly proportional to the distribution coefficient K_{av} . The values of K_D are plotted on a logarithmic scale as a function of T_a . The proteins were, in order of their number of amino acids, (1) cytochrome c (cy; 104 aa), (2) ribonuclease (rn; 124 aa), (3) lysozyme (ly; 129 aa), (4) myoglobin (my; 153 aa), (5) ovomucoid (om; 186 aa), (6) chymotrypsinogen (ch; 245 aa), (7) pepsin A (ps; 327 aa), (8) ovalbumin (ov; 385 aa), (9) hemoglobin (hb; 574 aa), (10) serum albumin (sa; 583 aa), and (11) immunoglobulin G (ig; 1320 aa). Adapted with permission from ref 98. Copyright 1970 National Academy of Sciences.

Unfortunately, the accessible surface area of a molecule of protein is not one of its more interesting properties; usually sieving is used to estimate the **number of amino acids** a protein contains. It has been noted by Ogston¹⁰⁵ that if a set of macromolecules were all spheres of radius R_i and the polymers of the network were infinitely long right cylinders of radius r_p , then

$$S_{app,i} = 4\pi(r_p + R_i)^2 \quad (8-38)$$

Because the partial molar volume of a molecule of protein is a function only of its composition of amino acids^{18,106} and because the amino acid compositions of most proteins are similar, each of their partial molar volumes should be directly proportional to the number of amino acids each protein contains (Table 8-2). To the extent that a molecule of protein i is a sphere and has the normal composition of amino acids, the number of amino acids it contains, $n_{aa,i}$, should determine its radius by the relationship

$$R_i^o = \left[\frac{3}{4\pi} \left(\frac{n_{aa,i} \bar{V}_{aa}}{N_A} \right) \right]^{1/3} \quad (8-39)$$

where \bar{V}_{aa} is the mean partial molar volume of the amino acids in the usual protein ($82 \text{ cm}^3 \text{ mol}^{-1}$) and the superscript has been added to R to indicate that this is a sphere equivalent in volume to the volume of the protein, which is never exactly a sphere.

When Equations 8-36, 8-38, and 8-39 are combined

$$\left(\frac{-\ln K_{av,i}}{4\pi b T_p} \right)^{1/2} = r_p + \left[\frac{3}{4\pi} \left(\frac{n_{aa,i} \bar{V}_{aa}}{N_A} \right) \right]^{1/3} \quad (8-40)$$

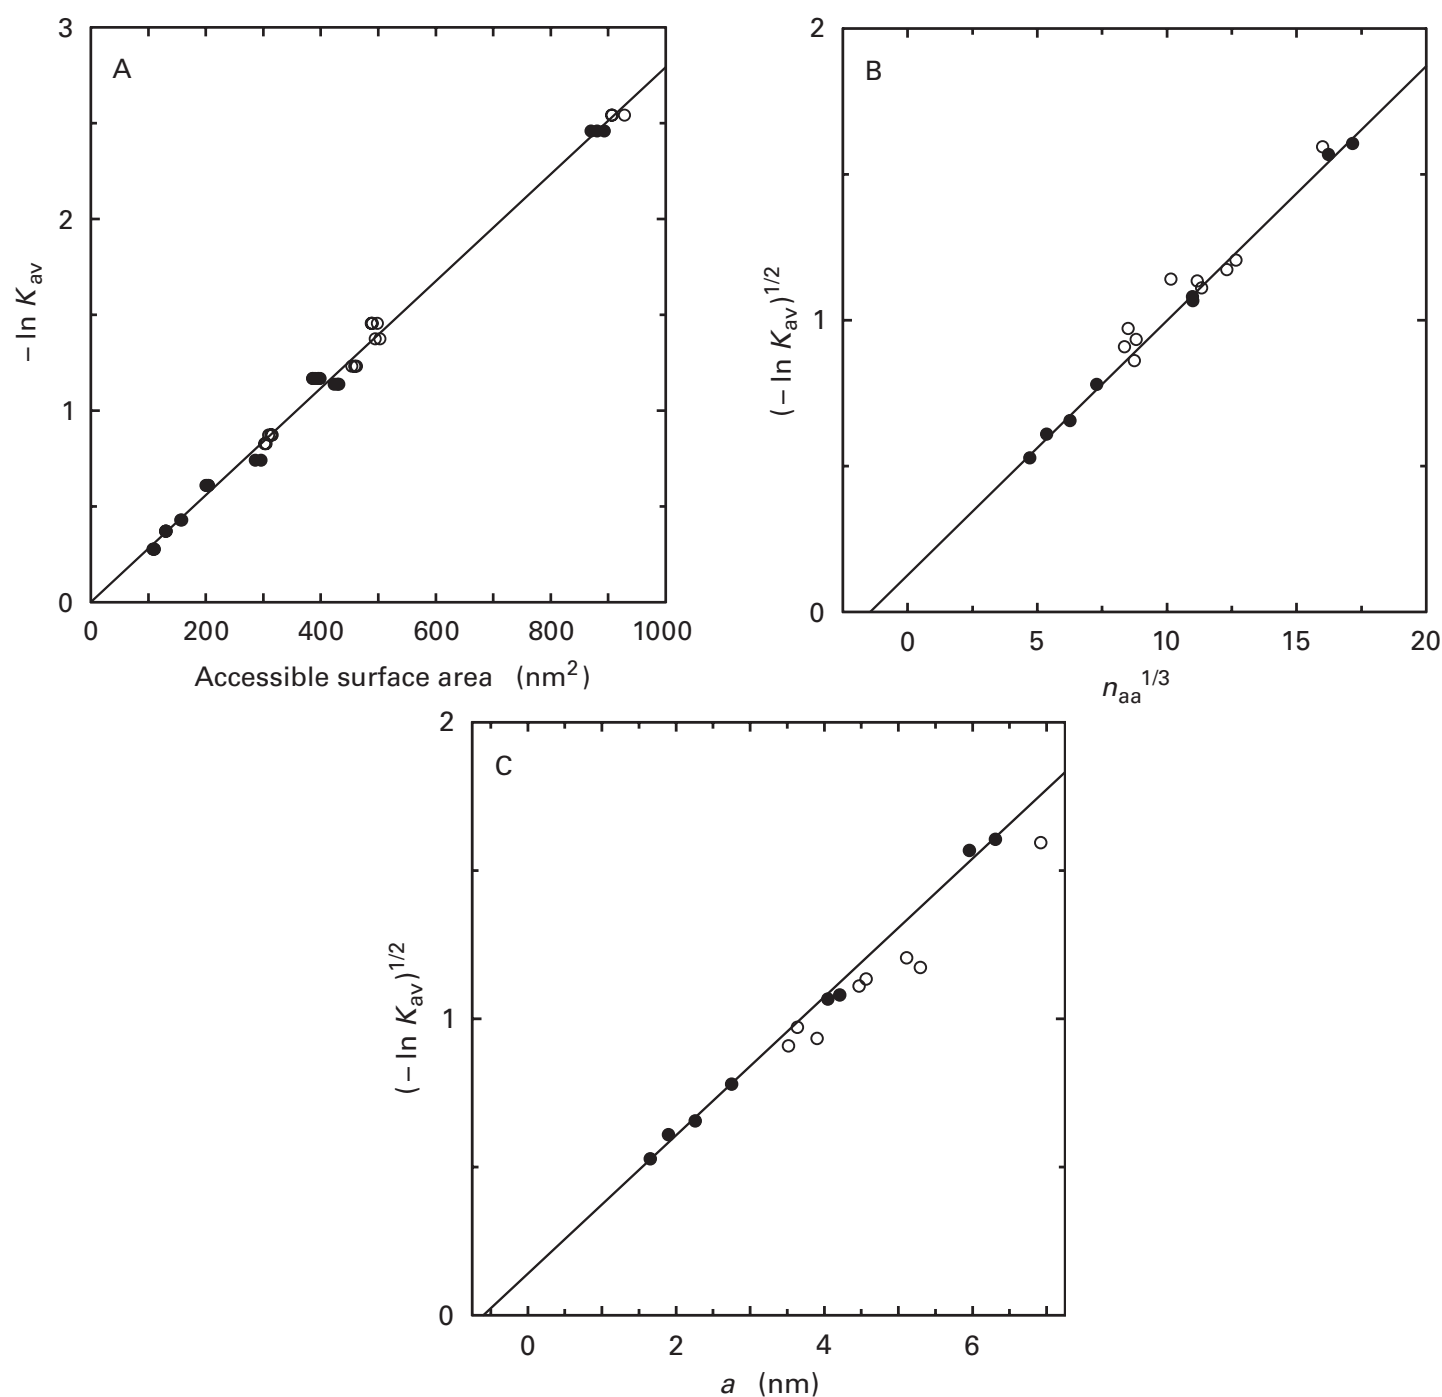

Figure 8-10: Sieving of globular proteins by molecular exclusion chromatography.¹⁰⁴ The proteins, dissolved in 0.1 M KCl at pH 7.5, were submitted to chromatography by molecular exclusion on a column (2.5 cm × 50 cm) of Sephadex G-200. The volumes at which the several proteins eluted from the column were tabulated. The distribution coefficient K_{av} for each was calculated (Equations 1-20 and 1-21) from its elution volume, V_e , and the void volume of the column, V_0 , and the included volume of the column, V_i (as determined by the volume at which sucrose eluted). It was assumed that $V_i = V_{H_2O}$, that $V_T = (1 - f_{poly})^{-1} V_{H_2O}$, and that $W_r = 20 \text{ mL g}^{-1}$. The proteins used by Andrews¹⁰⁴ were, in order of increasing total number of amino acids, equine cytochrome c ($n_{aa} = 104$), myoglobin from *Physeter catodon* ($n_{aa} = 153$), bovine chymotrypsinogen ($n_{aa} = 245$), ovalbumin from *G. gallus* ($n_{aa} = 385$), bovine serum albumin ($n_{aa} = 583$), bovine lactoperoxidase ($n_{aa} = 612$), the cytoplasmic isoform of malate dehydrogenase from porcine heart ($n_{aa} = 666$), bovine transferrin ($n_{aa} = 685$), glyceraldehyde-3-phosphate dehydrogenase from muscle of *O. cuniculus* ($n_{aa} = 1328$), the A isoform of L-lactate dehydrogenase from muscle of *O. cuniculus* ($n_{aa} = 1324$), alcohol dehydrogenase from *Saccharomyces cerevisiae* ($n_{aa} = 1388$), the A isoform of fructose-bisphosphate aldolase from muscle of *O. cuniculus* ($n_{aa} = 1452$), the mitochondrial isoform of porcine fumarate hydratase ($n_{aa} = 1864$), bovine catalase ($n_{aa} = 2024$), β -galactosidase from *E. coli* ($n_{aa} = 4092$), equine apoferritin ($n_{aa} = 4368$), and urease from *Canavalia ensiformis* ($n_{aa} = 5040$). (A) The quantity $-\ln K_{av}$ is plotted as a function of the accessible surface area (6-12; nanometers²) of those molecules of protein for which crystallographic molecular models were available (all of the proteins used by Andrews except lactoperoxidase, alcohol dehydrogenase, and urease). The accessible surface areas were calculated with a spherical probe of radius 1.1 nm (Figure 6-20) by use of the program of Lee and Richards¹⁰³ as adapted by Dr Ilya Shindyalov of the Protein Data Bank. Of necessity, crystallographic molecular models of proteins from species other than the species providing the protein for the molecular exclusion often had to be used. The access codes of the crystallographic molecular models in the Protein Data Bank that were chosen are 5CYT, 3CYT, 1CYC, 1CRC, 1HRC, 1ABS, 1DXD, 1HJT, 1SWM, 2MBW, 1MCY, 2CGA, 4CHA, 1OVA, 1BJ5, 1UOR, 1BKE, 1AO6, 4MDH, 5MDH, 1DOT, 1OVT, 1CB6, 1CE2, 1GPD, 4GPD, 3GPD, 1LDM, 2LDX, 3LDH, 5LDH, 9LDB, 9LDT, 6ALD, 4ALD, 2ALD, 1FUR, 1YFM, 1DGF, 1DGG, 4BLC, 7CAT, 8CAT, 1BGL, 1BGM, 1FHA, 1AEW, and 1DAT. The closed circles are those for proteins the frictional ratios of which are less than 1.20. (B) The quantity $(-\ln K_{av})^{1/2}$ is plotted as a function of the cube root of the number of amino acids in each protein. (C) The quantity $(-\ln K_{av})^{1/2}$ is plotted as a function of the Stokes radius, a , of each protein calculated from its diffusion coefficient by Equation 1-67. In panel A the line was fit to the averages of the surface areas for each protein, but in panels B and C it was fit only to the eight points (closed circles) for the proteins the frictional ratios of which are less than 1.2.

and a plot of $(-\ln K_{av,i})^{1/2}$ against $(n_{aa,i})^{1/3}$ should be a linear relationship. When the data of Andrews¹⁰⁴ are displayed in this fashion,⁹⁸ they are linearly related (Figure 8-10B). The intercept of the line with the abscissa is at a negative value as predicted by Equation 8-40, and this intercept yields an estimate of r_p , the mean radius of the polymers of dextran, of 0.46 nm, which is not unreasonable when it is considered that this parameter also includes the irregularities of the surface of the protein and the hydration of the molecule of protein and the molecules of polymer.

Several of the points in Figure 8-10B deviate from

the line that was drawn. One way to quantify the deviation of a molecule of protein from spherical behavior is to define a **frictional ratio**, $f(f_0)^{-1}$, which is simply the quotient between the measured frictional coefficient of the protein and the frictional coefficient it would have if its mass were distributed to form a hard sphere of the same partial specific volume. The measured frictional coefficient, f , is calculated from the diffusion coefficient (Equation 1-64) and the ideal frictional coefficient (Equation 1-66) is defined by

$$f_0 = 6\pi\eta R^0 \quad (8-41)$$

where R° is defined by Equation 8-39. For the most spherical of proteins, values of the frictional ratio of 1.1–1.2 are observed.⁵¹ The values of the frictional ratio are always greater than 1 because the water bound to a protein and the irregularities of its surface increase its actual frictional coefficient.

The solid circles in Figure 8-10B are those for all of the proteins chosen by Andrews that happen to have frictional ratios less than 1.2. They are, in ascending order of size (with the frictional ratios in parentheses), cytochrome *c* (1.09), myoglobin (1.16), chymotrypsinogen (1.12), ovalbumin (1.18), glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) (1.16), L-lactate dehydrogenase (1.17), apoferritin (1.15), and urease (1.18).^{*} The line in Figure 8-10B was drawn through these points because they should be the most ideal examples. It can be seen that several of the points for proteins with larger frictional ratios indicate that they are behaving as if they were larger than they are, which makes sense if their behavior is a function only of their surface area. Further validating the conclusion that it is only the surface area of a molecule of protein that determines its distribution coefficient is the fact that the distribution coefficients of proteins with larger frictional ratios (open circles in Figure 8-10A) show no more deviation from linear behavior than do those of the proteins with frictional ratios less than 1.20 (solid circles in Figure 8-10A) when they are plotted as a function of surface area rather than volume.

It has been argued^{101,108,109} that, rather than the apparent surface area of a molecule of protein, the fundamental variable in describing its behavior when it is submitted to sieving on chromatography by molecular exclusion is its effective radius, or **Stokes radius**, a , calculated from its diffusion coefficient (Equation 1-67). When the same values of $(-\ln K_{av})^{1/2}$ displayed in Figure 8-10B are replotted against the effective radii for the various proteins (Figure 8-10C), no significant improvement is seen. Something can be learned, however, when a line is again drawn through the points for the eight most globular proteins listed above, the properties of which should be least affected by the change to effective radius from $n_{aa}^{1/3}$. It can be seen that the use of the effective radius significantly overcompensates for the deviations from the linear behavior displayed in Figure 8-10B for almost all of the proteins that have larger frictional ratios. It is hard to explain why proteins with irregular shapes would behave as if they were smaller than more spherical ones.

It is the correlation between K_{av} and n_{aa} that is exploited when data from chromatography by molecular exclusion are used to estimate the number of amino

acids contained within a protein of interest.¹⁰⁴ This estimation requires that the distribution coefficients, K_{av} , for a series of uncomplicated **standard proteins** of known number of amino acids be used to define the line for the chromatographic system chosen for the particular experiment. The estimate for the number of amino acids in the protein of interest is interpolated from the known values for the standards. A standard line for a particular chromatographic column must be established by running standards on that column, because the properties of each commercial batch of chromatographic medium are unique.¹⁰¹ It is also important to run the chromatographic system with a buffer of ionic strength 0.1–0.2 M to eliminate the effect of the dimensions of the ionic double layer around the charged macromolecules on the parameter K_{av} .¹¹⁰

As a macromolecule moves through a polymeric network during **electrophoresis**, it is also being sieved. In this case, it must travel through the network in a kinetic process, rather than equilibrating with the internal volume of a bead, but it appears that this distinction is inconsequential. It has been argued⁹⁸ that one can view the solid matrix of the polymerized gel as an array of screens through which the macromolecule must travel. A random cross section through a random three-dimensional network of lines will provide a distribution of points. The probability that none of these points lies within the randomly placed, random cross section of a geometric solid of any shape is still described by Equation 8-35.⁹⁸ If those points represent one of the screens in the gel, if the macromolecule can pass only through openings in that screen large enough so that no point forming that screen is found within the cross section of the macromolecule, and if the rate of its movement through the screen is proportional to the probability that openings of the proper size or larger will be encountered, then the mobility of a macromolecule through a gel during electrophoresis should be described by

$$u_i = u_i^\circ \exp(-b T_P S_{app,i}) \quad (8-42)$$

It has already been noted that the electrophoretic mobilities of proteins (Figure 1-17), nucleic acids,⁹¹ and complexes between dodecyl sulfate and polypeptides (Figure 8-7) satisfy Equation 8-34, and therefore their behavior is also consistent with Equation 8-42. It should also be the case that

$$K_{r,i} = b S_{app,i} \quad (8-43)$$

The values for the **retardation coefficients** K_r for a series of standard proteins in their native conformations submitted to electrophoresis on a series of polyacrylamide gels cast from increasing concentrations of acrylamide (Figure 1-17) are directly proportional to their accessible

* Values of frictional ratios were calculated from diffusion coefficients cited by Andrews¹⁰⁴ or in the tables of the *CRC Handbook of Biochemistry*¹⁰⁷ and the actual number of amino acids in each protein.

surface areas calculated from crystallographic molecular models of the same proteins (Figure 8–11A).^{40,111}

As already noted, however, the property of a molecule of protein that is usually of interest is not its accessible surface area but the **number of amino acids** it contains. If it is assumed that a series of proteins resembles a series of spheres and that Equations 8–38 and 8–39 are still valid approximations, then

$$\left(\frac{K_{r,i}}{4\pi b}\right)^{1/2} = r_p + R_i^{\circ} \quad (8-44)$$

and a plot of $(K_r)^{1/2}$ against $(n_{aa})^{1/3}$ for this series should yield a linear relationship.⁹⁸ When the data of Hedrick and Smith¹¹¹ and Bryan⁴⁰ for the retardation coefficients, $K_{r,i}$, of a series of native proteins that had been sieved by electrophoresis through gels cast from increasing concentrations of acrylamide, T_a , are plotted against the cube root of the number of amino acids they contain,

they do display linear behavior (Figure 8–11B).^{40,98,111} Again, the intercept with the abscissa is at a negative value as predicted by Equation 8–44, and this intercept yields a value of r_p , the mean radius of the polyacrylamide, of 0.9 nm.⁹⁸ Unlike the behavior of globular proteins on chromatography by molecular exclusion (Figure 8–10B), the proteins with higher frictional ratios (open symbols in Figure 8–11B) do not deviate systematically from linear behavior more significantly than those with frictional coefficients less than 1.20 (closed symbols in Figure 8–11B).

It has been suggested by Hedrick and Smith¹¹¹ that this linear correlation permits the number of amino acids in a native protein of unknown size to be estimated from its behavior on electrophoresis. This is particularly useful in situations in which only the electrophoretic mobility of the protein of interest can be measured.

Two types of macromolecules that are of interest in biochemistry are globular macromolecules, such as many of the proteins in their native state, and extended

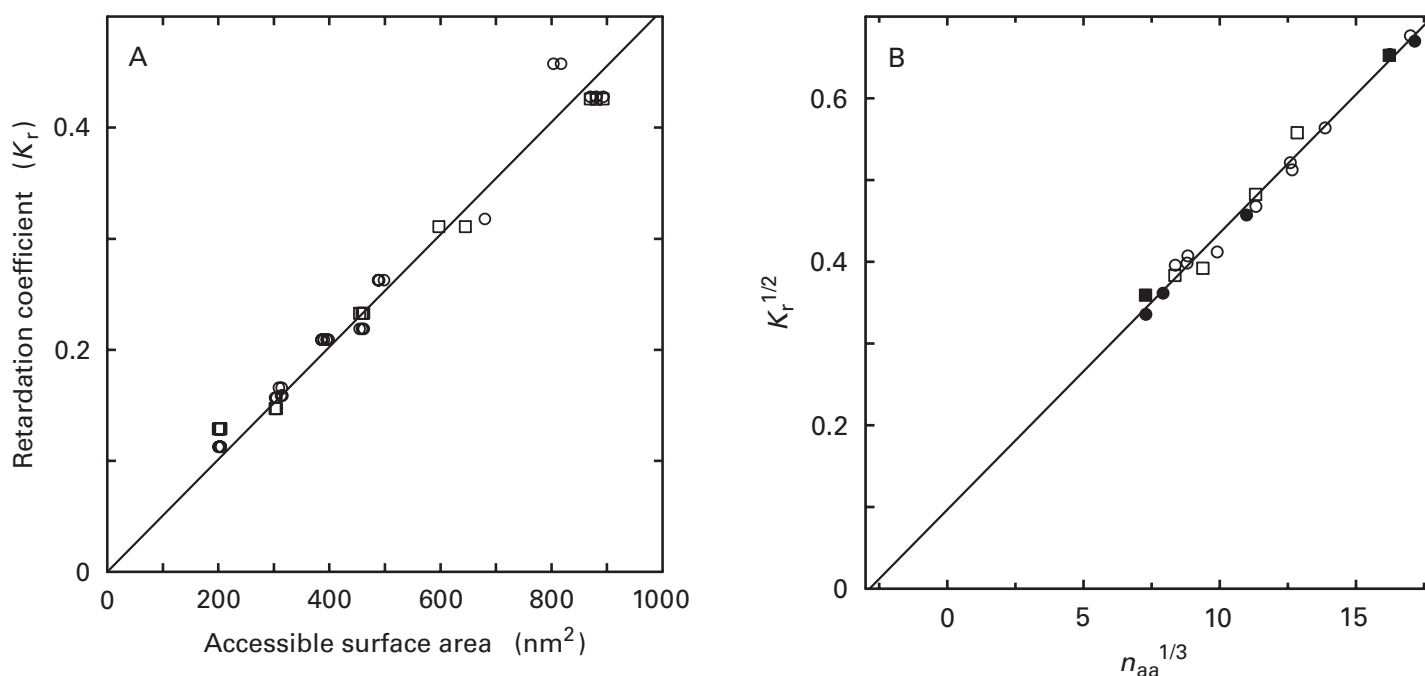

Figure 8–11: Relationship between the retardation coefficients K_r measured by electrophoresis and the surface areas or the numbers of amino acids n_{aa} for a set of proteins.^{40,111} A series of proteins were submitted to electrophoresis, each protein on a series of gels cast from solutions of increasing concentrations of acrylamide. The slopes of the lines from plots of the logarithm of the relative mobility against the percent of acrylamide were used to calculate K_r for each protein. The proteins used, in order of increasing number of amino acids, were ovalbumin from *G. gallus* ($n_{aa} = 385$), porcine α -amylase ($n_{aa} = 496$), bovine serum albumin ($n_{aa} = 583$), human transferrin ($n_{aa} = 679$), ovotransferrin from *G. gallus* ($n_{aa} = 686$), aspartate kinase–homoserine dehydrogenase from *Zea mays* ($n_{aa} = 828$), hexokinase from *S. cerevisiae* ($n_{aa} = 970$), the A isoform of L-lactate dehydrogenase from muscle of *O. cuniculus* ($n_{aa} = 1324$), the A isoform of fructose-bisphosphate aldolase from muscle of *O. cuniculus* ($n_{aa} = 1452$), β -amylase from *Ipomoea batatis* ($n_{aa} = 1992$), bovine catalase ($n_{aa} = 2024$), the M1 isoform of pyruvate kinase from *O. cuniculus* ($n_{aa} = 2120$), bovine xanthine oxidase ($n_{aa} = 2662$), equine apoferritin ($n_{aa} = 4272$), ribulose-bisphosphate carboxylase from *Chlamydomonas reinhardtii* ($n_{aa} = 4904$), and urease from *C. ensiformis* ($n_{aa} = 5040$). (A) The values of the retardation coefficients K_r are plotted as a function of the accessible surface areas (nanometers²) of the proteins calculated as described in Figure 8–10A with a spherical probe of 1.1 nm. Surface areas were calculated for ovalbumin, serum albumin, transferrin, ovotransferrin, L-lactate dehydrogenase, aldolase, pyruvate kinase (1PKM, 1A49), catalase, xanthine oxidase (1FO4), apoferritin, and ribulose-bisphosphate carboxylase (1AA1, 1RCO). (B) The square roots of the retardation coefficients for all of the proteins are plotted as a function of the cube roots of their number of amino acids. In both panels, circles are for the data of Hedrick and Smith¹¹¹ and squares are for the data of Bryan;⁴⁰ in panel B, solid symbols are for proteins with frictional ratios less than 1.20.

polymers, such as unfolded single-stranded DNA and unfolded polypeptides. **Extended polymers**, the shapes of which are unable to be approximated as spheres, nevertheless display regular behavior when they are submitted to sieving. The apparent surface areas, S_{app} , of extended, flexible polymers, such as unfolded polypeptides or unfolded single-stranded DNA, should increase linearly with their lengths, n_{aa} , because as each monomer is added, it increases S_{app} by the same increment, once the polymer is beyond a certain length. In this case,

$$S_{app,i} = c + d(n_{aa,i}) \quad (8-45)$$

where c incorporates all of the properties of homologous short polymers only a few segments in length.

When proteins are dissolved in solutions of guanidinium chloride, they unfold and their individual polypeptides become separated, random coils.¹¹² A series of these **randomly coiled polypeptides**, the lengths of which are now precisely known, were submitted to chromatography by molecular exclusion on beaded agarose, and the values of K_D (Equation 1-22) were reported.¹¹³ Combining Equations 1-21, 1-22, 8-36, and 8-45

$$-\ln K_{D,i} = \ln K_{av,R} + bT_P(c + dn_{aa,i}) \quad (8-46)$$

where $K_{av,R}$ is the distribution coefficient of the small reference solute R used to determine the apparent internal volume. This equation predicts that a plot of $\ln K_{D,i}$ against $n_{aa,i}$ should be linear, and it is (Figure 8-12).¹¹³ It has been proposed that the length of a polypeptide, the sequence of which is unavailable, could be estimated from its distribution coefficient by use of such a standard curve.

The regular behavior of **single-stranded nucleic acids** upon electrophoresis is crucial to the strategies for determining their sequences. The relative electrophoretic mobilities of the components in the ladder of single-stranded RNA displayed in Figure 3-13 can be measured from the photograph. Each relative mobility can in turn be related to the relative mobility of one of the components chosen as a standard, for example, the mobility of the one containing 30 nucleotides.¹¹⁴ If Equations 8-34, 8-43, and 8-45 are combined, and if it is remembered that u_i° for all unfolded single-stranded nucleic acids is the same, then

$$-\ln \left(\frac{u_i}{u_{30}} \right) = bT_a d(n_{b,i} - 30) \quad (8-47)$$

This predicts that a plot of $\ln(u_i/u_{30})$ against $n_{b,i}$ should be linear, and it is (Figure 8-13) with the exception of the compression at the discontinuity in the figure.

It could be ascertained, because sequencing was being performed,¹¹⁴ that the bands for the components

Figure 8-12: Sieving of unfolded, randomly coiled polypeptides on chromatography by molecular exclusion.¹¹³ Each of a series of proteins was dissolved in 6 M guanidinium chloride and 0.1 M 2-mercaptoethanol and submitted to chromatography on a column (1.5 cm × 90 cm) of beaded 6% agarose. The elution volume of each polypeptide was used to calculate its distribution coefficient K_D . The negative natural logarithm of K_D ($-\ln K_D$) is plotted as a function of the number of amino acids in the respective sequence, n_{aa} . The polypeptides chosen were those composing equine cytochrome c ($n_{aa} = 104$), bovine hemoglobin ($n_{aa} = 145$), bovine β -lactoglobulin ($n_{aa} = 162$), immunoglobulin G light chain from *O. cuniculus* ($n_{aa} = 220$), the mitochondrial isoform of malate dehydrogenase from liver of *Rattus norvegicus* ($n_{aa} = 314$), the A isoform of fructose-bisphosphate aldolase from *O. cuniculus* ($n_{aa} = 363$), ovalbumin from *G. gallus* ($n_{aa} = 385$), immunoglobulin G heavy chain from *O. cuniculus* ($n_{aa} = 450$), α -amylase A from *Aspergillus oryzae* ($n_{aa} = 478$), bovine serum albumin ($n_{aa} = 583$), and human transferrin ($n_{aa} = 679$).

in the ladder representing single-stranded ribonucleic acids of lengths 24–27 had all overlapped, producing this compression. It is usually assumed that a compression results from the ability of the 3' end of the single-stranded nucleic acid to double back upon itself and form a double-stranded hairpin as soon as the length of the nucleic acid becomes greater than a critical value in the expanding series. As the series approaches the discontinuity, it behaves regularly, because no hairpin is imminent. At the discontinuity and beyond it, the hairpin is present in each component, but it is eventually found far enough in the interior for the series to resume its linear behavior with the same slope it had previously but with a displacement. The displacement indicates that the polymer is behaving as if it were smaller than it actually is, presumably because the surface area of the double-helical hairpin in its interior is smaller than the surface area of the same number of nucleotides in a single-stranded state.

Figure 8-13: Sieving of single-stranded ribonucleic acid on electrophoresis in a gel of polyacrylamide. The distance between the origin and the final position of each band on the gel in Figure 3-13 was measured. These distances were each divided by the distance for the band corresponding to the ribonucleic acid 30 bases in length to obtain mobilities relative to this internal standard (u/u_{30}). The negative natural logarithms of these mobilities are plotted as a function of the lengths in bases, n_b , of each single-stranded ribonucleotide.

Unfolded polypeptides and unfolded single-stranded nucleic acids are examples of well-defined extended polymers. **Complexes between dodecyl sulfate and polypeptides**, because they are not chemically defined covalent polymers, are not so well understood. Nevertheless, both the behavior of polypeptides dissolved in solutions of guanidinium chloride (Figure 8-12) and the behavior of single-stranded nucleic acids (Figure 8-13) when they are respectively submitted to sieving suggest that the extended, unfolded complexes that form between dodecyl sulfate and polypeptides, which resemble the former in their unfolded state and the latter in both their distribution of negative charge and unfolded state, should display electrophoretic mobilities correlated with the length of the polypeptides. In fact, it was noted by Shapiro, Viñuela, and Maizel¹¹⁵ that this is the case. The electrophoretic mobility of the complex between dodecyl sulfate and polypeptide i is generally reported as a relative mobility:

$$R_{f,i} = \frac{u_i}{u_{\text{STD}}} \quad (8-48)$$

where u_{STD} is the mobility of a standard, either a small dye that can be readily followed visually or one of the obvious boundaries on a discontinuous gel. The advantage of the former point of reference is that because the

dye is dissolved in micelles of dodecyl sulfate, it marks the mobility of a micelle and hence the free electrophoretic mobility of the complexes between the proteins and the dodecyl sulfate (Figure 8-7). The advantage of the latter point of reference is that its absolute electrophoretic mobility can be calculated.

Equations 8-34 and 8-48 can be combined, and

$$\ln R_{f,i} = \ln \left(\frac{u_{\text{STD}}^\circ}{u_i^\circ} \right) - K_{r,\text{STD}} T_a + K_{r,i} T_a \quad (8-49)$$

This equation can be combined with Equations 8-43 and 8-45, and

$$\ln R_{f,i} = \ln \left(\frac{u_{\text{STD}}^\circ}{u_i^\circ} \right) - K_{r,\text{STD}} T_a + b T_a (c + d n_{aa,i}) \quad (8-50)$$

Because u_i° should be the same for all complexes between well-behaved polypeptides and dodecyl sulfate⁹⁰ and u_{STD}° , $K_{r,\text{STD}}$, and T_a are all constant, this equation predicts that a plot of $-\ln R_f$ against n_{aa} should be linear. When the natural logarithms of the relative mobilities measured by Weber and Osborn⁹³ are plotted as a function of the now known lengths of these polypeptides, n_{aa} , they conform to this expectation (Figure 8-14).^{93*}

At the present time, the method almost universally used to **estimate the length of a polypeptide**, the sequence of which is not yet known, is to determine the mobility of its complex with dodecyl sulfate upon electrophoresis on polyacrylamide gels. The mobility of the unknown is compared to the mobilities of complexes between dodecyl sulfate and standard polypeptides of known length, usually by plotting the data as in Figure 8-14. It should be realized, however, that the widespread reliance on this method is based on the assumption that the polypeptide of interest binds the same amount of dodecyl sulfate (amino acid)⁻¹ as the standards used. A comparison of Figure 8-13, which describes the behavior of a series of polymers in which the uniformity of the charge distribution is covalently dictated, with Figure 8-14, which describes the behavior of a series of polymers in which the uniformity of charge distribution depends only on a fortuitous consistency in its composition producing a fortuitous consistency in its ability to bind a small electrolyte, emphasizes the drawbacks of this assumption.

* When complexes between dodecyl sulfate and polypeptides are submitted to electrophoresis on polyacrylamide gels in which the complexes are stacked by moving discontinuities,⁹⁶ the relative mobilities of the standards do not fall on a line when they are plotted as in Figure 8-14. Nevertheless, their mobilities increase monotonically with their length, and the length of an unknown polypeptide can be estimated by interpolation.

Figure 8-14: Sieving of complexes between dodecyl sulfate and unfolded polypeptides on electrophoresis in gels of polyacrylamide cast in solutions of sodium dodecyl sulfate.⁹³ A series of proteins (listed in Table I of ref 93) were submitted to electrophoresis as described in Figure 8-8. A marker dye was included in each sample, the mobility of which served as an internal standard. Its position was marked on each gel at the end of each run and the gels were stained. The distance migrated by each polypeptide was divided by the distance migrated by the marker dye to obtain a relative mobility R_f . The negative natural logarithms ($-\ln R_f$) of these values of relative mobility have been plotted as a function of the number of amino acids (n_{aa}) in the respective sequences of the polypeptides (www.expasy.org/sprot/).

Because they bind dodecyl sulfate with different stoichiometries, proteins that have peculiar compositions of amino acids,⁸⁷ that are excessively hydrophobic,⁸⁸ or that are significantly glycosylated do not have mobilities on polyacrylamide gels when they are coated with dodecyl sulfate that reflect only their lengths, and this procedure is unreliable in these instances.

A further problem that also should be realized is that beyond the ranges of relative mobilities displayed in Figure 8-14, the linear behavior of complexes between dodecyl sulfate and polypeptides often fails. This was originally pointed out by Weber and Osborn,⁹³ and it manifests itself in the tendency of complexes between dodecyl sulfate and very long polypeptides to travel faster than their lengths should permit. Because it is impossible to predict in what range of polymer lengths nonlinear behavior will become significant, a large collection of standard polypeptides the mobilities of which are close to and on either side of the mobility of the unknown should be chosen and the length of the unknown should be estimated by interpolation.

The failure of complexes between dodecyl sulfate and **long polypeptides** to behave as if they were geo-

metric solids is probably due to a change in the mechanism of sieving. It has been proposed that when the long dimension of a severely elongated macromolecule is significantly greater than the mean spacing between the fibers of polymer in a sieve, it will be hindered from reorienting significantly about any axes normal to that long dimension by the network itself. If so, it will be forced to move through the network as a worm in a randomly meandering burrow.¹¹⁶ At very low electric field gradients, the mobility of such a wormlike molecule should be proportional to n_{aa}^{-1} rather than $\exp(-n_{aa})$. At field gradients in the range normally used for electrophoresis, the burrow has a strong tendency to become aligned with the field, causing the mobility of the worm to become almost independent of n_{aa} .¹¹⁷ It is possible that the deviation of the retardation coefficients of complexes between dodecyl sulfate and longer polypeptides from linear behavior on gels of one polyacrylamide concentration^{88,93} results from a change in the mechanism of sieving that occurs as the longer dimension of the polymer becomes so long that it is forced to travel through the network as a worm rather than as a randomly reorienting, flexible geometric solid. The point at which this change in mechanism would set in would be a function not only of the length of the polymer but also of the spacing of the fibers in the network. If this is the case, it would explain the common observation that the behaviors of complexes between dodecyl sulfate and long polypeptides often become more linear when the concentration of polymer in the network is decreased.⁸⁸

Problem 8-10: A series of standards was run to calibrate a cylindrical column of Sephadex G-75 for chromatography by molecular exclusion¹⁰⁴ so that it could be used to estimate the number of amino acids in bovine α -lactalbumin. The void volume of the column, V_0 , was 71 mL, and the total volume of the bed, V_T , was 226 mL. The following elution volumes were observed:

protein	n_{aa}	elution volume
cytochrome c	104	138 mL
ribonuclease	124	136 mL
myoglobin	153	127 mL
chymotrypsinogen	245	113 mL
α -lactalbumin		131 mL

(A) Calculate $K_{av} = (V_e - V_0)/(V_T - V_0)$ for every protein.

(B) Estimate the number of amino acids in α -lactalbumin.

Problem 8-11: Glycogen phosphorylase from *Oryctolagus cuniculus* was dissolved in a solution of sodium dodecyl sulfate sufficient to saturate the protein and submitted to electrophoresis on a polyacrylamide gel cast in a solution of sodium dodecyl sulfate. The relative mobilities of the glycogen phosphorylase and several standard proteins were measured.⁹³

protein	length of polypeptide (amino acids)	mobility relative to marker dye
myosin	1938	0.10
β -galactosidase	1023	0.16
serum albumin	583	0.33
catalase	506	0.37
glutamate dehydrogenase	501	0.43
fumarate hydratase	466	0.47
fructose-bisphosphate aldolase	363	0.56
glycogen phosphorylase		0.23

Estimate the length of the polypeptide composing glycogen phosphorylase.

Problem 8-12: Estimate the length of the polypeptide that composes porcine pepsin A from the following relative mobilities of complexes between the polypeptides and sodium dodecyl sulfate on electrophoresis on polyacrylamide gels cast in a solution of dodecyl sulfate.⁹³

polypeptide	n_{aa}	distance migrated (cm)
serum albumin	583	1.78
immunoglobulin G heavy chain	450	2.92
D-amino acid oxidase	347	4.80
glyceraldehyde-3-phosphate dehydrogenase	332	4.80
aspartate carbamoyltransferase, catalytic	310	5.22

Cataloguing Polypeptides

Rather than the intact oligomeric complexes of subunits formed from properly folded polypeptides that are separated during the electrophoresis of native proteins (Figure 1-19), the components separated when a mixture of different proteins is submitted to **electrophoresis in the presence of dodecyl sulfate** represent individual, unfolded, unassociated polypeptides. Consequently, such an electrophoretic separation is a **catalogue of the polypeptides** present in a sample⁹³ rather than a catalogue of the proteins. A graphic example of such a catalogue can be seen in Figure 1-22.

When a purified protein the homogeneity of which has been verified by electrophoresis in its native state is

submitted to electrophoresis in the presence of dodecyl sulfate, the pattern observed is a dissection of the protein into the different polypeptides of which it is composed. Usually a protein is composed of only one polypeptide, and that one polypeptide is usually present in the native protein in several copies. There are, however, many proteins that contain two or more different polypeptides, and a comprehensive description of the quaternary structure of such a protein requires that each of its constituent polypeptides be recognized as a unique component of the overall complex.

A catalogue of the polypeptides from which a protein is formed is reliable only if the **shortcomings** of electrophoresis in the presence of dodecyl sulfate have been recognized and eliminated. First, it has already been noted that, on discontinuous electrophoresis, components of high mobility often fail to escape the descending boundary. Complexes between dodecyl sulfate and short polypeptides are often trapped in this way and are unresolved. Second, it is also the case that, for reasons not well understood, all complexes between dodecyl sulfate and polypeptides less than 100 amino acids in length seem to have the same electrophoretic mobility,¹¹⁸ regardless of the concentration of polyacrylamide. This lower limit below which resolution fails can be lowered to about 25 amino acids in length by adding 8 M urea to the polyacrylamide gel.^{97,119} Third, because the cleavage of one peptide bond out of the hundreds present in an intact polypeptide always produces two new polypeptides that will be separated from each other and from their parent by electrophoresis in the presence of dodecyl sulfate, any degradation of the native protein by endopeptidases during or before its purification can artifactually multiply the apparent number of polypeptides without significantly altering the native protein or its own electrophoretic mobility. Fourth, endopeptidases often unfold more slowly than other proteins upon exposure to dodecyl sulfate, and they cleave their unfolded neighbors before they in turn succumb. If the purified protein is contaminated with even minute amounts of the endopeptidases that are always present in a homogenate, they can degrade the polypeptides during the preparation of the sample. Because these cleavages of the unfolded polypeptides are produced at random, as opposed to the unique cleavages usually produced during the degradation of a native protein by endopeptidases, they cause polypeptides in the sample to disappear into hundreds of fragments smeared over the field, each present in very low yield. Such an apparent disappearance of a polypeptide or polypeptides can also occur during the purification of the protein rather than during preparation of a sample for electrophoresis. For example, it was once thought that the stoichiometry of the subunits of nicotinic acetylcholine receptor from the electric eel was simpler than that from the electric ray until it was demonstrated that the missing polypeptides appeared

when indigenous endopeptidases, unavoidably present during the purification, were intentionally inactivated.¹²⁰ Yet the acetylcholine receptor originally purified, even though it had been cut up at random, was still biologically active. Finally, if only a fraction of the disulfides have been reduced, cross-linked, unreduced and un-cross-linked, reduced forms of the same polypeptide will appear as separate components. All of these and other artifacts must be recognized and eliminated¹²¹ before the pattern observed upon electrophoresis in the presence of dodecyl sulfate gives a reliable assessment of the different polypeptides present in a protein.

Each of the various components separated by electrophoresis in the presence of dodecyl sulfate may or may not represent a single polypeptide with a unique sequence of amino acids. The majority of the time they do, but it sometimes happens that one of the components represents two different polypeptides the lengths of which are so close to each other that they cannot be resolved. For example, the two subunits with unrelated amino acid sequences and unrelated functions composing the multienzyme complex from *Salmonella typhimurium* responsible for anthranilate synthase, glutamine amidotransferase, and anthranilate phosphoribosyltransferase happen to be 530 and 520 aa in length and are not resolved by electrophoresis in the presence of dodecyl sulfate. They are, however, cleanly resolved by electrophoresis in 8 M urea, a solution in which they are also unfolded but in which their differences in charge are not swamped by the binding of dodecyl sulfate.¹²² It is also possible that one or more of the components on the gel represent fragments of a larger component, also seen on the same gel. One way to resolve both of these ambiguities is to perform peptide maps.

A **peptide map** is a characteristic and reproducible display of the peptides produced when a polypeptide is digested with a specific endopeptidase. The display is usually produced by chromatographically or electrophoretically separating the digest in two dimensions to produce a characteristic pattern or map. Usually, the two dimensions are the respective orthogonal directions on a sheet of chromatographic paper or a thin layer of cellulose on a backing of plastic. Originally, electrophoresis was performed in the first dimension and chromatography in the second. Peptide maps are sensitive methods for assessing the similarity of two polypeptides, demonstrating that one polypeptide is a fragment of another, or revealing that one of the components on a polyacrylamide gel represents two polypeptides that fortuitously have the same electrophoretic mobility.

The most reliable maps are obtained from **tryptic digests** of a polypeptide because trypsin is the most specific and dependable of the endopeptidases. Polypeptides usually contain about 5 mol % arginine and 7 mol % lysine,¹²³ and for every 100 aa in length, about 11

tryptic peptides should be present in the digest.* Each component on the map should represent a different tryptic peptide. Ideally, the resolution of the map should be high enough that every peptide in the digest appears as a separate, distinguishable component.

The initial triumph of analytical peptide mapping was in the examination of a mutant hemoglobin.¹²⁴ It had been proposed that the difference between normal hemoglobin, referred to as hemoglobin A, and hemoglobin S, a hemoglobin producing pathological distortions in erythrocytes, was due to a small difference in the amino acid sequence of the two proteins.¹²⁵ It was then shown that one and only one of the tryptic peptides on the respective peptide maps of the two proteins displayed an altered mobility (Figure 8–15).¹²⁶ It was concluded that all of the peptides the mobilities of which were the same between the two maps had identical sequences and the same relative locations in the two intact polypeptides, but that the one peptide the mobility of which was different had a sequence that differed between the two proteins by at least one amino acid. Because it is unlikely that the only two or three changes in the sequence of a polypeptide would occur in the same tryptic peptide, this result alone was substantial evidence that the two proteins differed from each other at only one location in their respective sequences. This was soon shown to be true by complete amino acid sequencing.

A similar strategy was used to evaluate the differences in the amino acid sequences of the different isoforms of actin.^{127,128} Each member of the set of the isoforms of actin chosen for the experiment, each of which had been isolated from a different species or a different tissue—a total of eight in all—was digested with trypsin, and each peptide map was compared to the peptide map of actin from skeletal muscle of *O. cuniculus*, the complete amino acid sequence of which was known. In all cases, the majority of the tryptic peptides were distributed over the map in the same pattern as the corresponding peptides on the map from the standard, and this permitted the various maps to be aligned with that of the standard. The peptides occupying the same positions in a pair of maps were assumed to be identical to each other in amino acid sequence. Amino acid analysis was used to verify these identities. Each unique peptide on the maps of the various unknowns was eluted and sequenced. Each of these amino acid sequences could be aligned with one of the tryptic peptides in the sequence of actin from muscle of *O. cuniculus*, and in this way the amino acid replacements in the sequences of the other actins could be readily established. This set of experiments relied on the fact that, aside from the first six amino acids in each sequence, all of the actins that were being compared show about 95% identity when their

* About 5% of the lysines and arginines in a protein are followed by proline, and trypsin is unable to cleave either a lysylproline or an arginylproline peptide bond.

Figure 8-15: Comparison of tryptic peptide maps of hemoglobin A (left panel) and hemoglobin S (right panel).¹²⁶ The respective hemoglobins were denatured at 90 °C for 4 min and the denatured proteins were digested with trypsin (1:50 trypsin/hemoglobin). The resulting digests were spotted on sheets of chromatographic paper, and the peptides were separated in the horizontal dimension by electrophoresis at pH 6.4 (negative pole to the left) and in the vertical direction by ascending chromatography in 1-butanol/acetic acid/water (3:1:1). The peptides were visualized with ninhydrin. A peptide in the middle of the right side of the left panel is replaced by a peptide in the center of the right panel. Reprinted with permission from ref 126. Copyright 1958 Elsevier Science Publishers.

amino acid sequences are aligned. This level of identity was what produced the underlying pattern that permitted the maps to be aligned and, in turn, permitted the ready identification of the peculiar peptides.

When the polypeptide is a long one, there may be so many components on a tryptic peptide map that they begin to overlap. One way to solve this problem is to modify the **tyrosine** side chains in the protein with radioactive iodine by electrophilic aromatic substitution. Because there are only 3–4 tyrosines for every 100 amino acids in a typical protein,¹²³ only about a third of the tryptic peptides become radioactive, and an autoradiogram* of the map is less cluttered than the entire map itself, but just as unique to the particular polypeptide. Such a map of tyrosine-containing chymotryptic peptides was used to show that the α polypeptides of Na^+/K^+ -exchanging ATPase from liver and kidney, respectively, both polypeptides now known to be 1018 amino acids in length with 24 mol of tyrosine (mol of polypeptide)⁻¹, were very similar if not identical to each other (Figure 8-16).¹²⁹ Another way of generating a peptide map from a long polypeptide is to digest the complex between it and dodecyl sulfate in a solution of dodecyl sulfate with an endopeptidase.¹³⁰ Under these conditions, the digestion is severely incomplete because the endopeptidase is rapidly inactivated by the dodecyl sulfate. Nevertheless, a reproducible set of large fragments of the polypeptide, characteristic of both it and the specificity of the endopeptidase used, is produced, and when these large fragments are separated by electrophoresis in the presence of dodecyl sulfate, the pattern of bands on the gel is a fingerprint unique to that polypeptide.

* An autoradiogram is a photographic image of the map on which only radioactive components are registered. It displays the distribution of radioactivity over the field.

Peptide mapping is sometimes performed by **adsorption chromatography** (Figure 3-7) because these separations are more rapidly accomplished,¹³¹ but this procedure is not so informative because it involves a separation in only one dimension. It is also possible to separate tryptic peptides from the digest of a polypeptide in one dimension by **mass spectrometry** following matrix-assisted laser desorption.^{132,133} The peptide map that results has the disadvantage that often only a portion of the tryptic peptides is present rather than a complete set so it functions mainly as a fingerprint of the particular polypeptide. Such a map, however has the advantages

Figure 8-16: Peptide maps of tyrosine-containing chymotryptic peptides from the α polypeptide of Na^+/K^+ -exchanging ATPase.¹²⁹ After Na^+/K^+ -exchanging ATPase was purified from rat liver or rat kidney by immunoabsorption, its α polypeptide was isolated by electrophoresis on polyacrylamide gels in solutions of dodecyl sulfate. Each of the respective purified polypeptides was then chemically modified at its tyrosines by electrophilic aromatic substitution with ¹²⁵I. The radioactive polypeptides were then digested separately with chymotrypsin, and the digests were separated in two dimensions on thin layers of cellulose. Electrophoresis was performed from right to left followed by ascending chromatography with butanol/pyridine/water/acetic acid (65:50:40:10 v/v/v/v) from bottom to top. Peptides containing *o*-[¹²⁵I]iodotyrosine were identified by placing photographic film over the chromatogram. The images are those of the developed films. (A) Map from α polypeptide of kidney; (B) map from α polypeptide of liver. Adapted with permission from ref 129. Copyright 1986 American Chemical Society.

that the resolution is high so one dimension is sufficient, that the molecular mass of each peptide appearing on it is registered, and that the peptides can subsequently be sequenced (Figure 3–8). If the amino acid sequences of two closely related proteins are known, mass spectrometric peptide maps can often tell a sample of one from a sample of the other.¹³⁴ Another advantage of a mass spectroscopic peptide map is that it can be performed on a small amount of protein (1 pmol).

If two polypeptides yield peptide maps similar enough that they are judged to be related, the **percentage of identity** between their two sequences will be high; if they yield peptide maps that cannot be regarded as similar, they may still have clearly homologous sequences. In two-dimensional mapping of either all the peptides in a digest or just the tyrosine-containing peptides, or in peptide mapping by adsorption chromatography or mass spectrometry, the evaluation of the similarity of two polypeptides is based on comparison of the two patterns in which the peptides are displayed (Figure 8–15). Only if a significant fraction of the peptides on the two maps have the same relative positions on the field and produce a pattern that can be recognized is the judgment made that the two polypeptides are similar to each other. This implicit criterion of similarity requires that a significant fraction of the respective peptides be identical to each other in sequence for the decision to be made that the two polypeptides are related. One difference in the sequence of two otherwise identical peptides is usually sufficient to cause them to have different mobilities (Figure 8–15). Because the mean tryptic peptide is eight amino acids in length, differences between the sequences of two polypeptides at more than 20% of the positions will cause the two maps to be completely different, even though the two polypeptides are similar enough to be unambiguously judged homologous in amino acid sequence. Each of the four polypeptides of nicotinic acetylcholine receptor, although they are all homologous in sequence to each other (averaging 40% identity), yields a completely different peptide map.¹³⁵ The order in which the three ways of detecting homologies among polypeptides fail as the percentage of identity becomes smaller is peptide mapping before alignment of amino acid sequences and alignment of amino acid sequences before superposition of tertiary structures.

Whenever two or more polypeptides appear upon electrophoresis of a purified protein in the presence of dodecyl sulfate, the possibility that the smaller polypeptide or polypeptides are **fragments of the largest** should be examined. Such a relationship can be established by peptide mapping. The protein ankyrin from human erythrocytes is present in the cell under physiological conditions as the complete polypeptide and three progressively smaller fragments of that polypeptide. That these four polypeptides represent such a nested set derived by digestion of the largest by cellular endopeptidases could be demonstrated by producing peptide

maps of each.¹³⁶ This was done by separating these polypeptides on polyacrylamide gels in solutions of sodium dodecyl sulfate, iodinating their tyrosines, digesting them with trypsin, and producing tryptic peptide maps. These peptide maps all displayed the same pattern, but the maps from the smaller polypeptides lacked one or two of the peptides present in those from the next larger one. When collagen type XIV is isolated from epidermis of *Macaca fascicularis*, the purified protein contains two polypeptides that can be separated by electrophoresis in the presence of dodecyl sulfate. The complexes between each of these two polypeptides and dodecyl sulfate were digested separately with glutamyl endopeptidase. In the range of lengths less than that of the shorter of the two polypeptides, the two patterns of fragments that resulted from these partial digestions were identical to each other, a result demonstrating that the shorter of the two polypeptides was itself a fragment of the longer.¹³⁷

Peptide mapping can be used to determine whether an apparently unique component resolved by electrophoresis in the presence of dodecyl sulfate represents only one polypeptide or **two or more polypeptides** that fortuitously have the same electrophoretic mobility. The electrophoretic mobility of the complex between dodecyl sulfate and the polypeptide in question can be used to estimate its length. The mole percent of lysine and arginine in the protein can be either determined directly by total amino acid analysis or estimated from the fact that this number is usually about 11 mol %.¹²³ The mole percent of lysine and arginine and the length of the polypeptide can be used to estimate the number of tryptic peptides that should be produced if the component observed on the gel does represent only one unique polypeptide. If the number of peptides observed on the map agrees with this expectation, the component probably represents only one unique polypeptide. If there are about twice as many spots as expected, it must represent two different polypeptides. If the component does represent two or more polypeptides, it should be possible to separate them chromatographically or electrophoretically. Such a separation can usually be performed in 8 M urea, a solvent that unfolds polypeptides and separates them one from the other but that does not interfere with either chromatography by ion exchange or electrophoresis. The two or more separated polypeptides should each give unique peptide maps, the sum of which should be the peptide map of the original mixture.

When phosphoglycerate dehydrogenase was saturated with dodecyl sulfate and submitted to electrophoresis, one component was observed, the electrophoretic mobility of which was that of a polypeptide 360 aa in length. The content of lysine plus arginine in the protein was determined by amino acid analysis to be 9.6 mol %. A tryptic digest of the protein was separated by cation-exchange chromatography, and each of the pools from this first dimension was submitted to

electrophoresis on paper. This two-dimensional peptide map displayed 39–40 major peptides. The content of tryptophan in the protein was 1.0 mol %, and four of the peptides gave a positive test for tryptophan. If all of the polypeptides in this protein are identical, there should have been 36 tryptic peptides, four of which should have contained tryptophan. The **agreement between the observed numbers and the expected numbers** led to the conclusion that phosphoglycerate dehydrogenase was composed of identical polypeptides.¹³⁸

Glutamate-tRNA ligase was submitted to electrophoresis in the presence of dodecyl sulfate, and a single component was observed, the mobility of which was that of a polypeptide 500 aa in length. The protein had a content of lysine plus arginine of 12 mol %; tryptophan, 1.0 mol %; arginine, 6.3 mol %; and cysteine, 1.0 mol %. It could be concluded¹³⁹ that the component observed upon electrophoresis represented only one polypeptide because the tryptic peptide map of the protein displayed 55 peptides, 30 of which gave a positive test for arginine, five of which gave a positive test for tryptophan, and five of which became radioactive after the protein was reduced and carboxymethylated with [¹⁴C]iodoacetic acid (Equation 3–17).

Upon electrophoresis in dodecyl sulfate, the molybdenum-iron protein that is one of the components of nitrogenase gave two bands of stained material of very similar and often indistinguishable electrophoretic mobility, the apparent lengths of which were 540 amino acids. When the protein was reduced, carboxymethylated with [¹⁴C]iodoacetic acid, and submitted to amino acid analysis, its content of ([¹⁴C]carboxymethyl)cysteine was 1.7 mol %. Eleven of the tryptic peptides on a peptide map of the reduced and carboxymethylated protein were radioactive when nine were expected. Instead of passing this off as the result of incomplete digestion or inaccurate values for content of cysteine, the investigators proceeded to show that when the protein was dissolved in urea, to unfold its polypeptides, two polypeptides could be isolated by cation-exchange chromatography on (carboxymethyl)cellulose. Both were submitted to reduction, carboxymethylation, and peptide mapping. Four of the radioactive, cysteine-containing peptides from the map of the total protein were found on the map of one of the polypeptides, and the other seven radioactive peptides from the map of the total protein were found on the map of the other polypeptide, and no overlaps occurred between the two maps. It could be concluded that the molybdenum-iron protein had the subunit stoichiometry $\alpha\beta$.¹⁴⁰

A similar situation arose with methylmalonyl-CoA carboxytransferase. When this protein was submitted to electrophoresis in the presence of dodecyl sulfate, a component was present the apparent length of which was 550 amino acids, but under some conditions it would split into two bands of equal intensity. It was found that the native enzyme could be dissociated at pH 9.0 into two

proteins that could be separated from each other by molecular exclusion chromatography. Each of these proteins was composed of polypeptides the apparent lengths of which were 550 amino acids.¹⁴¹ Although their complexes with dodecyl sulfate were almost indistinguishable in electrophoretic mobility, the polypeptides in these separated proteins produced completely different tryptic peptide maps.¹⁴² It was later shown that they were polypeptides of 519 and 604 aa in length, respectively, with unrelated amino acid sequences.

The use of tryptic peptide mapping to provide evidence for the homogeneity of the polypeptides in a protein relies on the assumption that the trypsin has digested the polypeptide completely. This should be independently demonstrated. For example, initial tryptic digests of the polypeptides composing glucose-6-phosphate isomerase produced only two-thirds to three-fourths as many peptides as had been expected from the assumption that they were all identical. It was found that less base was consumed during the digestion than should have been, and this suggested that the digestion had been incomplete. When the protein was carbamylated on all of its lysines and then digested with trypsin, the quantity of base consumed during the digestion and the number of peptides observed on the map were those expected theoretically.¹⁴³ A more sensitive measure of complete tryptic digestion is to compare the total content of lysine and arginine in the digest to the amount of lysine and arginine released from the peptides in the digest when a sample is in turn digested with an appropriate carboxypeptidase.

Electron transfer flavoprotein is another protein composed of two polypeptides the lengths of which are very similar. It was originally believed to be a dimer of two identical polypeptides.¹⁴⁴ Under certain circumstances, however, two narrowly separated components would appear upon electrophoresis in the presence of dodecyl sulfate, and these were different enough to be separated by preparative electrophoresis. Each of the separated polypeptides was cleaved with cyanogen bromide, and the fragments produced were in turn saturated with dodecyl sulfate and separated in one dimension by electrophoresis in a solution of 0.1% dodecyl sulfate in 8 M urea (Figure 8–17).^{119,145} The maps produced in this way from each separated polypeptide were unique, and their sum was equal to the map of the intact protein. These results established the fact that the quaternary structure of the electron transfer flavoprotein is $\alpha\beta$ and explained the observation that there is only 1 mol of flavin (1.8 mol of polypeptide)⁻¹ in the protein.

Many proteins in addition to the molybdenum-iron protein of nitrogenase, methylmalonyl-CoA carboxytransferase, and electron transfer flavoprotein are composed of **two or more different polypeptides**. Often there is a functional basis for this arrangement. Many multienzyme complexes, rather than being composed of a string of enzymatic domains each formed from a dif-

Figure 8-17: Peptide maps in one dimension performed by electrophoresis on a polyacrylamide gel of fragments derived from cleavage of electron-transferring flavoprotein from porcine liver with cyanogen bromide.¹⁴⁵ All proteins were reduced and alkylated with iodoacetamide before cleavage. Intact electron transfer flavoprotein (upper trace), its α polypeptide (middle trace), or its β polypeptide (lower trace), the latter two polypeptides isolated by preparative gel electrophoresis, were digested with cyanogen bromide (25 mM) in 88% formic acid and 0.03% sodium dodecyl sulfate for 24 h at 25 °C. The fragments produced were separated on gels cast from 13.4% acrylamide in 0.1% sodium dodecyl sulfate and 8 M urea¹¹⁹ and stained for protein. The gels were then scanned for absorbance as a function of length, and length was converted to mobility relative to the mobility of a marker dye. Reprinted with permission from ref 145. Copyright 1983 *Journal of Biological Chemistry*.

ferent region of the same polypeptide, are constructed from individual subunits gathered together in a larger complex. Functionally there is no distinction between these two types of **multienzyme complexes** because the important feature is that the different enzymes are gathered together, whether they are gathered as domains on

the same subunit or as different subunits. It has already been noted that methylmalonyl-CoA carboxytransferase is formed from different subunits. One of its three constituent polypeptides is folded to produce a protein that in isolation¹⁴⁶ can catalyze the reaction

and another, a protein that can catalyze¹⁴⁶ the reaction

The entire enzyme is composed of these two subunits and a third subunit formed from a single polypeptide bearing covalently attached biotin as a posttranslational modification of one of its lysines. The intact multienzyme complex catalyzes the overall reaction

In the case of the molybdenum-iron protein of nitrogenase, each of the two polypeptides of almost the same length (491 and 522 aa) forms one of its subunits. One of the two subunits contains the molybdenum and some of the iron, while the other subunit contains iron-sulfur clusters of a ferredoxin type. This assigns different functional roles to each of the subunits and explains the stoichiometries of the molybdenum and iron found in the intact protein.¹⁴⁰

Some of the proteins, however, thought to be composed of two different types of subunits, because they are isolated as complexes containing two different polypeptides, are actually the products of a **posttranslational cleavage**, either intentional or artifactual, of what was initially a single polypeptide. The internal modification of histidine decarboxylase from *Lactobacillus* producing the *N*-pyruvyl amino terminus (Equation 3-9) coincidentally produces two shorter polypeptides of lengths 81 and 229 amino acids from the originally intact precursor.^{147,148} Before the modification occurs, the protein is constructed from six identical copies of the intact polypeptide, each folded as an independent subunit. Many endopeptidases are normally stored safely as inactive precursors that are activated at the proper time by an internal cleavage or cleavages catalyzed by another molecule of endopeptidase. These cleavages occur in surface loops and have little effect on the overall structure of the protein, and the two resulting fragments are not separate subunits or even separate domains.¹⁴⁹ Another example of a posttranslational cleavage that produces two fragments of a constituent polypeptide occurs during the maturation of insulin receptor.¹⁵⁰

It was once believed that vertebrate acetyl-CoA carboxylase was constructed from two or three different polypeptides, each present in one or two copies.¹⁵¹ This belief was reinforced by the fact that the enzyme from *E. coli* is a multienzyme complex constructed from three different subunits,¹⁵² albeit folded polypeptides of lengths much shorter than the polypeptides found in the enzyme from vertebrates. When the vertebrate enzyme was purified by a rapid procedure employing affinity adsorption, however, it was found to be composed from only one polypeptide, the length of which (2345 amino acids) was more than twice the individual lengths of the separate polypeptides seen previously.¹⁵³ Only two folded copies of this longer polypeptide are present as subunits of the native protein. It was concluded that the smaller polypeptides seen previously were the products of artifactual digestion by endopeptidases.

The distinction between a protein that contains two different polypeptides because of a posttranslational cleavage and one that has been assembled from two separately translated polypeptides is significant. The posttranslational cleavage of a protein usually occurs after the entire polypeptide has folded because it is only in the folded polypeptide that the cleavage can be directed to a precise location. Although significant changes may occur in the vicinity of the cleavage, the overall structure of the protein remains what it was before the cleavage. For all intents and purposes, a polypeptide cleaved either naturally or artifactualy after it has folded remains structurally a folded single polypeptide. On the other hand, when a protein is assembled from separately translated polypeptides, they first must fold independently before they can recognize each other and join together. Each subunit begins as and remains as a discrete entity and appears as such when a crystallographic molecular model of the protein is viewed. Yet when the polypeptides are resolved on a polyacrylamide gel, these two very different situations cannot be distinguished, and as with the confusion surrounding the connotations of the term domain, the urge arises to confer the structural integrities of separate subunits to a protein that may contain two or more polypeptides only by virtue of posttranslational modification.

It is possible that the number of proteins assembled from two or more different subunits containing polypeptides with different sequences and different lengths has been overestimated. Even if this is not so, such heterooligomers represent only a minority of the oligomeric proteins. Most oligomeric proteins are constructed from only one polypeptide that is present in two or more identical copies in the complete protein. The length of that polypeptide is estimated by electrophoresis in the presence of dodecyl sulfate. The number of copies present in the intact protein is counted.

Problem 8–13: Glucose-6-phosphate isomerase catalyzes the conversion

The enzyme has been purified from muscle of *O. cuniculus*. When it was dissolved in a solution of sodium dodecyl sulfate and submitted to electrophoresis, the following results were obtained:¹⁴³

protein	n_{aa}	R_f
ovalbumin	385	0.42
catalase	506	0.32
serum albumin	583	0.26
glucose-6-phosphate isomerase		0.30

The enzyme was unfolded in 6 M guanidinium chloride and modified with potassium cyanate, the reagents were removed by dialysis, and the protein was digested with trypsin. The following two maps were made of this tryptic digest. The only difference in these two maps is the pH at which the electrophoresis was performed.

The amino acid composition of the protein has been determined:

amino acid	moles (100,000 g of protein) ⁻¹	amino acid	moles (100,000 g of protein) ⁻¹
K	62	I	53
H	36	L	87

The protein was digested with trypsin, and a peptide map was prepared. It contained 26 well-defined peptides. The peptide map was stained for various amino acid side chains: five peptides were positive for arginine, 13 peptides were positive for histidine, four peptides were positive for methionine, three peptides were positive for tryptophan, and seven peptides were positive for tyrosine. The protein was carboxymethylated with [¹⁴C]iodoacetic acid and digested with trypsin. Three tryptic peptides containing radioactive (carboxymethyl)cysteine were isolated by ion-exchange

chromatography, and each of these was shown to have a unique composition of amino acids and to contain 1 mol of Cys (mol of peptide)⁻¹.

- (A) What is the length of a polypeptide composing this protein?
- (B) How many different types of polypeptides compose the protein?
- (C) Explain the peptide maps.

Cross-Linking

There arose a disagreement over the number of subunits contained in fructose-bisphosphate aldolase. The physical methods for estimating the molar mass of the native protein and the molar mass of its constituent polypeptides were unable to decide between three and four. It should be noted that everyone had an equal chance of being correct, so the point is not who turned out to be right but that the question could not be resolved simply by arguing over the numbers. What was needed instead was a different kind of experiment, and it was provided. When the fructose-bisphosphate aldolase in a homogenate from brain of *O. cuniculus* was submitted to electrophoresis in its native state, five evenly spaced components displaying enzymatic activity were observed (Figure 8-18).⁷⁶ Penhoet, Kochman, Valentine, and Rutter⁷⁶ decided that this must be due to the fact that, in the brain, two isoenzymatic polypeptides designated α and γ are translated from two different messenger RNAs continuously and coincidentally. These polypeptides fold separately to form monomeric subunits that then combine at random with subunits of their own kind or of the other isoenzymatic type to produce **hybrids** of the stoichiometries α₄, α₃γ, α₂γ₂, αγ₃, and γ₄, designated A, I, II, III, and C in Figure 8-18.* The two different subunits, α and γ, differ in the sequences of their polypeptides and hence in their charge. Each hybrid in turn has a different electrophoretic mobility because each has a different mean charge number *Z*. The hybrids are capable of forming in the first place because the two different polypeptides are homologous in their sequences, have superposable tertiary structures in their folded state, share a common ancestor, and have not diverged sufficiently from that common ancestor to have lost the ability to combine with each other in the same way that they are required to do with subunits identical to themselves. If this explanation is correct, the number of subunits in any molecule of aldolase can be determined by simply counting the components on the electrophoretic separation. There must be four. A similar hybridization was used to verify that chloramphenicol *O*-acetyltransferase is a trimer.¹⁵⁵

* The proteins with quaternary structures α₄ and γ₄ have been designated the A isoform and the C isoform, respectively, of fructose-bisphosphate aldolase.

Figure 8-18: Dissociation and reassociation of oligomeric hybrids of fructose-bisphosphate aldolase.⁷⁶ A clarified homogenate from brain of *O. cuniculus* was submitted to electrophoresis on cellulose acetate at pH 8.6, and the strip was then stained for the activity of fructose-bisphosphate aldolase. Five evenly spaced bands of enzymatic activity were observed (top pattern). On the basis of their calculated points of zero net charge, the most anionic component, labelled C in the figure, could be identified as isoform C of fructose-bisphosphate aldolase; and the most cationic, labelled A in the figure, as isoform A of fructose-bisphosphate aldolase. The homogenate was then submitted to substrate elution from cellulose phosphate followed by anion-exchange chromatography on (diethylaminoethyl)cellulose (Figure 1-2). The five components that differed in electrophoretic mobility could be identified on these chromatograms by their enzymatic activity and could be cleanly separated from each other in this way. Each was submitted to electrophoresis separately at pH 8.6 and only one respective component with enzymatic activity was found in each (the five patterns on the lower left). Each of these single components was then exposed to 0.33 M H_3PO_4 at pH 2.0 for 30 min at 0 °C and then brought back to pH 7.5. The low pH served to dissociate the subunits of each hybrid, and the neutralization reassociated them but at random. Each of the dissociated and reassociated mixtures of hybrids was then resubmitted to electrophoresis, and the strips of cellulose acetate were stained for enzymatic activity (the five patterns on the right). Reprinted with permission from ref 76. Copyright 1967 American Chemical Society.

In the experiments with fructose-bisphosphate aldolase, the investigators proved that the components observed upon electrophoresis were the hybrids that they proposed by isolating each of them, dissociating each to subunits, reassociating the subunits, and demonstrating that each of these reassociated samples contained a new set of hybrids consistent with the random rearrangement of the stoichiometry assigned to the parent (Figure 8-18). For example, α_4 gave back only α_4 and γ_4 gave back only γ_4 , but $\alpha_2\gamma_2$ gave all five hybrids in

approximately binomial ratios. It was also shown that an equal mixture of α_4 and γ_4 when dissociated and reassociated reproduced all five hybrids.

It is possible to increase the difference in charge between two isoenzymatic polypeptides, and hence the spacing between the bands on electrophoresis, or to produce a charge variant of a single polypeptide by mutating lysines to glutamates.¹⁵⁵ It is also possible to make **electrophoretic variants** by simply succinylating any native protein of interest,¹⁵⁶ rather than relying on isoforms coincidentally provided by nature. The pattern of functional heterogeneity, rather than the pattern of electrophoretic heterogeneity, of a hybrid mixture formed from subunits with differences in function, rather than differences in charge, can also be used to count the subunits in an oligomer.¹⁵⁷ Nevertheless, the number of subunits in a native protein is rarely counted by hybridization. The point, however, is not that hybridization solves the problem of determining the stoichiometries of subunits but that an experiment can be designed so that the number of subunits can be counted directly instead of calculated from physical measurements. This new way of looking at the problem stimulated the development of a technique that could be used to count the number of subunits in most soluble proteins. This technique relies upon cross-linking.

A reagent capable of covalently **cross-linking** two polypeptides is a chemical compound that contains at least two electrophilic functional groups attached to each other by the remainder of the molecule. Aromatic diisocyanates, such as *m*-xylylene diisocyanate¹⁵⁸

were among the first such reagents to be used for this purpose, but they suffer from problems of low solubility. A widely employed cross-linking agent, and the one originally used to count subunits,¹⁵⁹ is dimethyl suberimide

By far the most prevalent and accessible nucleophiles on the surface of a molecule of protein are the primary amines of its **lysines**, and the majority of the reagents, such as the diisocyanates and the diimidoesters, are directed to lysines.

There have been a large array of reagents synthesized over the years for cross-linking proteins. They have been designed to react with a broader array of amino acids than just lysine. They have also been designed to form cross-links that can be reversed.¹⁶⁰ A reagent that illustrates all of the various elements in the design of such **cross-linking reagents** is sulfosuccinimidyl 2-(7-azido-4-methylcoumarin-3-acetamido)-ethyl-1,3'-dithiopropionate:¹⁶¹

The ester of *N*-hydroxysulfosuccinimide is an electrophile that reacts with lysines. The *N*-hydroxysulfosuccinimide is used as a leaving group, rather than *N*-hydroxysuccinimide, to increase solubility. The azide is photoactivated to the nitrene that has a broader spectrum of reactivity than a more common electrophile. The two electrophiles react respectively with two nucleophiles on the protein to cross-link them. The disulfide can be reductively cleaved to reverse the cross-linking. The coumarin makes the reagent and hence the products of the cross-linking fluorescent. At the other end of the scale of complexity is the cross-linking of two proteins by the oxidative formation of covalent dimers between a tyrosine on one of the proteins and a tyrosine on the other.¹⁶²

Cross-linking reagents that contain an activated disulfide that reacts efficiently with cysteines on the surface of a protein are also widely used. A mixed disulfide with 2-thiopyridine, an excellent leaving group, can be used to attach an electrophile to a cysteine on the first protein. For example, *N*-succinimidyl 3-(2-pyridyldithio)propionate¹⁶³

reacts by disulfide interchange (Figure 3-20) with the thiol of a cysteine to form a mixed disulfide between that cysteine and the *N*-succinimidyl 3-thiopropionate. The reagent can be directed to a particular location on the first protein by inserting a cysteine at a particular position in its sequence by site-directed mutation.¹⁶⁴ The ester of *N*-hydroxysuccinimide can then react with a lysine on a second protein, cross-linking it to the first protein. The cross-link is reversible because the mixed disulfide can be reduced by disulfide interchange with a

mercaptan such as dithiothreitol (Equation 3-18). This reaction generates a thiol at the location on the second protein that participated in the cross-link. This unmasked thiol can then be used to isolate a peptide from the second protein containing the amino acid that was cross-linked.¹⁶⁴ Because the position in the amino acid sequence of the first protein at which the reagent was attached was determined by the site-directed mutation and the position in the second protein with which the electrophile reacted can be identified by isolating a peptide containing the modified amino acid, the cross-linking reaction can be used to identify adjacent amino acids in the complex that forms between the two proteins.

The most commonly used cross-linking reagents are **bisimidates** and bisaldehydes. An imidoester such as the ones in **8-2** reacts with a primary amine to form an amidine:

When a molecule of dimethyl suberimidate happens to react at one of its ends with a lysine on one subunit and at its other end with a lysine from another subunit, those two subunits become covalently cross-linked and their polypeptides migrate together upon electrophoresis in the presence of dodecyl sulfate with the mobility of a polypeptide the length of which is equal to the sum of the lengths of the two polypeptides so joined.

The intramolecular cross-linking of an oligomeric protein provides a **count of the number of subunits** it contains. At concentrations of protein below 10 μM , no significant intermolecular cross-linking between separate molecules of protein occurs when a solution of protein is mixed with a cross-linking agent such as dimethyl suberimidate. Instead, what is observed are the products that result from intramolecular cross-linking among the fixed number of subunits of which the protein is composed.¹⁵⁹ When the products of such intramolecular cross-linking are separated on a polyacrylamide gel, a ladder of bands, vaguely reminiscent of the ladders seen with randomly cleaved nucleic acids, is observed (Figure

8–19).¹⁶⁵ These ladders, however, end abruptly because no more polypeptides can be cross-linked than are present in the complete protein. A count of the rungs in the ladder provides the number of subunits in the protein. In the case of glycerol kinase, the protein used for the analyses presented in Figure 8–19, it could be concluded that it is composed of four and only four subunits.¹⁶⁵ Peptide maps showed that all four of the polypeptides composing the subunits are identical to each other.¹⁶⁵

There are three **reassurances** that should be provided. First, the relative mobility of each of the bands in

Figure 8–19: Definition of the number of subunits in glycerol kinase.¹⁶⁵ Three samples of a solution of glycerol kinase were mixed with final concentrations of 10 mg mL⁻¹ dimethyl suberimidate (inset, gel C), 0.25 mg mL⁻¹ dimethyl suberimidate (inset, gel B), or no additions (inset, gel A). After 4 h at pH 8.5, the samples were dissolved in a solution of sodium dodecyl sulfate and subjected to electrophoresis on polyacrylamide gels cast in 0.1% sodium dodecyl sulfate. The gels were stained for protein. The irregular line at the bottom of each gel is a line of India ink used to mark the position of the marker dye at the end of the electrophoresis. The band of stain just above this mark on gels A and B is the un-cross-linked polypeptide of glycerol kinase. The mobilities of the four components on gel B relative to the marker dye were calculated from the photograph, and the negative natural logarithm of each of these mobilities ($-\ln R_f$) is plotted against a scale of successive integers. Adapted with permission from ref 165. Copyright 1971 *Journal of Biological Chemistry*.

the ladder should be shown to be a regular function of its number (graph in Figure 8–19).¹⁶⁶ This is a reassurance that one of the members of the set is not missing from the pattern. Second, the cross-linking reaction should be forced to completion so that only the highest oligomer is seen (gel C, inset to Figure 8–19). This result provides the reassurance that this oligomer does represent a true limit to the reaction and that the solution contains only one unique multimer of the subunits rather than a mixture of multimers each containing a different number of subunits. Third, the possibility that intermolecular cross-linking is occurring should be ruled out by varying the concentration of protein. The amounts of the components arising from intramolecular cross-linking will not vary with the concentration of protein, but those that arise from intermolecular cross-linking will. Random intermolecular cross-linking also yields a distribution that gradually declines in its amplitude with band number rather than displaying an abrupt limit at a certain unique polymer size. It is this discontinuous behavior that is the logical basis for believing the results.¹⁵⁹

It is in fulfilling the requirement that the reaction be forced to completion that dimethyl suberimidate usually fails. The reaction of an imidoester with a primary amine in aqueous solution is a competition between formation of the desired amidine and hydrolysis of the imidoester to amide and ester:

There is no way to avoid this competition by some informed adjustment of the conditions; it can only be made worse. It complicates the reaction because when one end of the diimidoester has attached to a lysine, there is a significant probability that its other end has either already been hydrolyzed or will hydrolyze before it can react with another lysine. A high percentage of the lysines end up with defunct reagent after all of the lysines have become amidines and no further reaction can occur

regardless of how much reagent is added. Because of this, it is often the case that not all of the subunits can be cross-linked among themselves. The logical chemical solution to this problem would be to use an electrophile at the two ends of the cross-linking reagent that is more selective for a primary amine relative to a hydroxide anion, but this has not been explored systematically. Rather, it has been inadvertently accomplished.

The most versatile cross-linking agent is **glutaraldehyde**:

Unfortunately, the chemistry of its reactions with proteins has never been elucidated. Presumably as an aliphatic aldehyde it engages in all of the same chemical reactions with lysine that occur after aliphatic aldehydes are produced in collagen by protein-lysine 6-oxidase (Figure 3-19). It is part of the lore surrounding glutaraldehyde that the freshly distilled reagent is far less active; this is meant to suggest that compounds derived from glutaraldehyde itself, such as its aldol and dehydrated aldol, are important to the cross-linking. The dehydrated aldol as well as many of the products resulting from the imine formed upon the reaction of glutaraldehyde with a lysine are $\alpha\beta$ unsaturated aldehydes or imines. It is the greater preference of these $\alpha\beta$ unsaturated aldehydes and imines for reaction with the weak base lysine rather than the strong base hydroxide that produces a higher yield of cross-linked product when glutaraldehyde is used. In situations when the cross-linking reaction with dimethyl suberimidate cannot be forced to completion, cross-linking with glutaraldehyde will usually produce the fully cross-linked protein in high yield. The efficiency of glutaraldehyde has permitted it to be used to provide a quantitative catalogue of the various oligomeric complexes present in a heterodisperse solution of a single, pure protein.

Quantitative cross-linking is cross-linking carried to an extent sufficient to connect covalently every subunit in a macromolecular complex to every other subunit in the same macromolecular complex, either directly or indirectly, but not to any subunit in another macromolecular complex. In order for glutaraldehyde to perform quantitative cross-linking, the formation of intermolecular covalent connections between independent, unassociated oligomeric complexes in the solution must be negligible because every covalent complex must represent only the product of intramolecular cross-linking, and every multimeric complex in the solution must be completely cross-linked within itself so that every one of its constituent subunits is covalently attached to all of the others. Cross-linking with appropriately high concentrations of glutaraldehyde often fulfills these requirements.¹⁶⁷⁻¹⁷⁰

This fulfillment can be illustrated with two experiments. In the first experiment, a monodisperse solution containing a homogeneous population of the oligomeric protein L-lactate dehydrogenase, a protein known to be a tetramer composed of four identical subunits, was mixed with glutaraldehyde.¹⁶⁷ The reaction was permitted to proceed a short period of time, and the products were examined by electrophoresis on polyacrylamide gels in the presence of dodecyl sulfate. At high enough concentrations of glutaraldehyde, the only component that was observed contained the number of polypeptides, four, known to be present in the protein, all covalently connected to each other (Figure 8-20).¹⁶⁷ No larger products, which would have resulted from intermolecular cross-linking, and no smaller products, which would have resulted from incomplete intramolecular cross-linking, were observed. In the second experiment, the receptor for epidermal growth factor was cross-linked. This protein forms an α_2 dimer from two α monomers upon the addition of epidermal growth factor to the solution. Before the epidermal growth factor was added, only the monomer of the receptor was seen on the polyacrylamide gel after the protein had been cross-linked with glutaraldehyde and then dissolved in a solution of dodecyl sulfate. When epidermal growth factor was added and samples were removed at different times and then cross-linked, unfolded in a solution of dodecyl sulfate, and submitted to electrophoresis, the un-cross-linked monomer was seen to be gradually but completely replaced by the covalent cross-linked dimer.¹⁷⁰ If any intermolecular cross-linking had been occurring after the glutaraldehyde was added, covalent dimer should have been observed in the absence of epidermal growth factor, but it was not. If incomplete intramolecular cross-linking were occurring after the glutaraldehyde had been added, some un-cross-linked monomer should have remained after completion of the dimerization, but it did not.

There are two possible **problems** that can affect the outcome of quantitative cross-linking. First, if the protein is cross-linked at a concentration that is significantly lower than its physiological concentration, a naturally occurring oligomer may dissociate; or if it is cross-linked at a concentration significantly higher than its physiological concentration, artifactual aggregation may occur. Second, if the electrophilic cross-linking reagent reacts with nucleophilic side chains on the protein that are involved in its function and if its intact function is required for maintenance of its proper oligomerization, the protein could dissociate or artifactually associate because of its chemical inactivation before it becomes cross-linked. For example, glutaraldehyde inactivates the ATPase of the chaperone protein GroEL within 2 s of its application, and the ATPase activity is required to maintain the correct oligomerization of the protein. Controls were devised to demonstrate that the oligomeric state of the protein nevertheless did not change in the time required for quantitative cross-linking to be accomplished.¹⁶⁶

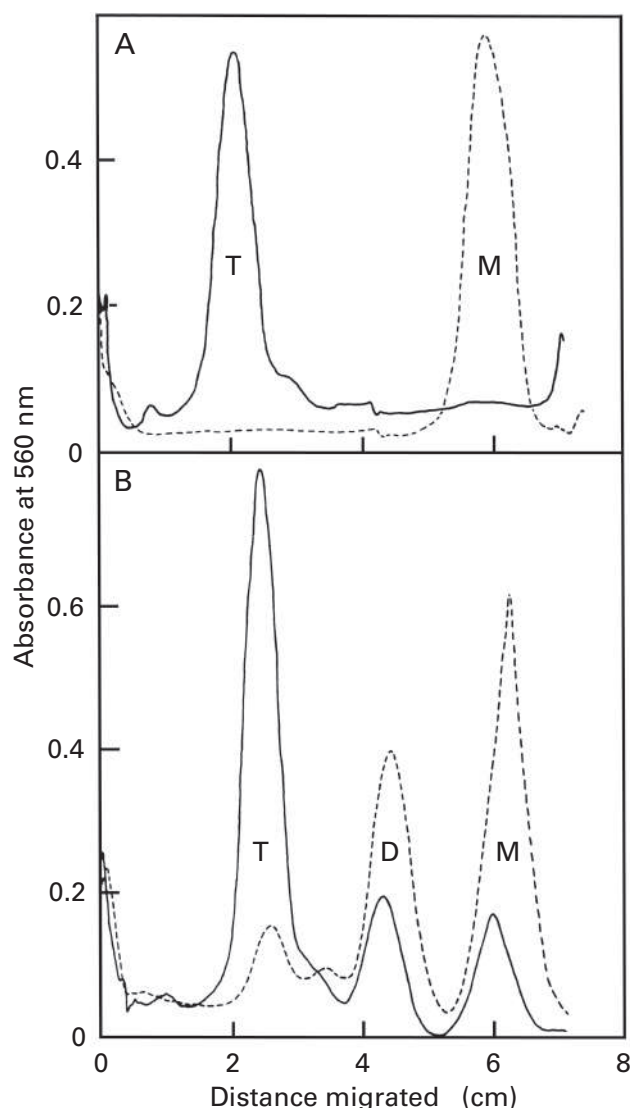

Figure 8-20: Cross-linking of L-lactate dehydrogenase.¹⁶⁷ Samples of L-lactate dehydrogenase were submitted to cross-linking for 2 min with 0.4 M glutaraldehyde at 20 °C and the reaction was terminated by adding sodium dodecyl sulfate to 20 μ M. The samples were then submitted to electrophoresis on polyacrylamide gels, the gels were stained for protein, and the absorbance at 560 nm as a function of the distance migrated is presented. (A) Cross-linking in a solution of native tetramers (20 nM). Equivalent samples were either cross-linked (solid line) or not cross-linked (dashed line). In the former, only fully cross-linked tetramers (T) are observed; in the latter, only un-cross-linked monomers (M). (B) Cross-linking of reassembling L-lactate dehydrogenase after it had been dissociated into subunits. L-Lactate dehydrogenase was dissociated into subunits at pH 2.3 and then diluted into a solution at pH 7.6 (final concentration of subunits 340 nM). After 210 s (dashed line) and 1 h (solid line), samples were removed and complexes (M, monomer; D, dimer; T, tetramer) were catalogued by cross-linking them for 2 min with 0.4 M glutaraldehyde. Reprinted with permission from ref 167. Copyright 1979 *Nature*.

If all of these requirements have been satisfied, quantitative cross-linking can be used to define the **quaternary structure** of a protein. For example, it has been used to show that 1-aminocyclopropane-1-carboxylate synthase is a dimer of two identical subunits.¹⁷¹ The

(α_7)₂ tetradecamer of GroEL, the (α_7)₂ β_7 heterooligomer of GroEL and GroES, and the β_7 (α_7)₂ β_7 heterooligomer of GroEL and GroES are each also quantitatively cross-linked by glutaraldehyde.¹⁷²

While the preceding examples illustrate how glutaraldehyde can be used to define the oligomer present in a monodisperse solution of a protein, it can also be used to provide a catalogue of the **oligomers in a heterodisperse solution**. When Na⁺/K⁺-exchanging ATPase is dissolved in a solution of nonionic detergent, a mixture is formed of various oligomers, ($\alpha\beta$)_{*n*}, which are combinations of the two different subunits, α and β , from which this protein is composed. The fraction of the total protein engaged in each of these oligomers, respectively, could be rapidly and accurately determined by quantitative cross-linking (Figure 8-21).^{169,173} From the pattern displayed in the figure, it could be calculated that before the glutaraldehyde had been added to the solution, the fractions of the protein present as the ($\alpha\beta$)₄ tetramer, the ($\alpha\beta$)₃ trimer, the ($\alpha\beta$)₂ dimer, and the $\alpha\beta$ monomer were 0.25, 0.19, 0.28, and 0.31, respectively.

As was done with the receptor for epidermal growth factor, cross-linking with glutaraldehyde can also be

Figure 8-21: Cross-linking of the oligomers in a heterodisperse solution of Na⁺/K⁺-exchanging ATPase.¹⁶⁹ A suspension of biological membranes containing only Na⁺/K⁺-exchanging ATPase was dissolved in a 5 mM solution of the nonionic detergent octa(ethylene glycol) dodecyl ether. After the solution was clarified by centrifugation, glutaraldehyde was added to 8 mM. After 45 min at 22 °C, sodium dodecyl sulfate was added, and the sample was submitted to electrophoresis on a gel cast from 3.6% acrylamide and 0.1% dodecyl sulfate. After the gel was stained, it was scanned for absorbance at 560 nm as a function of the distance migrated. By their mobilities the components were identified as covalently cross-linked $\alpha\beta$ monomer (M), ($\alpha\beta$)₂ dimer (D), ($\alpha\beta$)₃ trimer (T), and ($\alpha\beta$)₄ tetramer (T) of the enzyme, which in its native form is a monomer ($\alpha\beta$) of one α subunit and one β subunit in noncovalent association.¹⁷³ Because the enzyme is a complex of an α subunit and a β subunit, almost no un-cross-linked α polypeptide (α) or β polypeptide (β) remained following the cross-linking. Reprinted with permission from ref 169. Copyright 1982 American Chemical Society.

used to follow the **kinetics of the assembly** of a protein. When L-lactate dehydrogenase is transferred to a solution at pH 2.3, it dissociates into monomers consisting of single subunits, and when it is transferred back to pH 7.6, it reassociates over an hour to its normal tetrameric state. The concentration of monomer, dimer, and tetramer can be ascertained at any given minute by removing a sample and cross-linking it with glutaraldehyde (Figure 8–20B).¹⁶⁷ An extensive study of the kinetics of this stepwise association could be performed in this way.¹⁶⁸ The rate and mechanism of the association of the subunits of the catalytic trimer of aspartate carbamoyltransferase were also monitored by quantitative cross-linking,¹⁷⁴ as well as the conversion of the $(\alpha_7)_2$ tetradecamer of GroEL into the $(\alpha_7)_2\beta_7$ and $\beta_7(\alpha_7)_2\beta_7$ heterooligomers of GroEL and GroES caused by MgATP.¹⁷²

Cross-linking has also been used to determine the **stoichiometric ratio** between two dissimilar subunits. For example, the fact that the α and β polypeptides of succinate-CoA ligase (ADP-forming) from *E. coli* disappear in concert almost entirely during the formation of a covalent $\alpha\beta$ heterodimer and covalent $(\alpha\beta)_2$ heterotetramer (Figure 8–22)¹⁷⁵ means that they must be present in equimolar ratio in the protein. A similar result was observed with the two α and β polypeptides composing Na^+/K^+ -exchanging ATPase.¹⁷⁶ In either of these cases, if the polypeptides had not been present in equimolar ratio, either one polypeptide would have disappeared from its position on the polyacrylamide gel more rapidly than the other during the formation of a covalent $\alpha\beta$ heterodimer or significant amounts of covalent products of the form $\alpha_2\beta$ or $\alpha\beta_2$ would have appeared in addition to the covalent $\alpha\beta$ heterodimer.

The patterns seen in the ladders from partially cross-linked samples of a protein (Figure 8–19) can provide information about the **arrangement of the subunits** in the oligomer. Succinate-CoA ligase (ADP-forming) from *E. coli* is a protein composed of two different subunits, 388 and 288 amino acids in length, each present in two copies. These subunits could have been arranged in at least two ways to produce stoichiometries of either $(\alpha\beta)_2$ or $\alpha_2\beta_2$. The former designation implies that the association between an α subunit and a β subunit is more intimate than that between either two α subunits or two β subunits; the latter implies the reverse. Examples illustrating this distinction would be either a dimer of two identical subunits, each of which was posttranslationally cleaved to produce a pair of subunits, each an entwined α polypeptide and β polypeptide, or a heterotetramer assembled from a fully folded α_2 dimer and a fully folded β_2 dimer, respectively. Succinate-CoA ligase (ADP-forming) was reacted with enough dimethyl suberimidate to cross-link completely the α and β polypeptides among themselves but not enough to produce a high yield of the completely cross-linked product.¹⁷⁵ The covalent $\alpha\beta$ heterodimer was by far the major product of this incomplete reaction. A reasonable yield of the covalent heterote-

trimer, $(\alpha\beta)_2$, was also produced during the reaction, but little or no covalent trimer, covalent $\alpha\alpha$ homodimer, or covalent $\beta\beta$ homodimer was seen (Figure 8–22).

This result demonstrates that the formation of a cross-link between one folded α polypeptide and one folded β polypeptide in native succinate-CoA ligase (ADP-forming) is a far more likely event than the formation of a cross-link between either two α polypeptides or two β polypeptides, and it suggests that α and β polypeptides are more intimately associated with each other than are α polypeptides with α polypeptides or β polypeptides with β polypeptides. This conclusion has been validated by the crystallographic molecular model.¹⁷⁷ Therefore, the proper designation for the arrangement of the subunits in the native, un-cross-linked protein is $(\alpha\beta)_2$.

The yield of heterotrimer on the gel in Figure 8–22 is significantly lower than the yield of heterotetramer. A similar disparity among the products of a partial cross-linking reaction was seen when several tetrameric proteins, each composed of four identical subunits, were examined.¹⁷⁸ L-Lactate dehydrogenase, pyruvate kinase, fructose-bisphosphate aldolase, fumarate hydratase, and catalase were each partially cross-linked with various dimethyl bisimides. In each case, the yield of the covalent trimer was 2–6-fold lower than that of either the covalent dimer or the covalent tetramer. This result is reminiscent of the one seen with succinate-CoA ligase (ADP-forming), and its explanation is the same. Within

Figure 8–22: Cross-linking of succinate-CoA ligase (ADP-forming) from *E. coli*.¹⁷⁵ A solution of succinate-CoA ligase (1.0 mg mL^{-1}) was cross-linked with dimethyl suberimidate (2.0 mg mL^{-1}) for 30 min. The resulting covalent complexes were dissolved in a solution of sodium dodecyl sulfate and submitted to electrophoresis. (A) Un-cross-linked control showing the α and β polypeptides from which the enzyme is composed. (B) Cross-linked product. The components observed were assigned as the covalent $\alpha\beta$ heterodimer, the covalent heterotrimer, and the covalent $(\alpha\beta)_2$ heterotetramer on the basis of their apparent lengths (numbers to the left of each gel) determined by their mobilities on electrophoresis relative to a set of polypeptides of known length. each of these molecules of protein there must be associations between some pairs of α subunits that are more intimate than the associations between other pairs of α subunits. The results suggest that the proper designation for the arrangement of the subunits in each of these proteins is $(\alpha_2)_2$. To understand why this is so, the rules governing the evolution of oligomeric proteins must be understood. These rules are based on rotational axes of symmetry.

Davies, G.E., & Stark, G.R. (1970) Use of dimethyl suberimide, a cross-linking agent, in studying the subunit structure of oligomeric proteins, *Proc. Natl. Acad. Sci. U.S.A.* 66, 651–656.

Day, P.J., Murray, I.A., & Shaw, W.V. (1995) Properties of hybrid active sites in oligomeric proteins: kinetic and ligand binding studies with chloramphenicol acetyltransferase trimers, *Biochemistry* 34, 6416–6422.

Problem 8–16: Assume that each pure hybrid of fructose-bisphosphate aldolase shown in Figure 8–18⁷⁶ was dissociated completely and reassociated at random during the experiment described in the figure. Refer to the two types of subunits as α and γ .

- What is the respective subunit structure of each of the five purified hybrids?
- Assume the subunits reassemble at random by the binomial formula $a^4 + 4a^3c + 6a^2c^2 + 4ac^3 + c^4$, where a is the fraction of the dissociated subunits that are α and c is the fraction that are γ and predict the ratio of components expected from the reassociation of each of the five dissociated hybrids.

Problem 8–17: The following pictures are of polyacrylamide gels cast in 0.1% sodium dodecyl sulfate on which proteins unfolded with dodecyl sulfate were submitted to electrophoresis.¹⁵⁹

In all three experiments, the native proteins (at concentrations of 0.03–0.2 mM in subunit) were first treated with dimethyl suberimide (at concentrations of 3–7 mM) before they were unfolded with the dodecyl sulfate. In each experiment, the upper arrow marks the top

of the gel, and the lower arrow marks the stained band corresponding to the single polypeptide observed when treatment with dimethyl suberimide was omitted.

- By drawing a graph for each of the gels, A, B, and C, show that none of the products of the reaction between the respective protein and dimethyl suberimide were overlooked.
- What is the stoichiometry of the subunits of the protein run on gel A?
- What is the stoichiometry of the subunits of the protein run on gel B?
- What is the stoichiometry of the subunits of the protein run on gel C?

Assume in making all of these assignments that proteins A, B, and C are homooligomers.

- In making these assignments, you have ignored the minor bands of lower mobility seen in gels A and C. If you are correct in ignoring these bands, what should have happened to these bands if the proteins had been more dilute in concentration when they were treated with the same concentrations of dimethyl suberimide? Why?

Chapter 9

Symmetry

The arrangement in space of the subunits in a multimeric protein is its **quaternary structure**. Many multimeric proteins are composed of multiple copies of only one particular subunit. These subunits, each necessarily identical to the others when free in solution, combine together to form the final molecule of protein. In such homomultimeric proteins, each of the subunits in the crystallographic molecular model can be formally designated a protomer¹ of the final overall structure. A **protomer** of a multimeric protein is the smallest portion of that protein from copies of which its entire quaternary structure is created. Consequently, all of the protomers in the protein must be the same.

Some multimeric proteins, like the isoenzymatic hybrids of fructose-bisphosphate aldolase (Figure 8–18), are composed of two or more distinct subunits that are, nevertheless, each the offspring of the same common ancestor. Although different in amino acid sequence and in the atomic details of their tertiary structure, these subunits are still related closely enough to participate together to form the complete heteromultimeric protein, much as identical protomers would participate in a homomultimeric protein. In such instances, each of the individual subunits, although actually different, can be considered at low resolution to be one of the indistinguishable protomers forming the overall structure. In contrast to the hybrids formed by the isoenzymatic subunits of fructose-bisphosphate aldolase, other proteins built from such similar but distinct subunits usually incorporate those subunits in unvarying ratios. For example, hemoglobin is always an $(\alpha\beta)_2$ tetramer and acetylcholine receptor is always an $\alpha_2\beta\gamma\delta$ pentamer, even though the α and β subunits of hemoglobin or the α , β , γ , and δ subunits of acetylcholine receptor are respectively homologous to each other and necessarily superposable. These exclusive stoichiometries are established by the distinct atomic interactions between the subunits that take place as the multimer assembles.

Some multimeric proteins contain two or more dissimilar, unrelated subunits. For example, aspartate carbamoyltransferase contains α subunits and β subunits that are unrelated to each other. Even though the subunits composing such a protein are completely different, the final structure produced, when observed as a crystallographic molecular model, can often be divided formally into identical protomers, each containing one copy of each of the different subunits. A particular number of

these heterooligomeric protomers arranged in an array unique to that protein makes up its quaternary structure. Because every protomer is identical to all the others, the arrangement of the protomers of such a heteromultimeric protein is formally equivalent to the arrangement of the subunits of a homomultimeric protein.

Each of the multimeric proteins discussed so far can be divided formally into a set of identical protomers or almost identical subunits. Aside from a few peculiar exceptions, the rules that govern the way these protomers or these subunits are arranged in space to produce the complete molecular structure of the entire protein seem to be the same. In an oligomeric protein formed from a fixed number of identical protomers, those protomers are arrayed around rotational axes of symmetry. In an oligomeric protein formed from a fixed number of homologous but nonidentical subunits, those subunits are arrayed around rotational axes of pseudosymmetry. In a polymeric protein with an indefinite number of identical protomers or homologous subunits, those protomers or those subunits are arrayed around a screw axis of symmetry or a screw axis of pseudosymmetry, respectively.

There is also a set of multimeric proteins composed of nonidentical subunits that are assembled haphazardly with no regard, or sometimes a slight regard, for symmetry. In these proteins, the various subunits are associated with each other by interfaces that, other than their lack of symmetry, are almost indistinguishable in their details from those holding together symmetric proteins. Such asymmetric, heteromultimeric proteins are much more likely to assemble and disassemble under different situations, and such alternations in quaternary structure are often involved intimately in their function. There are also members of this set of heteromultimers, however, that have stable quaternary structures. Unlike symmetric homomultimeric proteins and symmetric heteromultimeric proteins, asymmetric heteromultimeric proteins seem to be cobbled together in the absence of any set of rules.

Rotational and Screw Axes of Symmetry

The **fundamental symmetry operations** that are available to asymmetric objects such as the protomers of a protein when they assemble into a homomultimeric

structure are those around rotational axes and screw axes. If a protein is constructed with rotational symmetry, only a finite number of protomers produce the final structure. If a protein is assembled with screw symmetry, a potentially infinite number of protomers usually can combine to produce a polymer of indefinite length. In a few isolated instances observed so far, a protein, although it is assembled from subunits arranged with screw symmetry, is nevertheless forced to have only a finite number of protomers in the final structure. Such finite structures assembled with screw symmetry are thought to be very rare.

Consider two proteins that illustrate the observation that multimeric proteins constructed from identical protomers are assembled around rotational or screw axes of symmetry. The proteins are malate dehydrogenase from *Aquaspirillum arcticum* (Figure 9-1A),² a dimer built from two identical protomers that are each folded polypeptides 329 amino acids in length, and actin (Figure 9-1B,C),³⁻⁶ a protein that forms helical polymeric fibers of indefinite length with each fiber built from many identical protomers, each of which is the same folded polypeptide 375 amino acids in length.⁴

A **rotational axis of symmetry** is a line about which a structure can be rotated by $360^\circ/n$, where n is an integer larger than 1, to superpose upon itself. An exact 2-fold rotational axis of symmetry runs through the center of the α_2 dimer in the crystallographic molecular model of malate dehydrogenase. If the two subunits of malate dehydrogenase, still held together by the same interface, had been distorted intramolecularly by the structure of the protein itself into significantly different conformations or if they had had different sequences but were nevertheless homologous to each other, a rotational axis of pseudosymmetry would superpose one of them upon the other. A **rotational axis of pseudosymmetry** is a line about which the structure of a protein can be rotated by $360^\circ/n$ to superpose upon each other subunits with identical sequence but significantly different conformation, subunits of different sequence but the same common fold, or distinct but homologous domains.

The value of n is the **fold of the symmetry**. The 2-fold rotational axis of symmetry in the crystallographic molecular model of malate dehydrogenase is a line perpendicular to the plane of the page in Figure 9-1A passing through the center of the molecule of protein. If the image of the upper protomer in the figure is rotated 180° about this axis, it superposes exactly on the lower protomer. Because of this rotational axis of symmetry, the two protomers in the protein are indistinguishable.

Through the center of the indefinitely long **helical polymer** of actin, of which only a segment is drawn in Figure 9-1B, runs a screw axis of symmetry. A **screw axis of symmetry** is a line, passing through a structure, about which the structure can be rotated by an angle between -180° and 180° and along which the structure can be simultaneously translated to superpose upon itself. In

the molecular model of the actin filament, the screw axis of symmetry is a vertical line parallel to the plane of the page. If the image of any protomer is transposed by being rotated -166° (left-handed) around this axis while it is lifted 2.8 nm in a direction parallel to it, it superposes on the next protomer in the helical polymer. Because this operation can be repeated indefinitely, all of the protomers are indistinguishable from each other except by their place in line.

A rotational axis of symmetry (Figure 9-1A) is necessarily 2-fold, 3-fold, 4-fold, and so forth. This requirement arises from the fact that as one of the images of a protomer is being rotated to superpose it on its neighbor, all of the images of its neighbors are also simultaneously being rotated (Figure 9-1A). When the rotation is completed, each of the images must superpose on its respective partner. This can be accomplished only if the protomers are arrayed about the axis at angles to each other that are **integral quotients** of 360° ($360^\circ/n$). The integer defines the number of times the rotation can be accomplished before returning to the beginning. The rotational axis of symmetry within malate dehydrogenase is a 2-fold rotational axis of symmetry. After two superpositions, the original locations are regained. For the rotation to superpose the images of all protomers simultaneously each time, no translation along the axis can occur.

Screw axes of symmetry are defined by a rotation through any angle and a translation of any distance, and they are designated as left-handed or right-handed by the same rules as apply to α helices. If the translation is not zero, a screw axis of symmetry produces a helical array. By the principle that the majority rules, right-handed screws are given a positive sign and left-handed screws are given a negative sign. For example, one of the screw axes of symmetry in the actin polymer, the left-handed one, has a rotational angle of -166° . Trivially, it is also possible to generate an actin polymer with a right-handed screw axis of $+194^\circ$ but, less trivially, by two coaxial right-handed screw axes of $+28^\circ$. A helical array always comes with such a set of different coaxial screw axes. A rotational axis of symmetry is simply a special case of a screw axis of symmetry where the translation is zero and the rotational angle is required to assume values that are integral quotients of 360° .

A screw axis of symmetry, other than the special case of a rotational axis of symmetry, in which translation cannot occur, does not require the angular steps to be integral quotients of 360° . As the image of one of the protomers is rotating and rising, the point of superposition need not occur at any particular angular disposition along the helix produced by the screw axis. There is, however, one requirement that limits the angles and translations permitted a screw axis of symmetry. Its operation is most readily observed by comparing the crystallographic molecular models of the protomer of protocatechuate 3,4-dioxygenase from *Pseudomonas putida* (Figure

Figure 9-1: α -Carbon diagrams drawn from crystallographic molecular models of malate dehydrogenase from *A. arcticum*² and actin from *Oryctolagus cuniculus*.³ (A) Malate dehydrogenase is constructed from two subunits, one drawn with thicker line segments than the other. The view is down a crystallographic 2-fold rotational axis of symmetry in the space group $P2_12_12$ of the array. This drawing was produced with MolScript.⁴⁸⁵ (B) A model of the actin filament was constructed by placing individual actin monomers, a crystallographic molecular model for which is available,⁴ in positions and orientations indicated by the map of electron density calculated from an X-ray fiber diffraction pattern of a gel of oriented actin filaments.³ The orientation and position of the actin monomer that were assigned in this way are in agreement with the orientation and position of the protein encoded by the *mreB* gene of *Escherichia coli*, a homologue of actin, within its filament, which serendipitously happens to be present in a crystal of this protein.⁶ There are eight actin monomers in the segment of the filament displayed in this figure. The circles within each monomer designate the location of a bound Ca^{2+} ion. This drawing was produced with MolScript.⁴⁸⁵ The atomic coordinates on which the drawing is based were provided by Ken Holmes. (C) A low-resolution molecular model of the actin filament, calculated by image reconstruction of electron micrographs of ordered actin filaments,⁵ is included, at the same scale, to illustrate more clearly the packing of the monomers along the helix. Reprinted with permission from ref 5. Copyright 1983 Academic Press.

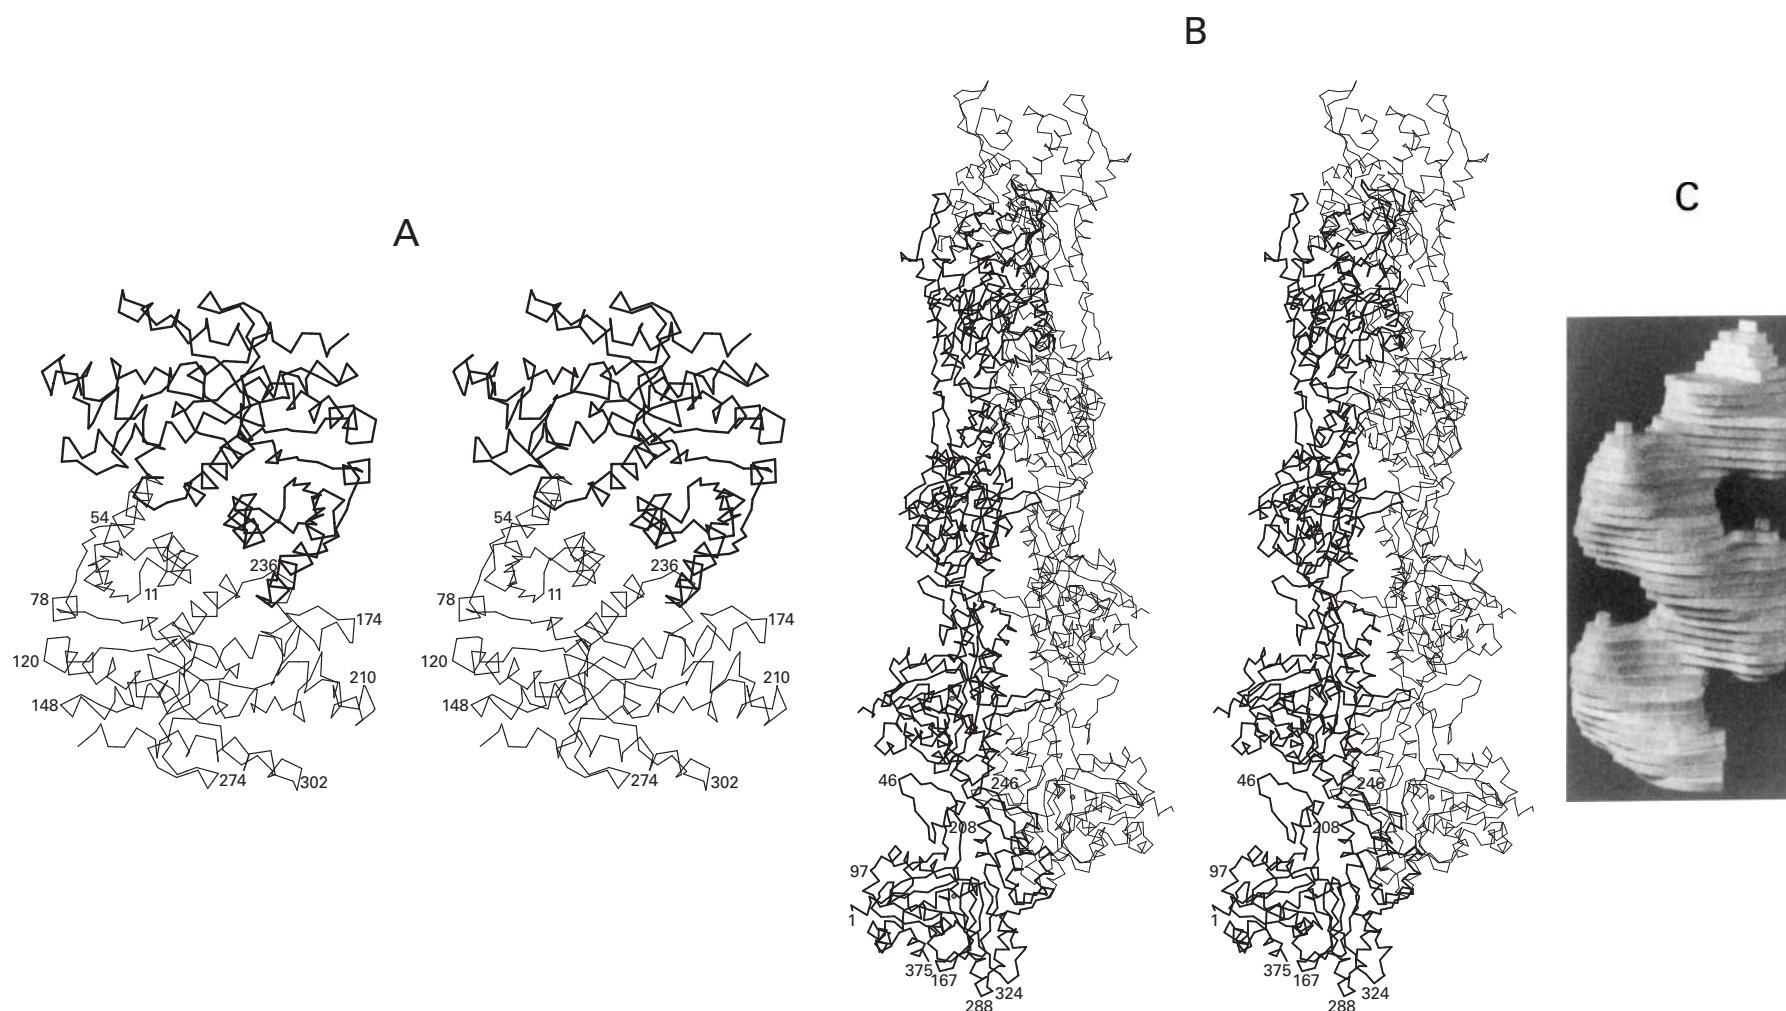

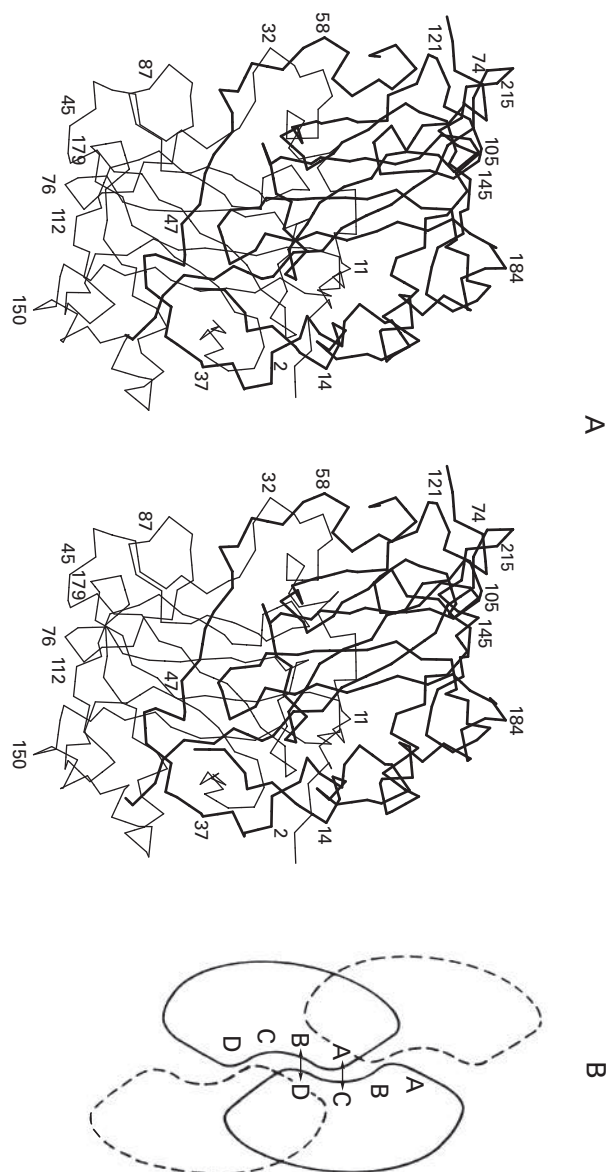

Figure 9-2: (A) α -Carbon diagram drawn from the crystallographic molecular model of the protomer of protococatechuate 3,4-dioxygenase from *P. putida*.^{7,8} The thickness of the line segments connecting the positions of the α -carbons differs between the two homologous subunits that are arrayed around the screw axis of pseudosymmetry. The α subunit is drawn with the thin line; the β subunit, with the thick line. The screw axis of pseudosymmetry is horizontal, in the plane of the page passing through the center of the protomer. The two different subunits have different sequences but homologous folds, except for an extension at the amino terminus in the β subunit of about 35 aa. Homologous positions in the respective subunits are numbered, with the equivalent numbers for the β subunit always about 35 greater than those for the α subunit. This drawing was produced with MolScript.⁴⁶⁵ (B) Schematic arrangement of the array of intersubunit interactions in a closed structure built around a screw axis of symmetry where there is translation. The dashed outlines indicate where adjacent protomers would add but for the steric effect. Reprinted with permission from ref 9.

9-2A)^{7,8} and actin (Figure 9-1B). The protomer of protococatechuate 3,4-dioxygenase is composed of two polypeptides of different sequence, but they are clearly homologous to each other because they share a common fold. Through the center of the $\alpha\beta$ heterodimer of protococatechuate 3,4-dioxygenase (Figure 9-2A) there runs a screw axis of pseudosymmetry. It is a horizontal line parallel to the plane of the page. If the image of the upper, β subunit is transposed by being rotated $+169.2^\circ$ around this axis as it is simultaneously shifted to the right 0.674 nm in a direction parallel to the axis, it superposes on the lower, α subunit.⁸

A helical polymer of actin can be constructed by placing one protomer upon an origin, properly oriented with respect to the axis of symmetry; transposing its image around the axis by -166° and along the axis by 2.8 nm; placing another protomer at this next location; and repeating this process indefinitely. Suppose this were attempted with the common subunit for protococatechuate 3,4-dioxygenase. Place an α subunit upon an origin, properly oriented with respect to the axis. Move the image of this subunit $+169.2^\circ$ around the axis and 0.674 nm along the axis. Place a β subunit at this next location. Move the image of this β subunit $+169.2^\circ$ around the axis and 0.674 nm along the axis and try to place an α subunit at this third location. This third subunit would have to overlap the first. The problem here is that the translation of the screw axis in protococatechuate 3,4-dioxygenase is insufficient to move the image of the subunit far enough along to clear the protomer next to it as the helical path completes the turn (Figure 9-2B).⁹ Therefore, two subunits can be combined to form a heterodimer, but three or more cannot be combined to form a polymer. The parameters of the helix generating actin do not cause such collisions. Actin forms a helical polymer of indefinite length, while protococatechuate 3,4-dioxygenase is limited to a dimer. In an additional example that reinforces the concept, two identical subunits of hexokinase are arranged in crystals of the space group $P2_12_12_1$ along a screw axis of pseudosymmetry the translation of which, 1.38 nm, is so short and the rotation of which, 156° , is so large that the protein is also limited to a dimer.⁹

In theory, the same requirement restricting protococatechuate 3,4-dioxygenase and hexokinase to be dimers also restricts malate dehydrogenase to being a dimer. Because no translation occurs along the axis in malate dehydrogenase, the third protomer would completely intersect the first if the game just played with protococatechuate 3,4-dioxygenase were repeated with malate dehydrogenase. It is the inescapable and obvious rules of this game that cause protococatechuate 3,4-dioxygenase and malate dehydrogenase to be closed structures¹ and actin to be an open structure. A **closed structure** is a structure that contains a finite number of protomers distributed by rotational axes of symmetry or a screw axis of symmetry and to which the addition of further protomers by the

one or more of these symmetry operations is precluded. An **open structure** is a structure built upon a screw axis of symmetry to which protomers can be infinitely added by that symmetry operation. An **oligomeric protein** is a multimeric protein with a closed structure of a fixed number of protomers, and a **polymeric protein** is a multimeric protein with an open structure of an indefinite number of protomers and of an indefinite length.

Each multimeric protein composed of identical protomers, even a helical polymer of indefinite length, can be considered to be the manifestation of a set of interfaces between those protomers. Each of these **interfaces** includes all of the points of contact that lie between two protomers in the structure, and each is formed by the association of two **complementary faces**, one from each of the two protomers. These faces are particular regions on the respective surfaces of the two associating protomers. Because the structures of the protomers are identical to each other, each necessarily possesses on its own surface all of the unique faces forming the interfaces found in the complete molecule. The interface between the two subunits of malate dehydrogenase (Figure 9-1A) is formed from two identical faces, one on the surface of each of its subunits. Note the particularly intimate contact across the interface as the secondary structures, which mimic each other across the axis of symmetry, interdigitate.

Following its biosynthesis, a polypeptide folds to form a structure capable of recognizing and being recognized by other folded polypeptides. If it is to combine with its twins to form a multimeric protein constructed from identical subunits, it must do so in a series of individual steps, and each step must involve the formation of an interface from two complementary faces. The atomic contacts within each of these consecutively formed interfaces are as specific as the atomic contacts throughout the protein. For the same reasons that a folded polypeptide assumes a precise and unique atomic structure, the interface between two subunits has a precise and unique atomic structure.

If, as the result of evolution, a face appears anywhere on the surface of a folded polypeptide and a face complementary to the first appears anywhere else on the surface of the same folded polypeptide, the face on one copy of that folded polypeptide will associate with its complement on another copy of the same folded polypeptide. Any such **random association** between any two identical asymmetric objects always defines a unique screw axis, an angle of rotation about that screw axis, and a translation along that screw axis that will superpose the image of one of the asymmetric objects upon the other. Either these three parameters are consistent with an open structure or they are consistent with a closed structure. If they are consistent with an open structure, the very fact that the one interface can form means that many others will subsequently form. A series of such interfaces is a helical polymer.

The interfaces that are repeated throughout a multimer composed of identical protomers are the origin of the geometry of the final structure. Because they are created by **evolution**, their appearance is determined by a completely random process. As time passes, variation in the identity of the amino acids on the surface of a given monomeric protein occurs. At some point, in some organism, in some species, a constellation of amino acids appears on the surface that permits a stable interface to form between two of these identical monomers.

Natural selection operates at this point. It takes little imagination to realize that if the vast majority of multimeric proteins were not closed structures, the cell would rapidly fill with helical polymers and become a solid, inflexible object incapable of the pliability essential to life. The difficulties encountered with helical polymers of hemoglobin S in sickled erythrocytes dramatically illustrate this problem.¹⁰ An example of a polymerization that is undesirable for a different reason is that of a tRNA-intron endonuclease from *Archaeoglobus fulgidus*, which can form a helical polymer that is enzymatically inactive because the active site is sterically blocked by neighboring monomers in the polymer.¹¹ If a monomeric protein were to sustain a series of mutations dictating that it combine with its twins in such a way that a polymeric fiber necessarily results, this set of mutations would probably be eliminated by natural selection. Mutations leading to closed structures, however, aside from lowering the osmotic pressure of the cytoplasm, may be neutral initially, but oligomeric proteins have potentials denied to monomeric proteins, and the appearance of an oligomeric protein during evolution is the first step in the eventual exploitation of these potentials. Nevertheless, if the interface is compatible with a closed structure, it can initially be fixed by genetic drift as a neutral variation. With its fixation within that species, the protein has become an oligomer of identical protomers.

There remains one perplexing fact. As in the case of malate dehydrogenase (Figure 9-1A), the vast majority of homomultimeric proteins that have been examined conclusively are built around rotational axes of symmetry. Often, as in the case of malate dehydrogenase, these rotational axes of symmetry can be proven to be exact; they always seem to be exact. In fact, protocatechuate 3,4-dioxygenase (Figure 9-2) is one of the few exceptions to this rule, and it is not even a homodimer. If rotational axes of symmetry are no more than severely restricted cases of screw axes of symmetry, and if a screw axis of symmetry is compatible with a closed structure, why are multimeric proteins almost always rotationally symmetric?

The main difference between a dimer like malate dehydrogenase and a dimer like protocatechuate 3,4-dioxygenase lies in the respective interfaces defining these structures. In a rotationally symmetric dimer such as malate dehydrogenase, individual interactions between the two protomers come in **sets of identical**

pairs. The best way to see this is to consider the α helices containing Isoleucines 59 on either side of the rotational axis of symmetry (Figure 9–1A). These α helices and their carboxy-terminal loops of random meander insert into pockets in the opposite protomers. Consider a specific position such as Isoleucine 59 in the segment of the sequence of the lower protomer forming this insertion. The amino acid at this location is making several contacts with amino acids in the pocket in the upper protomer. Suppose a mutation occurred at position 59 that strengthened these interactions by a certain increment. Because the upper protomer was read from the same gene, at sequence position 59 in its α helix the same favorable change would occur automatically so the increment for the increase in stability for the whole interface would be twice that of each individual increment. The same argument could be made for each location in the interface.

In a protein built on a screw axis of symmetry, however, the amino acids at the same sequence positions in the two protomers never interact with the same amino acids from the other protomer across the screw axis of symmetry (Figure 9–2B). A mutation, occurring anywhere in the interface, that adds an increment of stability to the dimer is not duplicated automatically. It follows that as variation proceeds during evolution, the incremental changes that occur within an interface built around a 2-fold rotational axis of symmetry are amplified 2-fold relative to those that occur within each interface around a screw axis. This conclusion is valid whether one of these interfaces has already appeared during evolution or is merely incipient.

The formation of an interface between two identical monomeric proteins, which is the evolutionary event that precedes the appearance of a multimeric protein, is not an all or none phenomenon. The chemical reaction in question is

Associated with this reaction is a change in standard free energy, and it is this change in standard free energy that determines the extent of the reaction. The numerical value of this change in standard free energy is dictated by the particular interactions that occur among the amino acids within the interface. The particular interactions that occur are the product of evolution by natural selection. Each explicit variation in one of these interactions adds or subtracts an increment of free energy to the overall change. If the increments are automatically doubled, overall decreases in the standard free energy change for the reaction proceed more rapidly over evolutionary time.

Incremental decreases in the standard free energy change, however, are also doubled. Although rotationally symmetric dimers should appear more frequently, they should also disappear more frequently, unless they rep-

resent **advantageous variations**. Improvements in a certain protein are retained by natural selection, and their retention is unaffected by the frequency with which retrograde changes arise. Mutations turning the dimer back into a monomer, such as those that can be performed experimentally,^{12,13} would be eliminated by natural selection if they were disadvantageous. It is possible that oligomerization of a protein has an immediate advantageous effect. If it did, the fact that most oligomeric proteins are built around 2-fold rotational axes of symmetry would be a reflection of the fact that such oligomers arise with a high frequency and of the fact that they are fixed by natural selection because oligomers are advantageous.

Because events were discussed in the opposite order of the normal progression, a summary of the historical and logical sequence seems appropriate. As a result of genetic variation among the individuals in a given species, a constellation of amino acids appears on the surface of a monomeric protein within one of those individuals. The constellation causes molecules of that previously monomeric protein to associate with each other. This association necessarily creates an interface. This interface necessarily forces the two protomers it brings together to be related to each other by a unique screw axis of symmetry. The association between the two or more protomers created by this screw axis of symmetry is tested by natural selection. Occasionally, a helical polymer, which necessarily results from a screw axis that is not closed, is advantageous and is retained. Most of the time, however, the survivors of natural selection are closed oligomeric proteins the interfaces of which dictate rotational axes of symmetry.

Problem 9–1: Using as your three examples malate dehydrogenase, protocatechuate 3,4-dioxygenase, and filamentous actin, discuss the topics of rotational axes of symmetry, screw axes, open structures, closed structures, interfaces, and helical polymers.

Space Groups

Screw and rotational operations around axes of symmetry occur within crystals of proteins in addition to the translational operations relating the unit cells. These axes of symmetry are the fundamental operations that define the space groups. A **space group** of identical enantiomeric objects is a potentially infinite array of those objects, the positions and orientations of which are related to each other by screw axes of symmetry, rotational axes of symmetry, and translational operations.

For reasons mainly associated with the phenomenon of diffraction, a unit cell is defined solely in terms of translation. A unit cell is the smallest unit from exact copies of which, distributed only by simple translational movements, the entire crystal is created. In contrast, the **crystallographic asymmetric unit** is the smallest unit from exact copies of which, distributed both by translation and by rotation around axes of symmetry, the entire crystal is created. Crystallographic asymmetric units are usually delineated to include one or more intact subunits of a protein or one or more intact molecules of a protein.

If crystallographic asymmetric units containing one or more subunits or one or more molecules of a protein were always distributed in a crystal so that each of those asymmetric units had exactly the same rotational orientation, all unit cells would be of the same type, *P1*, and each unit cell would contain only one crystallographic asymmetric unit. **Packing** the same asymmetric units in different rotational orientations to form a crystal, however, is not forbidden, and strangely shaped enantiomeric objects, such as asymmetric units containing protein, usually are packed with greater efficiency when they can assume different rotational orientations. If these rotational orientations are to be compatible with the infinite regular array that is a crystal, they must be related by particular symmetry operations. Dismissing mirror symmetry, which is irrelevant to enantiomeric objects such as proteins, one is left with axial symmetry.

In a diagram of the simple **space group *P2*** (Figure 9-3), the array of unit cells portrayed represents one of the layers in a three-dimensional crystal. The array of the enantiomeric objects is created by distributing them about rotational axes of symmetry and by translational operations. Within each unit cell, the two identical enantiomeric objects are related by a central 2-fold rotational

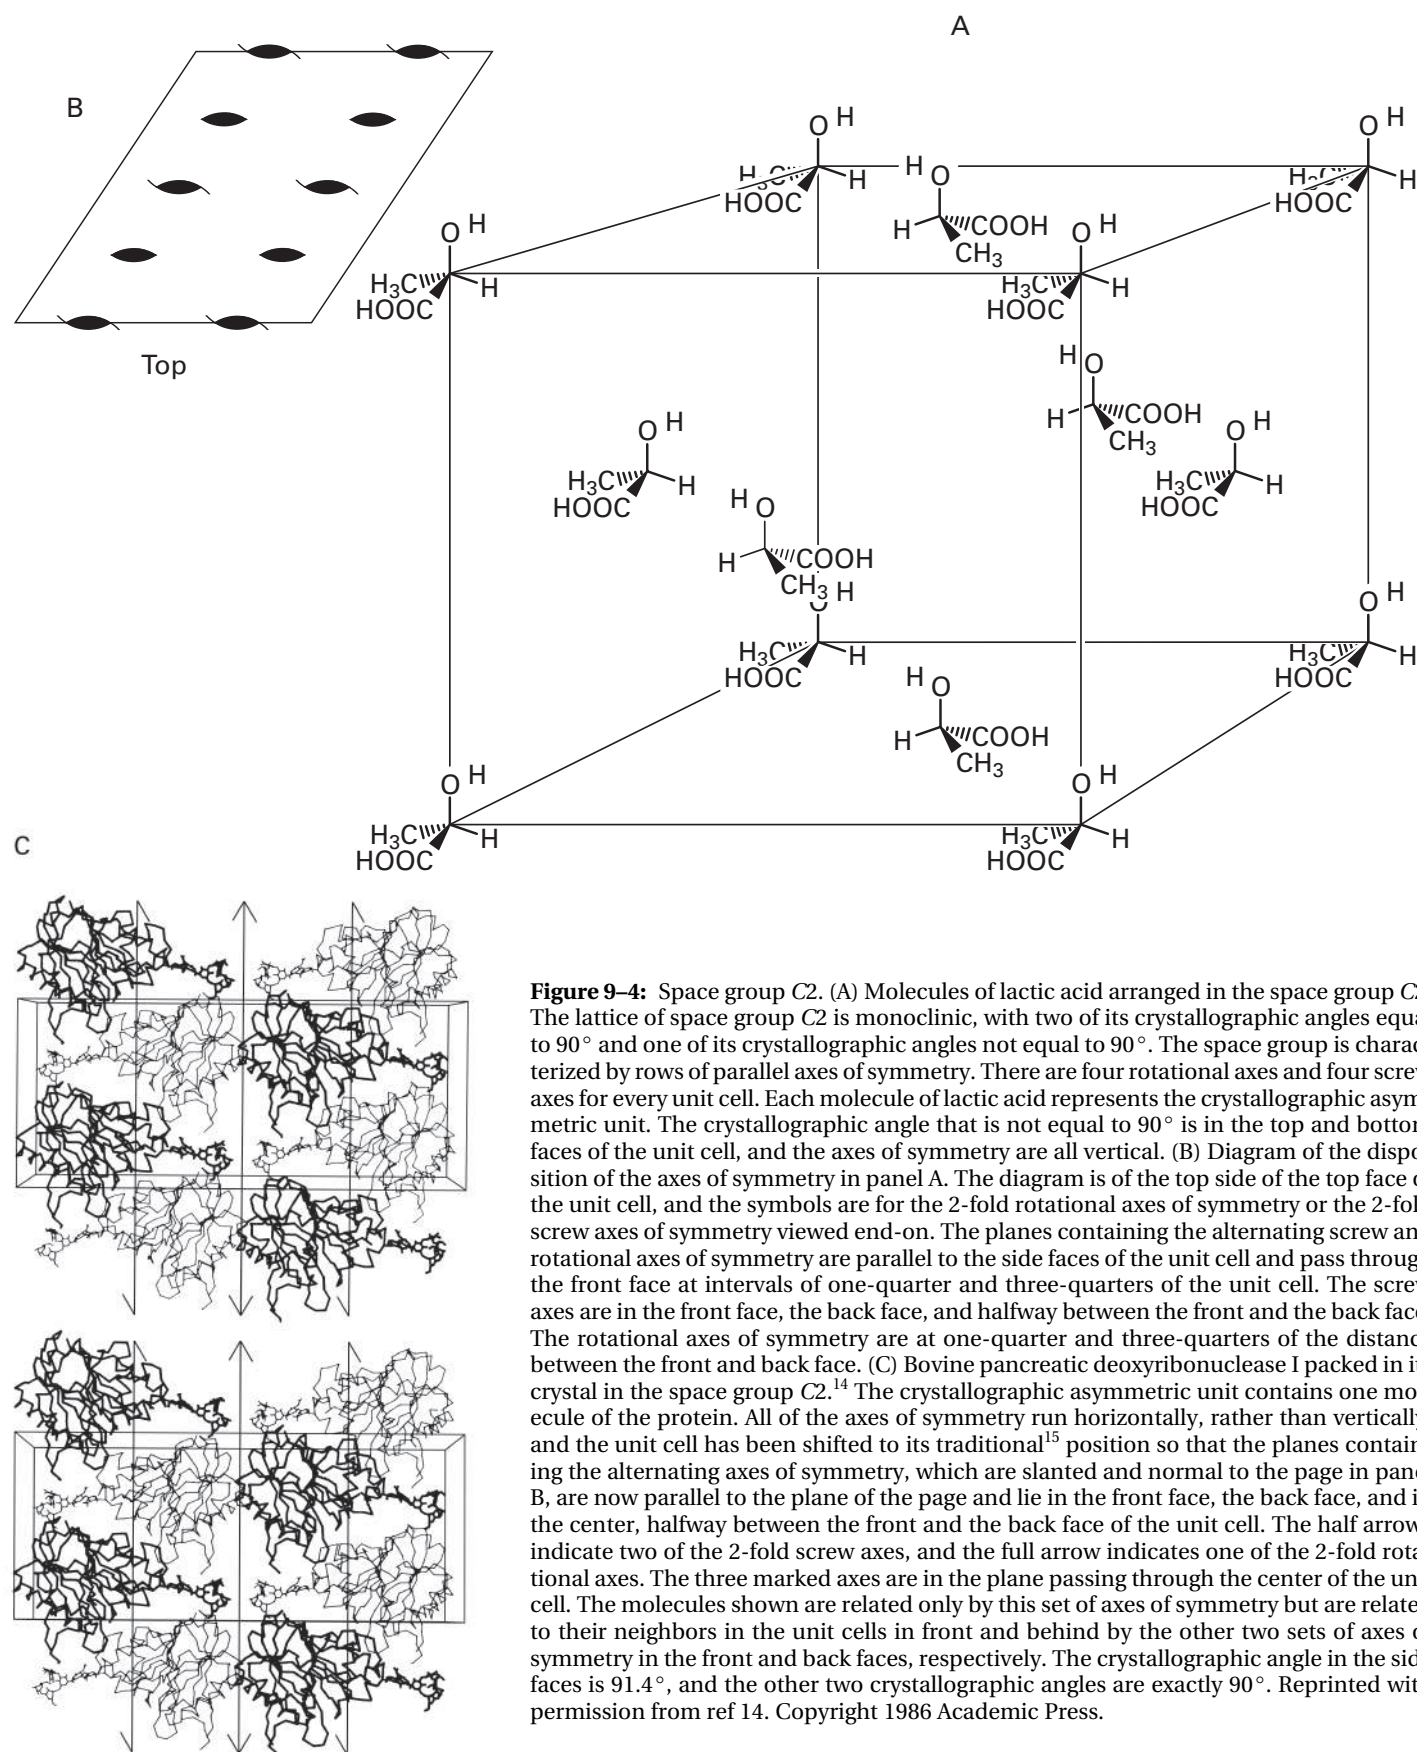

Figure 9-3: Packing of identical asymmetric objects, which represent the crystallographic asymmetric units from which the array is formed, in the space group *P2*, in which they alternately assume two different rotational orientations. The symbol ● indicates a 2-fold rotational axis of symmetry perpendicular to the page.

axis of symmetry perpendicular to the page. Because of the two rotational dispositions, which arise only because of the increased efficiency of packing, the unit cell ends up containing two of the enantiomeric objects rather than one. Each of the 2-fold rotational axes in the center of each of these unit cells is itself a rotational axis of symmetry for the entire array if it is assumed that the array is infinitely propagated in three dimensions. There are also three distinct sets of 2-fold rotational axes of symmetry between the unit cells. It is a feature of axes of symmetry in space groups that more than one distinct set appears at a time, and together these **sets of axes of symmetry** define the space group.

In crystals, as opposed to individual oligomers and polymers, screw axes of symmetry are required to have rotational angles that are integral quotients of 360° . This arises from the fact that these screw axes of symmetry operate on the entire array in the crystal. As the image of one of the crystallographic asymmetric units from which the crystal is composed is rotating and rising around the screw axis, the images of every other asymmetric unit in the array are rotating and rising around the same axis. At the completion of the operation, all of the images in the array must superpose on identical partners. This can occur only if the rotations of both the screw axes and the rotational axes of symmetry in a space group are 2-fold, 3-fold, 4-fold, or 6-fold. No other rotational multiplicities are compatible with an infinite array of asymmetric objects. Space groups never have 5-fold rotational or screw axes of symmetry because an infinite repetitive array of pentagons cannot be formed. Any translational distance, as long as it is compatible with an unclosed screw axis of symmetry, is compatible with an infinite array. Technically no crystal is infinite, but it always has the potential to be so, and this potential is all that matters.

The arrangement of asymmetric units in a space group can be displayed by distributing drawings of an enantiomeric object representing a crystallographic asymmetric unit of protein around appropriately positioned axes of symmetry. It is convenient to use an enantiomeric object familiar to all chemists, as well as one that is easy to draw, namely, a small enantiomeric molecule. Lactic acid is one of the smallest enantiomeric molecules. Drawings of distributions of lactic acid in the space groups *C2*, *P2₁2₁2₁*, and *P3₁21* (Figures 9-4, 9-5, and 9-6, respectively)¹⁴⁻¹⁸ illustrate certain properties of space groups, their rotational axes of symmetry, and the unit cells they create.

Although there are four distinct sets of 2-fold rotational axes in the space group *P2* of Figure 9-3, it is considered to be a simple 2-fold array, designated by the single integer 2, because all of its axes are parallel to each other and no set can exist without all of the others. The presence of a rotational axis of symmetry in a space group is indicated by an unadorned integer: 2, 3, 4, or 6. The presence of a screw axis of symmetry is indicated by

an integer, 2, 3, 4, or 6, followed by another integer in subscript, for example, the 3_1 screw axes of symmetry in the space group $P3_121$ (Figure 9–6). The main integer, n , is the integer by which 360° is divided to obtain the rotational angle of the steps. The integer in subscript, m , determines the fraction, m/n , of the unit cell over which the translation occurs with each rotational step. The translation is always right-handed to the rotation. Consequently, by this convention a 3_1 screw and a 4_1 screw are right-handed, and a 3_2 screw and a 4_3 screw are left-handed.

The **designation of the space group** in a crystalline array takes the form of a capital letter* followed by one or more numbers. An example would be $P2_12_12_1$, which would mean a primitive lattice made of rectangular parallelepipeds intersected by three orthogonal sets of 2-fold screw axes of symmetry (Figure 9–5). The arrangements of the axes in a particular space group can be learned only by consulting a diagram of that space group.¹⁵

The crystallographic asymmetric unit has a volume that is always an integral quotient of the unit cell and thus its volume is equal to or smaller than that of the unit cell. An integral number of asymmetric units, but not necessarily of intact asymmetric units, composes a **unit cell**. For example, one whole, two halves, four fourths, and eight eighths gathered from 15 different asymmetric units, each represented by one intact molecule of lactic acid, can together create a unit cell containing a total of four asymmetric units in the space group $P2_12_12_1$ (Figure 9–5). The crystallographic asymmetric unit in Figure 9–4C is one molecule of deoxyribonuclease I, and the unit cell contains a total of four asymmetric units but not four intact molecules of the protein.

The space group imposes certain **constraints** on the structure of the unit cell. For example, in the space group $P2$ that produces the array of Figure 9–3, the 2-fold rotational axes of symmetry must be normal of the plane of Figure 9–3 or the superposition cannot occur. Therefore, each unpictured asymmetric unit above and below the plane of the page in the lattice must be perpendicularly aligned with one of the asymmetric units in the plane of the page. This requires that the two angles of the fundamental unit cell aligning the axis normal to the page be precisely 90° . A lattice where two of the angles must be 90° is monoclinic (caption to Figure 4–2). In the space group $P2_12_12_1$ displayed in Figure 9–5, the three necessarily orthogonal sets of screw axes force the unit cell to be a rectangular parallelepiped and the lattice to be orthorhombic. Each space group other than the most

primitive, $P1$, which lacks axial symmetry entirely, enforces one or more of the angles of the unit cell to be 90° or 120° or enforces one or more of the axes of the unit cell to be the same length or enforces requirements on both angles and lengths. These are not coincidental identities but required identities. They are dictated by the symmetry operations and are thus exact quantities. If the angle in the monoclinic crystal of Figure 9–3 were not exactly 90° , the crystal would be filled with fractures and would not be a crystal.

Reality seems to take place in Cartesian space, and there are only 71 space groups into which an infinite array of identical crystallographic asymmetric units, each containing one or more subunits of protein, can be arranged in Cartesian space to produce a crystal. Every crystal of protein has its crystallographic asymmetric units arrayed in one of these space groups. The space group is established as the crystal nucleates and grows in the dish; it cannot be dictated by the investigator. She can only try to change the conditions of crystallization in the hope that another space group will be generated by the process. This is often attempted because the identity of the space group determines how difficult it will be to calculate a map of electron density.

The 71 space groups available to a crystallizing protein are distinguished one from the other by the arrangement in space of their respective screw axes and rotational axes of symmetry. In turn, the space group of the particular crystal of protein that is formed is identified by the investigator from a characteristic pattern created in the data set by its particular arrangement of axes of symmetry. These are patterns in which identities occur in the amplitudes of the reflections. For example, in the oscillation photograph in Figure 4–1B, the fact that the patterns of the intensities of the reflections above and below the equator are mirror images of each other is consistent with the existence of a rotational axis of symmetry in the crystal parallel to the axis of oscillation. The particular **pattern of identities** within the entire data set identifies the axes of symmetry in the crystal and their arrangement in space, and hence the space group of the crystal.

The packing of deoxyribonuclease I in the space group $C2$ (Figure 9–4C),¹⁴ that of the lectin from *Pisum sativum* in the space group $P2_12_12_1$ (Figure 9–5E),^{16,17} that of telokin from *Meleagris gallopavo* in the space group $P3_221$ (Figure 9–6C),¹⁸ that of porin from *Rhodobacter capsulatus* in the space group $R3$ (Figure 9–7),¹⁹ and that of ferredoxin from *Aphanothece sacrum* in the space group $P4_1$ (Figure 9–8)²⁰ illustrate the accommodations of the molecules of proteins to the axes of symmetry defining these five space groups.

There are no rotational axes of symmetry, only screw axes of symmetry, relating the asymmetric units in the space groups $P2_12_12_1$ and $P4_1$, but in the space groups $C2$, $P3_121$, and $R3$, pairs of asymmetric units are disposed around 2-fold rotational axes or triplets of asymmetric

* The capital letter refers to the particular relationship between the underlying lattice and the unit cell for the space group of interest. These relationships are primitive (*P*), C-face centered (*C*), A-face centered (*A*), B-face centered (*B*), all-face centered (*F*), body centered (*R*), or hexagonally centered (*H*).

Figure 9-5: Space group $P2_12_12_1$. (A) Molecules of lactic acid arranged in the space group $P2_12_12_1$. The lattice of space group $P2_12_12_1$ is orthorhombic, with all three crystallographic angles equal to 90° , and the unit cell is rectangular. This results from the fact that there are three sets of 2-fold screw axes of symmetry, each set is necessarily orthogonal to the others, and in each set the screw axes are parallel to one of the crystallographic axes. There are four screw axes for each unit cell in each of the three sets. The molecule of lactic acid represents a crystallographic asymmetric unit, and from any one molecule of lactic acid the entire array can be created by performing the operations of 2-fold screw symmetry in the three orthogonal directions. (B) The four parallel horizontal screw axes of symmetry passing through the left face of the unit cell in panel A from front left to back right. These axes are in the top face, bottom face, and halfway between the top face and bottom face, one-quarter and three-quarters of the way across the unit cell. (C) Vertical 2-fold screw axes of symmetry passing through the top face of the unit cell in panel A. Half of these vertical axes coincide with each vertical column of lactic acids, of which there are two for each unit cell. The other half of these vertical screw axes of symmetry coincide with vertical lines in the center of each vertical face. When rotated 180° about any one of these vertical axes while simultaneously rising half of a unit cell, the lattice superposes on itself. (D) The four parallel horizontal screw axes of symmetry passing through the front face of the unit cell in panel A from front right to back left. These axes are at one-quarter and three-quarters of the distance between top and bottom face and one-quarter and three-quarters of the distance between the side faces. The symbols in panels B–D are the 2-fold screw axes of symmetry seen end-on. (E) The lectin from *P. sativum* packed in its crystal in the space group $P2_12_12_1$.^{16,17} The asymmetric unit contains one complete molecule of the protein, which is a homodimer of identical subunits related by a local noncrystallographic 2-fold rotational axis of symmetry. The unit cell is positioned in the traditional¹⁵ location with respect to the three orthogonal sets of 2-fold screw axes of symmetry so that the top is shifted one quarter of its width forward and the front is shifted one quarter of its width downward relative to their positions in panels C and D, respectively. The central, complete molecule of protein is represented in thicker lines. It is related to the two molecules drawn with thinner lines above and below it by one of the vertical screw axes of symmetry halfway across the unit cell and one quarter of the way forward from the back face. It is related to the two molecules to its upper right and upper left, respectively, by one of the horizontal screw axes of symmetry parallel to the plane of the page, one quarter of the way down the unit cell, and halfway between the front and back faces. And it is related to the two molecules to its lower right and lower left, respectively, by the two screw axes of symmetry normal to the plane of the page half of the way up from the bottom face and each one quarter of the way in from one of the sides. Reprinted with permission from ref 17. Copyright 1990 Elsevier B.V.

units are disposed around 3-fold rotational axes of symmetry that are inherent in the space groups. In the space groups $C2$ and $P3_121$, each and every asymmetric unit is related to at least one of its adjacent twins by a particular 2-fold rotational axis of symmetry. This unique relationship establishes a particular pair of twins. This pair is exceptional because the whole lattice can be divided into an array of these pairs, and in each of these pairs the orientation of the two twins to each other is the same. In the space group $C2$ pictured in Figure 9-4A, such a pair of twins includes any two lactic acid molecules that have their carboxylic acid functional groups opposite the hydroxyls of their neighbors. Every lactic acid molecule in the crystal participates in one and only one such symmetric relationship.

The particular 2-fold rotational axes of symmetry connecting the noted pairs of rotationally symmetric twins are crystallographic axes. A **crystallographic axis of symmetry** is any one of the axes of symmetry that defines the space group of the crystal. It exists only when the protein is in a crystal. The 2-fold rotational axis of symmetry running through the center of malate dehydrogenase (Figure 9-1) and connecting its twin subunits is a molecular axis of symmetry. A **molecular axis of symmetry** is an axis of symmetry that exists in the molecule of a protein regardless of whether or not that molecule is in solution or in a crystal. Crystallographic axes and molecular axes arise under different circumstances. The molecular axes of symmetry are created as the oligomeric protein assembles in the cell, and the crystallographic axes of symmetry are created as the crystal grows in a dish. These two types of axes of symmetry are independent properties. They can, however, but they are never required to, coincide. If a molecular rotational axis of symmetry coincides with a crystallographic rotational axis of symmetry, it can be stated that the molecular axis

when it is within the crystal is an exact rotational axis of symmetry because a crystallographic axis of symmetry is necessarily an exact rotational axis of symmetry. If a crystallographic axis of symmetry were not exact, crystal growth could not continue because the small equal deviations between the actual rotational operation and an exact rotational operation would add up across the crystal and eventually produce an interruption in the lattice. An **exact rotational axis of symmetry** in a protein is a rotational axis which, in a crystallographic molecular model of that protein, coincides with a crystallographic axis of symmetry.

The molecular 2-fold rotational axis of symmetry in the middle of each dimer of malate dehydrogenase from *A. arcticum* (Figure 9-1) coincides with one of the crystallographic 2-fold rotational axes of symmetry in the space group $P2_12_12$ in which it crystallizes.² Consequently, the molecular axis is exact. The molecular 3-fold rotational axis of symmetry in the middle of each trimer of porin from *R. capsulatus* coincides with one of the crystallographic 3-fold rotational axes of symmetry in the space group $R3$ in which it crystallizes (Figure 9-7)¹⁹ and is exact.

There is one crystal that contains an educational exception to this rule that a molecular axis of symmetry coinciding with a crystallographic axis of symmetry is exact. Each $\alpha\beta$ protomer of the $(\alpha\beta)_3$ trimeric portion of rat mitochondrial H^+ -transporting two-sector ATPase²¹ is found in its own asymmetric unit when the protein crystallizes in the space group $R32$. Each $(\alpha\beta)_3$ trimer, however, has one and only one γ subunit associated with it. Consequently, only one of the asymmetric units in each triplet of asymmetric units containing the entire $(\alpha\beta)_3$ trimer can contain a particular segment of a γ subunit. In fact, the γ subunits are distributed at random among the three so the map of electron density contains

Figure 9-6: Space group $P3_121$. (A) Molecules of lactic acid arranged in the space group $P3_121$. The lattice of space group $P3_121$ is trigonal, with two crystallographic angles of 90° and one crystallographic angle of 60° . The angle of 60° is in the bottom faces of the three unit cells that are drawn. The space group $P3_121$ has a set of right-handed 3-fold screw axes of symmetry. In the drawing, two of the 3-fold screw axes of symmetry of each unit cell coincide with the vertical columns of lactic acid molecules. The third 3-fold screw axis of symmetry of each unit cell coincides with the vertical edge of each unit cell. Because the other crystallographic angle in the bottom face is 120° , counterclockwise rotation of 120° about this latter axis while simultaneously rising one-third of a unit cell causes the three upward columns of lactic acid around this axis to superpose on themselves and the three downward columns of lactic acid around this axis to superpose on themselves. Normal to each of the 3-fold screw axes of symmetry running along each vertical edge of the unit cells and intersecting perpendicularly with these latter vertical axes are 2-fold rotational axes of symmetry arrayed at 60° angles to each other. In the bottom face of the unit cell, the first 2-fold rotational axis of symmetry is the diagonal bisecting the 120° angle. Each successive 2-fold rotational axis of symmetry is 60° counterclockwise to the one below it and one-sixth of the distance up the axis of the unit cell. (B) Diagram¹⁵ of the arrangement of all of the axes of symmetry in space group $P3_121$. The view is looking down onto the bottom face of the unit cell containing the 60° angle. The flared triangles denote 3-fold screw axes normal to the page. The full arrows are 2-fold rotational axes of symmetry, and the half arrows are 2-fold screw axes of symmetry parallel to the plane of the page. The fractions indicate how far up the vertical edge or vertical face of the unit cell the axes parallel to the plane of the page are found. Reprinted with permission from ref 15. Copyright 1983 D. Reidel. (C) Telokin from the gizzard of *M. gallopavo* packed in its crystal¹⁸ in the closely related space group $P3_221$. The protein is a monomer of a single folded polypeptide, and the asymmetric unit contains only one of these monomers. The view is from the top so the 3-fold screw axes of symmetry in this view are normal to the plane of the page rather than vertical. They are in the same locations in the unit cell as those in the space group $P3_121$ (panel B) but are left-handed rather than right-handed screw axes (hence the 3_2 instead of 3_1). This difference causes the 2-fold screw axes of symmetry and 2-fold rotational axes of symmetry parallel to the plane of the page (panel B) to be encountered in a clockwise succession rather than a counterclockwise succession but at the same locations, angles, and depths. Reprinted with permission from ref 18. Copyright 1992 Elsevier B.V.

three overlapping, symmetrically displayed copies of the γ subunit each copy having one third the expected electron density. The actual individual asymmetric units in each molecule of the protein in the crystal are not symmetric within themselves, but the crystal is 3-fold symmetric. The individual molecular rotational axes of pseudosymmetry relating the three $\alpha\beta$ protomers is precisely 3-fold, but the symmetry of each molecule is perturbed by the presence of the necessarily asymmetric γ subunit.

The results from several crystallographic experiments serve to illustrate the **distinction between crystal symmetry and molecular symmetry** and the consequences of their coincidence.

Triose-phosphate isomerase, a dimer composed of two identical subunits, crystallizes in the space group $P2_12_12_1$. The crystallographic asymmetric unit is the α_2 dimer, and the 2-fold molecular rotational axis of symmetry within the dimer cannot coincide with a crystallographic rotational axis of symmetry because there is none.²² Glyceraldehyde-3-phosphate dehydrogenase (phosphorylating), an $(\alpha_2)_2$ tetramer composed of four identical subunits, also crystallizes in the space group $P2_12_12_1$, and the asymmetric unit is necessarily the entire tetramer. Glutathione peroxidase, however, also an $(\alpha_2)_2$ tetramer composed of four identical subunits, crystallizes in the space group $C2$, and the asymmetric unit is the α_2 dimer.²³ Consequently, in this instance one of the molecular axes of symmetry coincides with a crystallographic axis of symmetry, and the two α_2 dimers composing the $(\alpha_2)_2$ tetramer must be related to each other by an exact 2-fold molecular rotational axis of symmetry. The other two molecular 2-fold rotational axes of symmetry orthogonal to the one that coincides cannot also coincide with orthogonal crystallographic 2-fold rotational axes of symmetry because there is none.

Phosphorylase *b*, a dimer composed of two identical subunits, crystallizes in the space group $P4_32_12_1$, the asymmetric unit is one subunit,²⁴ and the dimer must be constructed upon an exact 2-fold molecular rotational axis of symmetry. Alcohol dehydrogenase, a dimer composed of two identical subunits, crystallizes in the space group $C22_12_1$, and the molecular 2-fold rotational axis of symmetry coincides with a crystallographic 2-fold rotational axis of symmetry and must be exact.²⁵ The α_3 trimer of chloramphenicol *O*-acetyltransferase from *E. coli* crystallizes in the space group $R32$,²⁶ and the α_3 trimer of bovine purine-nucleoside phosphorylase crystallizes in the space group $P2_13$,²⁷ and in both crystals molecular and crystallographic 3-fold rotational axes of symmetry coincide, and the molecular axes must be exact. L-Lactate dehydrogenase, a tetramer composed of four identical subunits, crystallizes in the space group $F422$, and one single subunit is the asymmetric unit.²⁸ Consequently, the tetramer is constructed around three exact orthogonal 2-fold molecular rotational axes of symmetry that coincide with three precisely orthogonal crys-

tallographic 2-fold rotational axes of symmetry. (S)-2-Hydroxy-acid oxidase crystallizes in the space group $I422$. As a result, its molecular 4-fold rotational axes of symmetry and its four molecular 2-fold axes of symmetry coincide with crystallographic rotational axes of symmetry²⁹ and must be exact. Dihydrolipoyllysine-residue acetyltransferase from *Azotobacter vinelandii*³⁰ and dihydrolipoyllysine-residue succinyltransferase from *E. coli*,³¹ related oligomers each composed of 24 identical subunits, both crystallize in the space group $F432$ in which the asymmetric unit is a single subunit, and the three molecular 4-fold rotational axes of symmetry, the

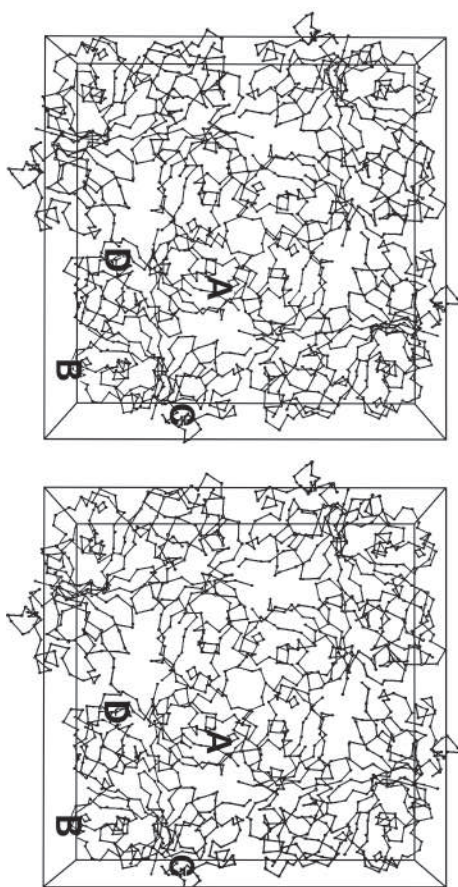

Figure 9-7: Molecules of porin from *R. capsulatus* packed in the space group $R3$ of its crystal.¹⁹ The lattice of space group $R3$ is trigonal with two crystallographic angles of 90° and one of 60° . Three-fold rotational axes of symmetry and 3-fold screw axes of symmetry normal to the front face pass along its edges and through its interior. The protein is a trimer of three identical folded polypeptides, and the asymmetric unit contains only one single folded polypeptide of this trimer. Each molecule of the protein has one of the crystallographic rotational axes of symmetry running through its center so that each of its subunits is exactly the same as the others and related to them by an exact 3-fold rotational axis of symmetry. The 3-fold screw axes of symmetry running between the trimers all superpose trimers on other trimers. Reprinted with permission from ref 19. Copyright 1992 Elsevier B.V.

Figure 9-8: Molecules of ferredoxin I from *A. sacrum* packed in the space group $P4_1$ of its crystal.²⁰ The lattice of space group $P4_1$ is tetragonal, with all crystallographic angles equal to 90° , and the top face of the unit cell is necessarily a square. Four-fold screw axes of symmetry run normal to the page at the four corners of the square and in its center. Consequently, 2-fold screw axes of symmetry normal to the page are located in the middle of each edge of the square. The protein is a monomer of a single folded polypeptide, and the asymmetric unit contains four copies, labeled A through D in the lower right hand asymmetric unit. Each A molecule participates in an interface with an adjacent A molecule around the central 4-fold screw axis of symmetry. The same interface joins B molecules around the 4-fold screw axes of symmetry at the corners and alternating C and D molecules around the 2-fold screw axes of symmetry. Within the asymmetric unit the only symmetry is a local 2-fold screw axis of symmetry relating an A molecule to a B molecule. Reprinted with permission from ref 20. Copyright 1990 Elsevier B.V.

four molecular 3-fold rotational axes of symmetry, and the four molecular 2-fold rotational axes of symmetry all coincide with crystallographic axes of symmetry and must be exact. Because both the 2-fold molecular axis of symmetry of the decamer of DNA with the sequence ATGACGTCAT and the 2-fold molecular axis of symmetry running through the coiled coil of α helices in the α_2 dimer of the crystallographic molecular model of a

portion of the general control protein GCN4 coincide with the same crystallographic axis of symmetry, the molecular axis of the DNA must be exact and the molecular axis of the coiled coil must be exact and precisely perpendicular to the central helical axis of the DNA.³²

Each of the last eight oligomeric proteins has all of its subunits arranged with a perfect rotational symmetry that can be conclusively proven. The coincidences of their molecular axes of symmetry and the crystallographic axes of symmetry that permitted these proofs, however, were by chance, and it seems reasonable to assume that in solution, the first three proteins, that just happened to crystallize in space groups incompatible with one or more of their molecular rotational axes of symmetry, are no less symmetric than the last eight. Consequently, while it is sometimes possible to deduce the whole symmetry of the protein from the crystallographic symmetry, the absence of the appropriate coincidences permitting this deduction does not mean that the molecule of protein lacks the missing symmetry.

Often it is assumed that molecular axes of symmetry within the asymmetric unit of a crystal are exact so that the electron density of the protomer can be enhanced by averaging around those molecular axes. Cystathionine γ -synthase from *Nicotiana tabacum*, an α_4 tetramer of folded polypeptides 445 aa in length, crystallizes in the space group $P2_12_12_1$ with two $(\alpha_2)_2$ tetramers in each of the four asymmetric units. Data could only be gathered to Bragg spacing of 0.29 nm, but when the electron densities of the eight protomers in the asymmetric unit were superposed about the respective molecular axes of symmetry and averaged, the map of electron density that resulted was a remarkable improvement over any one of the unaveraged maps.³³

Once **averaging around noncrystallographic rotational axes of symmetry** has been used to obtain a map of electron density accurate enough to build a convincing molecular model of the protomer, copies of the individual protomers are placed in their locations in the asymmetric unit, and the refinement of the molecular model is performed without rotational averaging. Only by refining the individual structures without rotational averaging do the differences among the protomers in the asymmetric unit, often dramatic ones,³⁴ become apparent. Often these differences, even though significant, can be dismissed as being due to distortions of an otherwise symmetric structure resulting from the asymmetric demands of packing it into the crystal.

When molecular axes of symmetry fail to coincide with crystallographic axes of symmetry, other criteria are used to evaluate the precision of the molecular rotational symmetry. For example, in the case of the $(\alpha_2)_2$ tetramer of glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) in the space group $P2_12_12_1$, the spacing of the heavy metal atoms in the isomorphous replacement³⁵ and the final map of electron density³⁶ were both consistent with the tetramer being

constructed around three orthogonal apparently exact 2-fold molecular rotational axes of symmetry. The molecular 2-fold rotational axis of symmetry of the dimeric lectin from *P. sativum* does not coincide with a crystallographic rotational axis of symmetry because there is none in its space group $P2_12_12_1$ (Figure 9–5), but when the one folded polypeptide in the crystallographic molecular model is rotated around the molecular axis of symmetry, its α carbons superpose on those of its twin with a root mean square deviation of 0.06 nm.¹⁶ The rotational angle around the molecular axis of symmetry producing the smallest root mean square deviation (0.019 nm) of the **superposed α carbons** of the two subunits in the crystallographic molecular model of formate dehydrogenase from *Pseudomonas* was 179.9° .³⁷ In similar superpositions, the α carbons of the two subunits of triose-phosphate isomerase from yeast coincided with a root mean square deviation of less than 0.04 nm,³⁸ and those of the two subunits of transketolase from yeast, by 0.024 nm.³⁹ The error in the coordinates for the crystallographic molecular model of inorganic diphosphatase from yeast was estimated to be 0.037 nm; upon superposition of the one of its subunits on the other by rotation around the molecular axis of symmetry, the root mean square deviation of all of the atoms in the two polyamide backbones was only 0.038 nm.⁴⁰ Although there were functional indications that the subunits of ribulose-bisphosphate carboxylase were in different environments in solution, when the different folded polypeptides in the crystallographic molecular model were superposed by rotation around the molecular axes of symmetry, their α carbons coincided with a root mean square deviation of less than 0.02 nm, well within the accuracy of the coordinates themselves, and it was concluded that there was no structural evidence for asymmetry.⁴¹

When such superpositions are performed about molecular rotational axes of symmetry that do not coincide with crystallographic rotational axes of symmetry, it is often found that flexible regions of the crystallographic molecular model do not coincide as well as more rigid regions because they respond readily to variations in their surroundings resulting from **differences in crystal packing**.⁴² For example, most of the α carbons of the five identical β subunits of heat-labile enterotoxin from *E. coli* superpose to within 0.04 nm upon successive rotations about the molecular 5-fold rotational axis of symmetry, but the positions of the α carbons in the flexible loop between Glycine 54 and Serine 60 deviate by 0.1–0.2 nm from each other.⁴³ Unlike malate dehydrogenase from *A. arcticum*, cytoplasmic malate dehydrogenase from *Sus scrofa* crystallizes in the space group $P2_12_12_1$ with its α_2 dimer in each asymmetric unit.⁴⁴ The rotational angle around the molecular axis of symmetry producing the superposition with the minimum root mean square deviation is 174° instead of 180° . It was, however, concluded that this observation was mislead-

ing because it had been shown previously that crystallization of the protein causes several of its enzymatic properties, which are uncomplicated in solution, to become asymmetric. Consequently, it was concluded that crystal packing forces caused an otherwise symmetric protein to become remarkably asymmetric.

There are, however, a few observations suggesting that there may be subtle **asymmetries** in some homooligomers. For example, when the subunits of the crystallographic molecular model of the $(\alpha_2)_2$ tetramer of L-2-hydroxyisocaproate dehydrogenase were superposed intramolecularly, it was found that two superposed well on each other (root mean square deviation of 0.02 nm) and the other two did also (root mean square deviation of 0.03 nm) but that neither member of one of these pairs superposed well on either member of the other pair (root mean square deviation of 0.13 nm).⁴⁵ This asymmetry seemed too large to be due to crystal packing, and it is possible that this protein may be asymmetric in solution.

It is also possible to perform a **self-rotation function** on the asymmetric unit in the space group of a crystal to detect molecular symmetry before phases are available. The 11-fold molecular rotational axis of symmetry in the *trp* RNA-binding attenuation protein from *Bacillus subtilis*, which cannot coincide with any of the permissible crystallographic rotational axes of symmetry, was readily detected within the asymmetric unit of its space group C2 by performing a self-rotation function.⁴⁶

On three rectangles representing the front, the side, and the bottom, respectively, of the unit cell in the orientation of the figure, indicate the positions of any screw axes of symmetry or rotational axes of symmetry passing through the unit cell. Use symbols for rotational or screw axes of symmetry like those in the diagrams in Figures 9–3 to 9–8.¹⁵

Problem 9-3

Oligomeric Proteins

A protomer is the smallest portion of a protein from copies of which its entire quaternary structure is created. The protomers of a homooligomeric protein are arranged around rotational axes of symmetry, and the number of protomers and the way in which they are arranged designates the point group to which the oligomer belongs. A **point group** is the distribution in which a particular number of protomers are arranged about one or more particular rotational axes of symmetry oriented at particular angles to one another and intersecting at a common origin, in which all of the centers of mass of the protomers are equidistant from this origin, and in which all of the symmetrically related positions are occupied. The finite and specific number of the protomers, their equidistance from the origin, and the common intersection of all of the rotational axes of symmetry distinguishes the point groups from the space groups as well as from the linear groups, which designate open linear multimers such as helical polymers. Oligomeric proteins have exploited all of the available point groups lacking mirror planes.

A **cyclic point group** arranges protomers in a circle about only one rotational axis of symmetry, and the different cyclic point groups are distinguished by the fold of the axis. In the simplest of these cyclic point groups,

point group $2(C_2)$,* two protomers are arranged around a 2-fold rotational axis of symmetry to form a dimer. Half of all homooligomeric proteins are dimers (Table 9-1) the protomers of which, with few exceptions (Figure 9-2), are arranged with the symmetry of point group $2(C_2)$. Malate dehydrogenase (Figure 9-1A) and κ bungarotoxin from *Bungarus multicinctus* (Figure 9-9)⁴⁹ are examples of oligomers of point group $2(C_2)$.

κ Bungarotoxin crystallizes in the space group $P6$ with an α_2 dimer in the crystallographic asymmetric unit. In the crystal, one protomer superposes on the other upon a 178.5° rotation about the molecular axis of symmetry. With the exception of the flexible loops between Cysteine 27 and Proline 36 and between Proline 15 and Glutamine 18, which adjust malleably to the constraints of crystal packing, the α carbons superpose to a root mean square deviation of 0.05 nm around the molecular rotational axis of symmetry, which probably differs from 180° also because of crystal packing. The interdigitations of the side chains forming the interface mimic each other across the axis of symmetry, for example, the hydrophobic cluster containing Isoleucine 20, Cystine 46/58, and Valine 60 from one protomer and Phenylalanine 49 from the other. The axis of symmetry itself runs through the hydrogen bond between the two Glutamines 48. The structure is unquestionably closed; every amino acid in the common sequence of the two identical polypeptides that is enclosed within the interface from one of the protomers is also enclosed from the other.

In larger proteins with more than one domain, it is often the case that the interface forming the dimer connects only one of the domains to its twin in the other pro-

* There are two notations currently in use to identify the individual point groups. Crystallographers use the Hermann-Mauguin notation, 2, 3, 4, ..., 222, 322, 422, ..., 23, 432, and 532, which will be the notation used here out of parentheses. Spectroscopists use the Schönflies notation, C_2 , C_3 , C_4 , ..., D_2 , D_3 , D_4 , ..., T , O , and I , which will be the notation used here within parentheses. Chemists other than crystallographers and spectroscopists will use one or the other of these notations depending on who taught them point groups or what book they happened to open.

tomers, but this limited interface nevertheless dictates the symmetry of point group $2(C_2)$ for the whole dimer.^{50,51} The domain (117 aa of the 450 aa in the intact protein) forming the entire interface holding together the dimer of glutathione-disulfide reductase⁵² has been detached genetically and shown to form by itself a dimer.⁵³ In the α_2 dimer of human hexokinase, each of the two subunits contains two internally duplicated domains, each superposable on a complete subunit of hexokinase from yeast, and they are connected by an α -helical segment of six turns. The amino-terminal domain of one subunit forms an interface with the carboxy-terminal domain of the other subunit and vice versa to form a dimer with two well-separated but identical interfaces on either side of the molecular 2-fold rotational axis of symmetry.⁵⁴

Proteins that associate with **double-helical DNA** are often dimeric, and such a dimer uses its own 2-fold rotational axis of symmetry to recognize a local 2-fold rotational axis of pseudosymmetry in the double helix of the DNA. Regardless of its sequence, between the two bases in any one of the pairs of bases in a molecule of DNA and running perpendicular to the hydrogen bonds between them is a local 2-fold axis of pseudosymmetry (Figure 3–9). A **local rotational axis** is an axis of rotation around which superpose upon one another only structural units immediately adjacent to that axis. Because a real molecule of DNA is rarely straight, if the whole molecule of DNA is rotated around one of these local axes by 180° , it roughly superposes on itself in the immediate vicinity of the axis but does not superpose beyond the immediate vicinity because of its curvature. Because the two bases in the central base pair are never the same, the base pairs on either side of the central base pair are usually not the same, and the DNA is usually curved, this local axis is always pseudosymmetric. Halfway between any consecutive two of these 2-fold rotational axes of pseudosymmetry and at an angle halfway between their two angles, there is also a local 2-fold rotational axis of pseudosymmetry.

The existence of this second set of local 2-fold rotational axes of pseudosymmetry means that **palindromic sequences*** such as

in which the two individual strands have the same sequence and the sequence of the duplex inverts at its center, have local 2-fold rotational axes of symmetry (indicated by \bullet). Rotation around any one of these axes by 180° superposes identical bases, within the segment.

* A **palindromic sequence**, for example, “able was i ere i saw elba”, is a sequence that superposes upon itself when rotated around an axis running through its center.

The existence of the local 2-fold rotational axes of pseudosymmetry running through the base pairs means that for the sequence

which contains a split palindrome, rotation about the local 2-fold axis of pseudosymmetry through the central

Figure 9-9: Two-fold rotational symmetry of point group $2(C_2)$. The crystallographic molecular model of the α_2 dimer of κ bungarotoxin from *B. multivittatus*⁴⁹ is formed from two identical folded polypeptides 66 aa in length arranged around a 2-fold rotational axis of symmetry running through the center of the molecule normal to the page. This drawing was produced with MolScript.⁴⁸⁵

Figure 9–10: Alignment of the 2-fold rotational axis of symmetry of the dimer of *met* repressor from *E. coli* with the local 2-fold axis of pseudosymmetry of the palindromic double-stranded DNA that it recognizes.⁵⁵ The portion of the crystallographic molecular model displayed is of an α_2 dimer of *met* repressor bound to a segment of chemically synthesized double-stranded DNA with the self-complementary sequences TTAGAGTCT and AGACGTCTA. The view is down the aligned molecular 2-fold rotational axis of symmetry of the dimer of protein and the local 2-fold rotational axis of pseudosymmetry of the DNA. Because the DNA is not completely palindromic, neither of these local, molecular axes of symmetry is able to coincide with one of the crystallographic 2-fold rotational axes of symmetry in the space group 6_222 . The double-stranded DNA is in the rear, and the protein is in the front. The DNA is drawn with thick gray lines, and the two subunits of the α_2 dimer are drawn with black lines of different thickness. Only the polyaniline backbone of the protein is represented. An antiparallel β sheet of two identical strands, one from each subunit, arrayed around the molecular 2-fold rotational axis of symmetry passes through the major groove of the DNA. The amino-terminal four amino acids assume different conformations in the two subunits. This drawing was produced with MolScript.^{48b}

G–C pair superposes the palindromic sequences in the boxes.

Many of the sequences of DNA that particular proteins are required to recognize are palindromic. A protein built from two copies of a folded polypeptide in

which the two copies are associated with each other around a molecular 2-fold rotational axis of symmetry can present, one on each copy, two identical faces complementary to faces on the surface of the palindromic segments of DNA. One of these surfaces can bind to one half of the palindrome and the other to the other half of the palindrome simultaneously if those surfaces are positioned relative to their own 2-fold rotational axis of symmetry as the two palindromes are to theirs. Evolution by natural selection has discovered that, by this simple strategy, the standard free energy of association between the DNA and the protein is automatically doubled and the specificity of the interaction is more than squared.

The *met* repressor of *E. coli* is a **dimeric protein** built from two copies of a folded polypeptide 104 aa in length that are associated with each other around a molecular 2-fold rotational axis of symmetry such that each copy presents a face complementary to a face on one half of the palindrome **9–1**. When the repressor is bound to the DNA, the molecular 2-fold rotational axis of symmetry of the protein coincides with the local palindromic 2-fold rotational axis of symmetry of the DNA (Figure 9–10).⁵⁵

The *arc* repressor of *E. coli* is a similarly symmetric protein that binds to the split palindrome in **9–2**.⁵⁶ When the palindrome is split, the protein can recognize both its symmetry and the length of the separation between its two halves in the segment of DNA. In the crystallographic molecular model⁵⁷ of the dimeric E2 DNA-binding domain of bovine papillomavirus-1, each of the identical subunits binds to one half of a palindrome, the two halves of which are split by four base pairs rather than five. In this complex, the molecular 2-fold rotational axis of symmetry of the protein and the molecular 2-fold rotational axis of symmetry of the DNA are coaxial and both coincide with a crystallographic rotational axis of symmetry.

In the cyclic **point group 3**(C_3), the three protomers of a homooligomeric protein are arranged around a 3-fold rotational axis of symmetry. Chloramphenicol *O*-acetyltransferase from *E. coli* is a trimer with symmetry of point group 3(C_3) (Figure 9–11).⁵⁸ It crystallizes in the space group $R32$ with one of its three identical folded polypeptides as the crystallographic asymmetric unit. Consequently, the molecular 3-fold rotational axis of symmetry is exact. The individual subunits are compact globular structures, and the three interfaces connecting them together are formed by the association of two relatively flat faces. The interfaces that produce the trimer are all identical to each other, and rotations of 120° about the axis of symmetry superpose them upon each other. Each subunit has on its surface one copy of each of the two distinct but complementary faces that form the interface. Three identical β strands, one from each subunit, direct their side chains into the center of the trimer at the axis of symmetry.

The frequency with which trimers with symmetry of

point group $3(C_3)$ arise during evolution by natural selection is about 10 times lower than the frequency with which dimers with symmetry of point group $2(C_2)$ arise (Table 9-1). In fact, at one time it was thought that such trimeric proteins did not exist, but there are now crystallographic molecular models for a number of them.^{19,59-66} It is by considering the problem of assembling a trimer relative to that of assembling a dimer that the reason for the scarcity of trimers becomes apparent.

The interface is the feature that evolves and not the oligomer. A dimer built around a 2-fold rotational axis of symmetry is held together by one more or less continuous **interface centered on the rotational axis of symmetry**. The axis divides the complete interface into two identical halves (Figures 9-1A and 9-9). Each half is the formal equivalent to one of the three identical interfaces distributed around the 3-fold rotational axis of symmetry in a trimer (Figure 9-11). The incremental decreases of free energy associated with favorable mutations are not automatically doubled during the evolution of an interface in a trimer as they are in the evolution of an interface in a dimer. Because termolecular collisions rarely occur, the assembly of an oligomeric protein must proceed through a series of bimolecular steps. A bimolecular collision producing a dimer automatically involves the simultaneous formation of the two halves of its interface and incorporates the free energies of formation of both halves into the immediate product. The first step in the assembly of a trimer, however, is the collision of two monomers to form only one of its three interfaces. This first interface, standing alone, must exist long enough or form often enough for the third protomer to complete the ring, yet it is the evolution of this initial interface that does not benefit from symmetry as does the evolution of the initial and final interface of the dimer. Therefore, trimers should appear less frequently than dimers during evolution. In favor of the symmetric trimer, however, is the fact that, as with the two halves of the interface in a dimer, its three identical interfaces can evolve simultaneously, a fact that magnifies the incremental decrease in free energy change in the overall formation of the complete oligomer for each favorable mutation.

If the 3-fold axis of symmetry of chloramphenicol O-acetyltransferase were not an exact rotational axis of symmetry but a closed screw axis, one of the interfaces could not be equivalent to the other two because the ring could not be completed. It is most likely that this peculiar one of the three interfaces would not fit together properly because it would be formed from the same two faces now required to associate in a different way from the way they associated at the other two interfaces. Such a structure would be significantly weaker than a rotationally symmetric trimer because of the one misaligned interface.

α_4 Tetramers with cyclic symmetry of point group 4 (C_4), such as L-lactate dehydrogenase (cytochrome) from *Saccharomyces cerevisiae* (Figure 9-12),⁶⁷ L-fucose-

phosphate aldolase from *E. coli*,⁶⁸ L-ribulose-phosphate 4-epimerase from *E. coli*,⁶⁹ and mammalian⁷⁰ and bacterial⁷¹ IMP dehydrogenase; α_5 pentamers with cyclic symmetry of point group 5 (C_5), such as acetylcholine-binding protein from *Lymnaea stagnalis*,⁷² the B subunit of heat-labile enterotoxin from *E. coli*,⁴³ and human serum amyloid P component;⁷³ α_6 hexamers with cyclic symmetry of point group 6 (C_6), such as transitional endoplasmic reticulum ATPase from *Mus musculus*⁷⁴ and the replicative DNA helicase encoded by the bacterial plasmid RSF1010;⁷⁵ and α_7 heptamers with cyclic symmetry of point group 7 (C_7), such as transcriptional

Figure 9-11: Three-fold rotational symmetry of point group $3(C_3)$. An α -carbon diagram of chloramphenicol O-acetyltransferase from *E. coli* is drawn from the crystallographic molecular model of this trimeric protein.³⁸ The three identical subunits are distinguished by the different widths of the line segments. This drawing was produced with MolScript.⁴⁸⁵

Figure 9–12: Four-fold rotational symmetry of point group 4(C_4). An α -carbon diagram of L-lactate dehydrogenase (cytochrome) from *S. cerevisiae* is drawn from its crystallographic molecular model.⁶⁷ The α_4 tetramer crystallized in the space group $P3_221$ with two subunits in the crystallographic asymmetric unit. The molecular 4-fold axis of symmetry coincided with a crystallographic 2-fold axis of symmetry, and both run through the center of the molecule normal to the plane of the page. The first 100 amino acids of the folded polypeptide form a separate domain, which is ordered and hence visible in two of the four subunits and disordered and hence invisible in the other two. To enhance the symmetry, these amino-terminal domains have been omitted. The four subunits have been drawn with lines that alternate in thickness around the circle. The carboxy-terminal 25 amino acids of each polypeptide cross over each other to form a central entwined cone around the 4-fold axis of symmetry. This drawing was produced with MolScript.⁴⁸⁵

activator NTRC1 from *Aquifex aeolicus*⁷⁶ and the small nuclear ribonucleoprotein from *Pyrobaculum aerophilum*,⁷⁷ are even more rare than trimers with cyclic symmetry of point group 3(C_3). Amazingly, however, there is a protein that is an α_{11} undecamer with symmetry of cyclic point group 11(C_{11}).⁷⁸

Tetramers are the second most common type of oligomeric protein (Table 9–1). Almost all tetrameric proteins have their protomers arranged in the symmetry of dihedral point group 222(D_2) instead of the symmetry of cyclic point group 4(C_4). A **dihedral point group** is a point

group in which the protomers are arranged on two circles of equal radius around a central n -fold rotational axis of symmetry and n 2-fold rotational axes of symmetry perpendicular to that central axis. In the **dihedral point group 222(D_2)**, the central axis is a 2-fold rotational axis of symmetry, there are two 2-fold rotational axes of symmetry orthogonal to it and to each other, and all of the axes intersect at the same point. If a sphere is placed at each of the four vertices of an equilateral tetrahedron, and if each of the four spheres has a diameter equal to the length of a side of the tetrahedron, the spheres will contact each other at six points (Figure 9–13A). If the spheres are asymmetric objects, for example, the subunits of a tetramer, then the six points of contact, for example, the six possible interfaces between pairs of subunits, are three identical twins, designated 1, 2, and 3 in the diagram, each different from the other two. Each of the six interfaces contains within itself one of the 2-fold rotational axes of symmetry. Each interface is superposed on its twin when rotation occurs about either of the two axes of symmetry orthogonal to the one passing through it, but no rotational axes of symmetry can superpose an interface 1 on an interface 2 or an interface 3 or superpose an interface 2 on an interface 3.

Ideally, a tetrameric protein with dihedral symmetry of point group 222(D_2) should have **three different pairs of interfaces**, but usually one pair does not form or is almost nonexistent because the tetrahedron is squashed in one dimension. For example, if the tetrahedral arrangement of spheres in Figure 9–13A were squashed from above the plane of the page, the interfaces 3 would pull apart. The tetramer of symmetry of point group 222(D_2) that is the crystallographic molecular model of 2,2-dialkylglycine decarboxylase (pyruvate) from *Burkholderia cepacia* is such a squashed tetrahedron (Figure 9–13B).⁷⁹ The two identical vertical interfaces, normal to the plane of the page through which runs the exact vertical molecular 2-fold rotational axis of symmetry in the plane of the page (the interfaces 1 in panel A), are the most extensive (75 nm² interface⁻¹)* and were designated by the crystallographers as the interfaces connecting the monomers that form the two dimers of the structure. In these two roughly flat interfaces, there are loops of polypeptide that interpenetrate the two subunits. The two identical horizontal interfaces,

* The size of an interface will be presented as the total accessible surface area from its two participants that is buried upon its formation. Consequently, each interface is formally defined as the adhesive interaction between any two subunits that holds only those two subunits together in the complex. This definition ignores any cooperativity that arises in interfaces in which n subunits are held together by a total of n interfaces around an n -fold rotational axis of symmetry when n is greater than 2, such as the stability gained when the third subunit is added to complete a cyclic trimer or the stability realized in the entwined cone of four carboxy termini (Figure 9–12) in the four formal interfaces around the 4-fold rotational axis of symmetry in L-lactate dehydrogenase (cytochrome).

Figure 9-13: A dimer of dimers with dihedral symmetry of point group $222(D_2)$. (A) Point group $222(D_2)$. Four spheres are placed at the vertices of an equilateral tetrahedron. The spheres are made asymmetric by placing the letter G inside of each. The letters G are superposed on each other by rotation around the three axes of symmetry, one vertical and one horizontal in the plane of the page and the third normal to the page. The three different pairs of interfaces between the spheres, labeled 1, 2, and 3, are each distinct: interfaces 1 connecting the open sides of the letters G, interfaces 2 connecting the bottoms of the letters G, and interfaces 3 connecting the T segments of the letters G. (B) α -Carbon diagram of the $(\alpha_2)_2$ tetramer of 2,2-dialkylglycine decarboxylase (pyruvate) from *B. cepacia* drawn from its crystallographic molecular model.⁷⁹ Two of the subunits have been drawn with thicker line segments than the other two. The protein crystallizes in the space group $P6_322$ with a single subunit in the crystallographic asymmetric unit, and all three molecular 2-fold rotational axes of symmetry coincide with crystallographic rotational axes of symmetry. This drawing was produced with MolScript.⁴⁸³

which are tilted somewhat from being normal to the plane of the page and through which runs the exact horizontal molecular 2-fold rotational axis in the plane of the page (the interfaces 2 in panel A), are less extensive ($24 \text{ nm}^2 \text{ interface}^{-1}$) and were designated as the interfaces holding together the two dimers to form the tetramer. The interfaces along the exact 2-fold rotational axis of symmetry normal to the plane of the page (interfaces 3 in panel A) are almost nonexistent because of the squashing of the tetrahedron.

Almost all tetramers of dihedral symmetry of point group $222(D_2)$ are constructed along these lines, with an almost nonexistent or a completely **nonexistent pair of interfaces** and with one of the remaining two pairs of interfaces being more extensive than the other. Consequently, tetramers of dihedral symmetry, which include almost all tetrameric proteins, are **dimers of dimers** and the complete structure of such a dimer of dimers can be designated as that of an $(\alpha_2)_2$ tetramer to distinguish it from an α_4 tetramer of cyclic symmetry of point group $4(C_4)$. The same points noted in the description of the evolution of a rotationally symmetric dimer from an ancestral monomeric protein are of equal validity in describing the evolution of a rotationally symmetric dimer of dimers from an ancestral dimeric protein. Also, for the same reasons, a dimer of dimers is a closed structure.

Because each of the three pairs of interfaces in a tetramer with dihedral symmetry is completely different, they each have different strengths, reflected in their **free energies of association**. One of the two or three pairs of interfaces must be the strongest, and if there is any dissociation of an $(\alpha_2)_2$ tetramer into its constituent α_2 dimers, it is usually this strongest pair of interfaces that will be retained, one in each of the two dimers. For example, the uncomplicated, **reversible dissociation** of $(\alpha_2)_2$ homotetrameric, enzymatically active bacterial 6-phosphofructokinase into enzymatically inactive α_2 dimers results from the sundering of the less extensive

of the two distinct types of interfaces that produce the structure of dihedral symmetry.⁸⁰⁻⁸²

Hemoglobin is an honorary homotetramer. It is built from two different polypeptides, α and β , each present in two copies to provide the four protomers. The two polypeptides are homologous in sequence⁸³ and their tertiary structures are superposable.⁸⁴ In the heterotetramer, the four protomers of hemoglobin occupy the same arrangement as the four protomers of 2,2-dialkylglycine decarboxylase (pyruvate), but two of the rotational axes are rotational axes of pseudosymmetry. The $\alpha\alpha$ in-

terface and the $\beta\beta$ interface, through which runs the molecular 2-fold axis of symmetry, are the rudimentary pair, so the structure can be represented as $(\alpha\beta)_2$.

The oxygenated form of hemoglobin in solution participates in the dissociation

and the value of the dissociation constant

$$K_d = \frac{[\alpha\beta]^2}{[(\alpha\beta)_2]} \quad (9-3)$$

is $1 \mu\text{M}$.⁸⁵ That the same interface always remains in the dimer follows from the fact that no hybrid dimers of the type $\alpha'\beta$ or $\alpha\beta'$ are formed under conditions where the reaction of Equation 9-2 is rapidly interconverting tetramers and dimers in a mixture of two hemoglobins, $(\alpha\beta)_2$ and $(\alpha'\beta')_2$, from two species, dog and human, respectively, even though **hybrids** of the type $(\alpha\beta)(\alpha'\beta')$ did form readily.⁸⁶ In this experiment, hemoglobins from the two species were used to permit isoelectrophoretic separation of the hybrids (as in Figure 8-18). As a control, it was shown that the hybrid dimers $\alpha'\beta$ and $\alpha\beta'$ could be artificially formed and easily separated isoelectrophoretically, from each other and from the parent dimers $\alpha\beta$ and $\alpha'\beta'$. The $\alpha'\beta$ and $\alpha\beta'$ hybrids also could not be shuffled by the reaction of Equation 9-2. Therefore one of the two different pairs of interfaces between α and β subunits in the hemoglobin tetramer⁸⁴ must be much stronger than the other.

A number of other oligomeric proteins also participate in dissociations the equilibrium constants for which are large enough to be measured. In fact, the dimer of interleukin-8 that is observed crystallographically has a dissociation constant so large that the protein is actually a monomer at physiological concentrations.⁸⁷ Most oligomeric proteins, however, have interfaces so strong that their dissociation does not occur within normal ranges of concentration.

A **molecular asymmetric unit** is the smallest unit of the structure of an oligomeric molecule that, when submitted to the appropriate symmetry operations, creates the entire structure. The individual subunits of the cyclic oligomers in Figures 9-9 to 9-12 are the molecular asymmetric units of their respective molecules. In the $(\alpha_2)_2$ tetramer of 2,2-dialkylglycine decarboxylase (pyruvate) (Figure 9-13B), the molecular asymmetric unit is, by inspection, the single folded polypeptide. If the one polypeptide is positioned in space, its image is rotated 180° around any one of the 2-fold rotational axes of symmetry, and another identical folded polypeptide is placed where the image of the first has thus been positioned, one of the three possible dimers in the tetramer is created. If the image of this dimer is then rotated about

another of the 2-fold rotational axes of symmetry and another identical dimer is placed where the image of the first has been positioned, then the entire tetramer is created.

If the tetrahedron of Figure 9-13A is squashed flat, the structure becomes a **ring of four protomers** that vaguely resembles a ring with cyclic symmetry of point group $4(C_4)$, often with a large hole in the middle.^{88,89} Nevertheless, it is easy to distinguish the former from the latter because its ring has dihedral symmetry of point group $222(D_2)$. The orientation of the protomers in an oligomer with dihedral symmetry alternates up-down-up-down around the ring, and the two orthogonal 2-fold rotational axes of symmetry in the plane of the ring between every pair of subunits, which do not exist in a structure with cyclic symmetry, remain.

As with protocatechuate 3,4-dioxygenase (Figure 9-2), which is a rare example of a dimer the subunits of which are arranged around a screw axis of symmetry, *lac* repressor from *E. coli*⁹⁰ and the lectin from *Arachis hypogaea*⁹¹ are tetramers in each of which a pair of rotationally symmetric dimers of identical subunits is arranged around a screw axis of symmetry.

Ribulose-phosphate 3-epimerase from chloroplasts of *Solanum tuberosum* (Figure 9-14A)⁹² is an $(\alpha_2)_3$ hexamer with the symmetry of **dihedral point group 322(D_3)** (Figure 9-14B), phosphoribulokinase from *Rhodobacter sphaeroides* (Figure 9-15A)⁹³ is an $(\alpha_2)_4$ octamer with the symmetry of **dihedral point group 422(D_4)** (Figure 9-15B), and peroxiredoxin from *Crithidia fasciculata* (Figure 9-16)⁹⁴ is an $(\alpha_2)_5$ decamer with the symmetry of **dihedral point group 522(D_5)**. The crystallographic molecular model of the $(\alpha_2)_3$ hexamer of ribulose-phosphate 3-epimerase has a central molecular 3-fold rotational axis of symmetry and three molecular 2-fold rotational axes of symmetry at angles of 60° to each other, each of them orthogonal to the central axis and one of them exact. The crystallographic molecular model of the $(\alpha_2)_4$ octamer of phosphoribulokinase has a central, exact 4-fold rotational axis of symmetry and four exact 2-fold rotational axes of symmetry at angles of 45° to each other and all of them orthogonal to the central axis. The crystallographic molecular model of the $(\alpha_2)_5$ decamer of peroxiredoxin has five molecular 2-fold rotational axes of symmetry at angles of 36° to each other, all of them orthogonal to the central molecular 5-fold rotational axis of symmetry.

In the dihedral point groups of odd fold (3-fold, 5-fold, and 7-fold), the **interfaces found at the two ends of each 2-fold rotational axes of symmetry**, although rotationally symmetric about the axis, are different from each other (Figure 9-14B); in the dihedral point groups of even fold (4-fold and 6-fold), the interfaces found at the two ends of each 2-fold rotational axis of symmetry are the same, but there are two different kinds of 2-fold rotational axes of symmetry that alternate around the central axis (Figure 9-15B). Nevertheless, in both instances, odd

and even, there are only two types of interfaces associated with the 2-fold rotational axes of symmetry regardless of how large the fold (hence the notation $n22$). A third type of n -fold symmetric interface can occur across the central n -fold axis.

In oligomeric proteins with dihedral symmetry there are usually a set of n strong, identical interfaces distributed around the central axis that connect pairs of subunits into dimers. Examples are the three interfaces approximately normal to the plane of the page each connecting an upper subunit with a lower subunit in Figure 9-14A and the five interfaces at about 2 o'clock, at about 5 o'clock, at 7 o'clock, at about 10 o'clock and at about 12 o'clock in Figure 9-16. As is the case with those in isolated dimers with cyclic symmetry, each of these interfaces has a 2-fold rotational axis of symmetry running through its center. In ribulose-phosphate 3-epimerase, phosphoribulokinase, and peroxiredoxin, these interfaces forming the dimers are more extensive than the interfaces joining the dimers into the hexamer, the octamer, or the decamer, respectively, so the proteins are a **trimer of dimers**, a **tetramer of dimers**, and a **pentamer of dimers**, respectively, all with dihedral symmetry.

There are three configurations in which such dimers can be assembled into rings with dihedral symmetry: eclipsed, staggered, and splayed (Figure 9-17). The dimers in ribulose-phosphate 3-epimerase (Figure 9-14A) are **eclipsed**; those in ribulokinase (Figure 9-15A) are **staggered**; and those in peroxiredoxin (Figure 9-16) are **splayed**. In ribulose-phosphate 3-epimerase the only interfaces holding the three dimers together are the six identical ones, three between the subunits in the upper ring and three between the subunits in the lower ring,⁹² and in peroxiredoxin the only interfaces holding five dimers together are the five identical ones, each between

an upper subunit and a lower subunit in neighboring dimers.⁹⁴ In phosphoribulokinase, however, the six identical interfaces connecting the three upper subunits to each other and the three lower subunits to each other are as extensive as the five identical interfaces between a lower subunit of one dimer and an upper subunit of a neighboring dimer, but the interfaces holding the dimers

Figure 9-14: A trimer of eclipsed dimers with dihedral symmetry of point group $322(D_3)$. (A) α -Carbon diagram of the homohexamer of ribulose-phosphate 3-epimerase from the chloroplasts of *S. tuberosum*, drawn from the crystallographic molecular model (space group $P3_121$) of the enzyme.⁹² The view is along one of the dihedral 2-fold rotational axes of symmetry, which coincides with a crystallographic rotational axis of symmetry. The central 3-fold noncrystallographic molecular rotational axis of symmetry is vertical in the plane of the page. The three eclipsed dimers are drawn with lines of different widths and different shading. There are no interactions between an upper subunit and any lower subunit other than the one with which it forms a dimer. The accessible surface area buried in the interface within each dimer is $21 \text{ nm}^2 \text{ interface}^{-1}$, and that within an interface connecting the dimers around the central 3-fold rotational axis of symmetry is $15 \text{ nm}^2 \text{ interface}^{-1}$. (B) Six molecules of lactic acid arranged with dihedral symmetry of point group $322(D_3)$. The molecules of lactic acid at 1, 5, and 9 o'clock are above the plane of the page, and those at 3, 7, and 11 o'clock are below the plane of the page. The three 2-fold rotational axes of the dihedral point group (arrows with full heads) are in the plane of the page, and the solid triangle denotes a 3-fold rotational axis of symmetry normal to the plane of the page. This drawing was produced with MolScript.⁴⁸⁵

together are three times more extensive than either of these types.⁹³ In the staggered hexamer of sulfate adenylyltransferase from *Penicillium chrysogenum*, which also has the symmetry of point group $322(D_3)$, the interfaces connecting each subunit in one trimer with one subunit in the other trimer and with another subunit in the other

Figure 9-15: A tetramer of staggered dimers with dihedral molecular symmetry of point group $422(D_4)$. (A) α -Carbon diagram of phosphoribulokinase from *R. sphaeroides*, drawn from the crystallographic molecular model (space group $P4_32$) of the enzyme.⁹³ The view is along the central 4-fold rotational axis of symmetry. All molecular axes of symmetry coincide with crystallographic axes of symmetry. The four subunits to the front are drawn with thin lines; the four to the back, with thick lines. The accessible surface area buried in the interface within each of the four fundamental dimers centered on the vertical and horizontal 2-fold rotational axes of symmetry is $35 \text{ nm}^2 \text{ interface}^{-1}$; that within an interface connecting a subunit to the front or a subunit to the back within one of those dimers to a subunit to the front or a subunit to the back, respectively, in a neighboring dimer is $6.4 \text{ nm}^2 \text{ interface}^{-1}$; and that within an interface connecting a subunit to the front or a subunit to the back within one of those dimers to a subunit to the back or a subunit to the front, respectively, in a neighboring dimer is $9.0 \text{ nm}^2 \text{ interface}^{-1}$. This drawing was produced with MolScript.⁴⁶⁵ (B) A drawing of eight molecules of lactic acid arrayed with dihedral symmetry of point group $422(D_4)$. The molecules at 2, 5, 8, and 11 o'clock are above the plane of the page, and the other four are below the plane of the page. The four 2-fold rotational axes of symmetry of the dihedral point group are in the plane of the page, and the solid square denotes a 4-fold rotational axis of symmetry normal to the plane of the page. The atomic coordinates on which this drawing is based were provided by David H. T. Harrison.

trimer, respectively, are formed by two different domains in that subunit.⁹⁵ In an eclipsed structure, a loop⁹⁶ or terminal segment⁹⁷ of polypeptide sometimes extends across the central plane of the structure to connect the upper subunit of one dimer to the lower subunit of a neighboring dimer and vice versa.

There are other examples of eclipsed trimers of dimers,^{98,99} staggered tetramers of dimers,^{100,101} and splayed pentamers of dimers¹⁰² as well as splayed trimers of dimers,^{103,104} a splayed tetramer of dimers,^{105,106} an eclipsed pentamer of dimers,⁹⁷ and an eclipsed hexamer of dimers.¹⁰⁷ In all of these proteins with dihedral symmetry, the fact that the most extensive interfaces in the structure are those holding the dimers together suggests that evolution assembled these oligomers from preexisting symmetric dimers. This conclusion would make sense because dimeric proteins are far more common than either trimeric proteins with cyclic symmetry, tetrameric proteins with cyclic symmetry, or pentameric proteins with cyclic symmetry.

One also comes to the conclusion that the dimer is the most common **fundamental unit** in the assembly of oligomeric proteins because there are examples of proteins that have different dihedral quaternary structures even though the α_2 dimers from which they are constructed are obviously related and are themselves held together by homologous interfaces. Human nucleoside-diphosphate kinase is a hexamer with dihedral symmetry of point group $322(D_3)$, but nucleoside-diphosphate kinase from *Myxococcus xanthus* is a tetramer with dihedral symmetry of point group $222(D_2)$, even though the α_2 dimer from human protein is readily superposable on the α_2 dimer of the protein from *M. xanthus*.¹⁰⁸ Within the

family of superoxide dismutases, a fundamental α_2 dimer, which is superposable among the proteins from different species, either stands alone or is arranged in several different ways to form distinct $(\alpha_2)_2$ tetramers.¹⁰⁹ The cytoplasmic ribulose-phosphate 3-epimerases from animals and plants are α_2 dimers rather than $(\alpha_2)_3$ hexamers, as are those from chloroplasts (Figure 9-14A).^{92,110} In fact, the dimeric ribulose-phosphate 3-epimerases from the cytoplasms of fungi and animals are more closely related to the dimeric ribulose-phosphate 3-epimerase from a given plant than is the hexameric ribulose-phosphate 3-epimerase from its own chloroplasts. The dihydrodipicolinate synthases from *Nicotiana sylvestris* and *E. coli* are tetramers with dihedral symmetry assembled from superposable α_2 dimers, but the dimers face each other in opposite directions in the two proteins.¹¹¹ Consequently, it seems that most oligomers with dihedral symmetry are $(\alpha_2)_2$ dimers of dimers, $(\alpha_2)_3$ trimers of dimers, $(\alpha_2)_4$ tetramers of dimers, $(\alpha_2)_5$ pentamers of dimers, and $(\alpha_2)_6$ hexamers of dimers.

There are of course exceptions to the observation that most proteins with dihedral symmetry are assembled from symmetric dimers. Histidine decarboxylase from *Lactobacillus* is a **dimer of trimers**,¹¹² glutamate-ammonia ligase from *Salmonella typhimurium* is a **dimer of hexamers**,¹¹³ and human serum amyloid P component is a **dimer of pentamers**.¹¹⁴ There are also two proteins, a chaperonin¹¹⁵ and an intracellular, multifunctional endopeptidase¹¹⁶ that are $[(\alpha\beta)_7]_2$ dimers of heptamers. The fact that the octamer of IMP dehydrogenase from *Tritrichomonas foetus* with dihedral symmetry of point group $422(D_4)$ dissociates into two tetramers with a dissociation constant of $1 \mu\text{M}$ demonstrates that it is a dimer of two tetramers, each of cyclic symmetry.¹¹⁷

In proteins with cyclic symmetry such as dimers¹¹⁸⁻¹²⁰ or trimers, tetramers, and pentamers¹²¹ as well as proteins with dihedral symmetry,¹⁰⁶ related superposable monomers have been assembled by evolution around different interfaces or into different quaternary structures. The malleability of the arrangements of protomers with both dihedral and cyclic symmetry within sets of oligomers of the same family of proteins or even the same species of proteins¹²⁰ leads to the conclusion that the quaternary structure of a protein provides little information about its **evolutionary relationships**.

If, however, the quaternary structure is retained in the same protein from widely different species of organisms, the evolutionary constraints within the interfaces producing that quaternary structure are as stringent as those in the interior of the protein. For example, in the heterodimer of isoform 1 and isoform 2 of the R2 protein of ribonucleoside-diphosphate reductase from *S. cerevisiae*, the interface closely resembles those in the homodimers of the same protein from *E. coli* and *M. musculus* even though the folded polypeptides of isoforms 1 and 2 from *S. cerevisiae* differ significantly from

their folded homologues from *E. coli* and *M. musculus* at their peripheries.¹²²

When monomers are transformed by evolution into a homooligomeric ring with cyclic symmetry (Figures 9-9, 9-11, and 9-12) or when homodimers are transformed by evolution into a homooligomeric ring with dihedral symmetry (Figures 9-14A, 9-15A, and 9-16), a face and the complement to that face must be created on the surface of the monomer or the monomer in the dimer, respectively. The face and its complement must be positioned,

Figure 9-16: A pentamer of played dimers with dihedral symmetry of point group $522(D_5)$. An α -carbon diagram of peroxidase from *C. fasciculata*⁹⁸ is viewed down its central noncrystallographic, molecular 5-fold rotational axis of symmetry. Because the space group of the crystal is $P2_1$, none of the 2-fold molecular axes of symmetry coincides with a crystallographic axis of symmetry. The subunits are drawn with lines of different thickness. Of the total accessible surface area of each subunit, 13% is buried in one interface and 8.5% in the other interface. This drawing was produced with MolScript.⁴⁸⁵

Figure 9-17: Interfaces between dimers in rings of dihedral symmetry. When dimers stand vertically around the ring, they are **eclipsed** when viewed along the central axis, and the interfaces connecting those dimers to each other are all identical and symmetrically displayed around dihedral 2-fold rotational axes of symmetry (Figure 9-14A). When dimers tilt sufficiently so that both the pair of interfaces symmetrically displayed around each of their central 2-fold rotational axes of symmetry and an interface along the adjacent 2-fold rotational axis of symmetry between an upper subunit and a lower subunit in a neighboring dimer are present simultaneously, the dimers are **staggered** when viewed along the central axis (Figure 9-15A). When the dimers tilt so much that only the interface between an upper subunit and a lower subunit in a neighboring dimer can form along alternate 2-fold rotational axes of symmetry, the dimers are **splayed** when viewed along the central axis (Figure 9-16). The transformation from staggered to splayed is formally equivalent to squashing the tetrahedron of spheres and losing interfaces 3 in Figure 9-13.

respectively, on the surface of the monomer or the monomer in the dimer so that they are directed relative to each other at angles of 60° , 90° , 108° , or 120° , consistent with the angles relating the orientations of the interfaces in each monomer in a triangular, square, pentagonal, or hexagonal ring, respectively. Only in this way can every interface lock fully into place in the complete ring. Because it is only when all of the interfaces are fully locked that the full standard free energy of formation is realized, most of the existing **rings are continuous and symmetric**.¹²³ In HNRNP arginine methyltransferase from *S. cerevisiae*, however, the face and its complement on each dimer that produces the trimer of dimers have evolved so they are directed outward at a little more than 60° to each other. As a result, one of the three interfaces cannot quite lock into place, and there is a gap in the ring.¹²⁴

The homooctamer of the repressor from bacteriophage λ , which has dihedral symmetry, dissociates neither into four cyclic dimers nor into two cyclic tetramers as do most homooctamers of dihedral symmetry. Instead, it splits apart along a cleavage plane parallel to the 4-fold rotational axis of symmetry and one of the 2-fold rotational axes of symmetry, equivalent to a horizontal plane normal to the plane of the page in Figure 9-15B, to produce two tetramers that each retain an exact 2-fold rotational axis of symmetry, equivalent to the vertical 2-fold rotational axis of symmetry in Figure 9-15B.^{125,126} The other two now local 2-fold rotational axes of symmetry, however, in each of these tetramers end up at an 80° angle to each other instead of the 90° angle they were forced to assume in the octamer. If two of these relaxed tetramers were to form an octamer, there would necessarily be a gap of 20° at one of the 2-fold rotational axes of symmetry. Unlike what happens in arginine methyltransferase, when the octamer of the repressor forms, the tetramers distort to close the gap and produce a structure with complete dihedral symmetry of point group $422(D_4)$. Because the strain of this distortion is relieved on dissociation, the octamer dissociates along an unexpected set of interfaces.

In many proteins, the folded polypeptides of which contain **internal duplications**, the two superposable, duplicated domains are related by a 2-fold rotational axis of pseudosymmetry. Thiosulfate sulfurtransferase is an example of such an arrangement (Figure 9-18).¹²⁷ The amino acid sequences of its two domains are not significantly related to each other (11% identity with no gaps upon structural alignment). Nevertheless, one domain superposes upon the other with a root mean square deviation of 0.2 nm (117 out of 146 α carbons) upon a 179° rotation about the axis of pseudosymmetry normal to the page in Figure 9-18 and a translation along that axis of less than 0.1 nm. As with other domains of this level of kinship, the central portions coincide well, but loops connecting elements of secondary structure differ, often dramatically. The two internally duplicated domains of methionyl aminopeptidase from *E. coli* (Figure 7-7B) superpose on each other upon a rotation of 174° and a translation of 0.06 nm along a screw axis of pseudosymmetry between them¹²⁸ and those of porcine pepsin superpose upon a rotation of 173° .¹²⁹ Other examples of proteins formed by internal duplication in which the two domains are related by an approximate 2-fold rotational axis of symmetry are arabinose binding protein,¹³⁰ chymotrypsinogen,¹³¹ and sulfite reductase.¹³²

Presumably, these 2-fold **rotational axes of pseudosymmetry** are the remains of the 2-fold rotational axes of symmetry in the dimers of two identical protomers that were the ancestors of each of these proteins before the gene duplication occurred. The duplicated polypeptide incorporated the original rotational axis of symmetry, but following the duplication the two halves began to evolve separately and diverge. Because the sequences have diverged, the superposition is not between struc-

tures with the same amino acid sequence, and the axis has become a 2-fold rotational axis of pseudosymmetry. There is at least one example of a protein in which a single folded polypeptide has an internal 3-fold rotational axis of pseudosymmetry^{133,134} and one with an internal 5-fold rotational axis of pseudosymmetry,¹³⁵ presumably the remains of an ancestral trimer and an ancestral pentamer, respectively. The first and the third of the three domains in the single folded polypeptide composing pyruvate oxidase from *Lactobacillus plantarum* superpose on each other with a root mean square deviation of 0.19 nm upon rotation of 190° around a rotational axis of pseudosymmetry between them.¹³⁶ These two halves of the duplicated gene, when unduplicated, encoded the two identical subunits of an α_2 dimer. There is, however, another unrelated domain of about the same size inserted into the polypeptide between the two that nevertheless remain symmetrically arrayed.

There are also examples of proteins in which an early gene duplication, which produced two domains now related by a 2-fold axis of pseudosymmetry bearing witness to that duplication, was then followed by a later gene duplication. This later duplication produced another 2-fold axis of pseudosymmetry relating two copies of the product of the early duplication.^{137,138} Because the three 2-fold axes of pseudosymmetry in each of these proteins, the two early ones and the one later one, are almost parallel to each other, the original protein must have been an α_2 dimer and after its two identical subunits were fused, the product of the fusion then evolved to become an α_2 dimer, the identical subunits of which were then fused. One of these proteins is now again an α_2 dimer of two subunits, each with four internally duplicated, symmetrically arrayed domains,¹³⁷ perhaps on its way to yet another duplication.

Not all folded polypeptides with internally repeating domains display such rotational axes of pseudosymmetry, and there is no direct correspondence between internally repeating domains and rotational axes of symmetry. Immunoglobulin G (Figure 7–13) contains two different polypeptides, one long and one short, that are both composed of internally repeating domains. Within neither of the polypeptides are any of the adjacent internally repeating domains related by a rotational axis of pseudosymmetry. Only proteins that were symmetric oligomers before the replication occurred can retain vestiges of their former rotational axes of symmetry.

Phaseolin from *Phaseolus vulgaris* contains an α_3 trimer with cyclic symmetry.¹³⁹ The subunit of phaseolin is the product of a gene duplication, and its two superposable domains are related by a 2-fold rotational axis of pseudosymmetry. In the trimer, these three 2-fold rotational axes intersect the central 3-fold rotational axis of symmetry and are normal to it. Consequently, the ancestral protein must have been a hexamer with dihedral symmetry, the constituent α_2 dimers of which were fused by gene duplication. It is certain that such an event

occurred to the ancestor of 5-carboxymethyl-2-hydroxymuconate Δ -isomerase. It is also a trimer with subunits containing internally duplicated domains around local 2-fold rotational axes of pseudosymmetry orthogonal to the central 3-fold rotational axis of symmetry. 4-Oxalocrotonate tautomerase is an enzymatically related protein, the monomer of which is homologous to both of the duplicated halves of the monomer of 5-carboxymethyl-2-hydroxymuconate Δ -isomerase. 4-Oxalocrotonate tautomerase is an α_6 hexamer with dihedral symmetry, the entire structure of which super-

Figure 9-18: α -Carbon diagram drawn from the crystallographic molecular model of the thiosulfate sulfurtransferase.¹²⁷ The amino acid sequence of the protein does not contain significant internal homology, but the internal duplication is manifest in the crystallographic molecular model of the folded polypeptide that forms this monomeric protein. The two domains, above and below a horizontal plane passing through its center, are related to each other by a 2-fold rotational axis of pseudosymmetry normal to the plane of the page running through the center of the protein. This drawing was produced with MolScript.⁴⁸⁵

Figure 9-19: An interface between the two subunits of an α_2 dimer. A portion of the crystallographic molecular model of protein Cro from bacteriophage 434¹⁴⁵ is represented. The backbone and side chains from the upper subunit are drawn with white sticks; those from the lower, with black sticks. The molecular 2-fold rotational axis of symmetry runs horizontally through the center of the interface. Because there are no crystallographic 2-fold rotational axes of symmetry in the space group $P2_1$ of the crystal, the 2-fold axis of symmetry is a molecular axis, and at the periphery of the interface, side chains differ noticeably from their twins in conformation (for example, the two Arginines 43 and the two Arginines 45).⁴⁶⁵ This drawing was produced with MolScript.⁴⁶⁵

poses on the trimer of 5-carboxymethyl-2-hydroxymuconate Δ -isomerase.¹⁴⁰ The tautomerase retains the quaternary structure of the common ancestor of itself and the isomerase, while the isomerase is an internal duplication of its ancestor.

The **interfaces between folded polypeptides** in an oligomeric protein are almost indistinguishable in their **hydropathy** from the interfaces between secondary structures within a folded polypeptide.¹⁴¹ In the interfaces between subunits, $65\% \pm 4\%$ of the accessible surface area of the complementary faces is nonpolar and $22\% \pm 7\%$ is polar but uncharged. These percentages are indistinguishable from those for interfaces between ele-

ments of secondary structure within a subunit ($70\% \pm 5\%$ and $24\% \pm 6\%$, respectively). The average interface between subunits, however, is enriched in its percentage of charged accessible surface area ($13\% \pm 5\%$) relative to the percentage of charged accessible surface area ($6\% \pm 2\%$) in the average interface between secondary structures within a subunit. Most of this **elevation in charged accessible surface area** is attributable to the guanidinium functional groups of arginines,¹⁴¹ and arginines are the donors in 33% of all of the hydrogen bonds located within interfaces between subunits. Otherwise, the amino acid composition of an interface is about the same as that of the buried interior of a folded polypeptide.

A representative set of ionized and un-ionized **hydrogen bonds** can be found in the interface between the two subunits in the dimeric carboxylesterase ESTA from *A. fulgidus* (Table 9-2). The compositions of the amino acids within interfaces, however, can vary widely. For example, each of the two identical symmetrically displayed interfaces creating the dimer of 4- α -glucanotransferase from *Thermotoga maritima* is formed from 11 side chains that are completely hydrocarbon (valines, leucines, isoleucines, and phenylalanines),¹⁴³ while the interface between the two subunits of phosphopyruvate hydratase from *E. coli*, through which the molecular 2-fold rotational axis of symmetry passes, has more than twice as many charged side chains as the average.¹⁴⁴

The interfaces between subunits are probably elevated in their composition of charged side chains because the constituent subunits, once they have folded, have to remain soluble until they can find a complementary partner. The charged groups prevent the folded subunits from aggregating nonspecifically with other proteins while they are searching for a partner.

A typical interface between two subunits of a dimer is that in the crystallographic molecular model of Cro protein from bacteriophage 434, through which the molecular 2-fold axis of symmetry runs (Figure 9-19).¹⁴⁵ To the right, there is a hydrophobic cluster of symmetrically arranged prolines, valines, leucines, phenylalanines, and tyrosines; to the left, a hydrogen-bonded cluster of glutamates, arginines, and the phenolic oxygen-hydrogens of the tyrosines. A significant portion of this polar half of the interface on the left, however, is formed from a hydrophobic cluster of the methylenes from the four arginines sandwiched between the two phenyl rings of two phenylalanines. **Arginine** is probably the most common charged amino acid in such interfaces because it provides charge to keep the folded subunit in solution but also has three methylenes that provide hydrophobic hydrogen-carbon bonds.

Because neither hydrogen bonds nor ion pairs can provide favorable standard free energy of formation to an interface between two folded polypeptides, the standard free energy of formation must be provided by the hydrophobic effect. Although there are clusters of

^aThe donor or acceptor in one subunit (subunit A) and its acceptor or donor, respectively, in the other subunit (subunit B) across the interface in the crystallographic molecular model¹⁴² of the homodimer of the carboxylesterase from *A. fulgidus* are tabulated. ^bThe atom performing the donation or the acceptance in each amino acid is in the notation of Figure 4–14. The crystallographic abbreviations for an acyl oxygen of the backbone and an amido nitrogen of the backbone are O and N, respectively. Two dimers together form the crystallographic asymmetric unit so the symmetrically arrayed hydrogen bonds have different lengths.

hydrogen–carbon bonds throughout the interface in the Cro protein (Figure 9–19), such clustering is not necessary for the expression of the **hydrophobic effect**. All that is required is that hydrogen–carbon bonds be removed from the aqueous phase and sequestered within the interface during its formation. What they end up next to is inconsequential.

Almost all of the interfaces between subunits in oligomeric proteins are those that form symmetric dimers. The 2-fold rotational axis of symmetry passes through the center of such an interface, and the detailed atomic contacts (Figures 9–9 and 9–19) or the interdigitations of secondary structure (Figure 9–1A) are **symmetrically duplicated**, except at the periphery where side chains in contact with the water are more flexible (for example, the hydrogen bonding of the Arginines 43 in Figure 9–19). The second most common interface is that forming a trimer with cyclic symmetry. Examples of the **symmetrically triplicated atomic contacts** and hydrogen bonds around a 3-fold rotational axis of symmetry are found around the exact rotational axes in the crystallographic molecular models of dihydrolipoyllysine residue acetyltransferase from *A. vinelandii* (Figure 9–20)³⁰ and the bacterial porins.¹⁴⁶ At the center of a tetramer with dihedral symmetry, where the three orthogonal 2-fold rotational axes of symmetry intersect, the atomic contacts and hydrogen bonds are also arrayed with the same dihedral symmetry about the point of intersection.^{147,148}

When the side chains of the twins across a rotational

axis of symmetry from each other intersect that axis, they usually assume alternate conformations in each of which one of the side chains sits on the axis and the other is pushed to one side and vice versa (Figure 6–29).¹⁴⁹ In the interface between the two subunits in the crystallographic molecular model of isoenzyme 3–3 of glutathione transferase from *Rattus norvegicus*, however, the stack of π molecular orbitals from the two stacked guanidiniums of the Arginines 77 is intersected through its center by the molecular 2-fold rotational axis of symmetry.¹⁵⁰ There are several examples in which the central sulfur–sulfur bond of a cystine sits upon a molecular 2-fold rotational axis of

Figure 9-20: An interface between three subunits arranged around a 3-fold rotational axis of symmetry. Portions of three of the 24 subunits in the crystallographic molecular model of the catalytic core (amino acids 382–637) of dihydrolipoyllysine-residue acetyltransferase from *A. vinelandii*³⁰ are presented. The exact molecular 3-fold rotational axis of symmetry, coinciding with one of the 3-fold rotational axes of symmetry in the space group *F*₄₃₂ of the crystal, runs back left to front right through the center of the interface. This drawing was produced with MolScript.⁴⁸⁵

symmetry.^{151–153} In the crystallographic molecular model of the α_2 dimer of human nitric-oxide synthase, a Zn^{2+} cation sits upon the molecular 2-fold rotational axis, symmetrically bound by the two Cysteines 110 and the two Cysteines 115;¹⁵⁴ and in the crystallographic molecular model of the $(\alpha_2)_2$ tetramer of methionine adenosyltransferase from *R. norvegicus*, a K^+ cation sits upon one of the molecular 2-fold rotational axes of symmetry symmetrically bound by the four amido oxygens of the backbone from the two positions 264 and the two positions 265.¹⁵⁵

Most of the interfaces between subunits in oligomeric proteins are formed from two complementary faces, each of which is a portion of the surface of its globular, folded polypeptide, and this portion is no more irregular than the usual exposed surface of the usual globular, folded polypeptide. In some instances, for example, glucose oxidase from *Aspergillus niger*,¹⁵⁶ superoxide dismutase from *Pseudomonas ovalis*,¹⁵⁷ chloramphenicol *O*-acetyltransferase (Figure 9–11), and ribulose-phosphate 3-epimerase (Figure 9–14A), the two faces are almost flat and the resulting interface is almost planar. Often, however, segments of secondary structure or loops between secondary structures will penetrate superficially the subunit across the interface (Figures 9–1A and 9–13B).

In contrast to such classical interfaces, there are interfaces that are formed from **regular arrays of secondary structure**. The most common examples of this type of interface are those in oligomers that are held together by coiled coils of α helices, as are general control protein GCN4 (Figure 6–29) and methyl-accepting chemotaxis protein II (Figure 6–30). The interface between the two subunits in the α_2 dimer of the variant surface glycoprotein from *Trypanosoma brucei* is an antiparallel coiled coil of four α helices, each about 50 aa long;¹⁵⁸ the interface between the two subunits of translocated intimin receptor is an antiparallel coiled coil of four α helices, each about 20 aa long;¹⁵⁹ the interface connecting the three subunits of human mannose-binding protein is a parallel coiled coil of three α helices, each 20 aa long;¹⁶⁰ and the interface between the two α_2 dimers of the tetrameric *lac* repressor from *E. coli* is an antiparallel coiled coil of four α helices, one from each subunit.⁹⁰ The central cores holding together the four subunits of the $(\alpha_2)_2$ tetramers of fumarate hydratase II from *E. coli*,¹⁶¹ histidine ammonia-lyase from *P. putida*,¹⁶² and adenylosuccinate lyase from *P. aerophilum*¹⁶³ are bundles of 20 antiparallel α helices, five from each subunit and each about 30 aa long.

Regular arrays of β structure also are used to connect subunits of oligomeric proteins together. In the α_3 trimer of UDP-*N*-acetylglucosamine diphosphorylase, the interfaces are formed by three identical β helices, one from each subunit that run parallel to each other around the molecular 3-fold rotational axis of symmetry, which coincides with a crystallographic axis.¹⁶⁴ Continuous β -pleated sheets run from one subunit into the other in

the α_2 dimers of concanavalin A,¹⁶⁵ alcohol dehydrogenase (Figure 6–9), κ bungarotoxin (Figure 9–9), and heme-binding protein 23 from *R. norvegicus*.¹⁶⁶ A β sheet of six strands is orthogonally (Figures 6–33 and 6–34) and symmetrically packed against an identical β sheet of six strands from the other subunit in the α_2 homodimer of the lectin from *A. hypogaea*,¹⁶⁷ and a β sheet of six strands is packed in parallel and symmetrically against an identical β sheet of six strands from the other subunit of the α_2 dimer of glucose-fructose oxidoreductase from *Zymomonas mobilis*.¹⁶⁸ In the α_4 cyclic tetramer of each half of the dihedral octamer of dihydroneopterin aldolase from *Staphylococcus aureus*¹⁶⁹ and in the α_2 dimer of each half of the dihedral tetramer of urate oxidase from *Aspergillus flavus*,¹²¹ each subunit contributes four β strands or eight β strands, respectively, to the dramatic antiparallel β barrel of 16 strands in the center of these oligomers. In the pentameric rings within the coat protein of rhinovirus 14, each of the identical subunits contributes one β strand to the parallel β barrel of five strands in the center of the oligomer.¹⁷⁰

Subunits in some homooligomeric proteins are joined to each other by **structural swapping**.¹⁷¹ When the subunit in such an oligomer is in its monomeric form, it is a compact, globular structure. When that monomer combines with another identical monomer, however, one or more of its elements of secondary structure, for example, an amino-terminal α helix,¹⁷² a β hairpin,¹⁷³ two α helices and two strands of β structure,¹⁷⁴ or a structural domain,¹⁷¹ takes the place of its twin on the other subunit, and its twin takes its place on its own subunit. Because the two elements of structure that have swapped are identical to each other, each can fit precisely into the cavity vacated by the other. The resulting α_2 dimer is held together by the respective strands of polypeptide connecting each swapped segment with the rest of its subunit. Often it is only these strands of random meander that hold the two subunits together and no formal interface is formed between them.¹⁷⁵ Conclusive proof of structural swapping requires a crystallographic molecular model of the unswapped monomer and the swapped dimer so that it can be shown that the swapped segments occupy in the same orientation the same locations in the dimer that were occupied by the unswapped segments in their respective monomers.^{171,172,176–178} In the coat protein of bacteriophage MS2, however, two of the three subunits in a homotrimeric substructure have swapped a β hairpin but in the third subunit that β hairpin occupies the same location on its own subunit occupied by the swapped β hairpins on the other two subunits.¹⁷³

The requirements for structural swapping have been examined by site-directed mutation.^{177,179} Site-directed mutation has also been used to convert an otherwise monomeric protein into a structurally swapped dimer.¹⁸⁰

Conclusive evidence of structural swapping is available for only a few proteins, but there are a number of oligomeric proteins in which one or more segments of the

polypeptide forming one subunit reaches over to embrace its neighboring subunit just as the same segments from its neighbor symmetrically embrace it. One example of this is the α_2 dimer of glucose-6-phosphate isomerase from *O. cuniculus*;¹⁸¹ another is the α_3 trimer of 4-chlorobenzoyl-CoA dehalogenase from *Pseudomonas*.⁶² In the symmetric α_2 dimer of human interleukin-5, the carboxy-terminal 24 amino acids of each subunit run symmetrically down one side of the other in random meander and then turn to run across the surface of the other in an α helix.¹⁸² In the α_2 dimer of ADP-ribose diphosphatase from *E. coli*, the first 57 amino acids of each subunit form a three-stranded antiparallel β sheet that lies upon the surface of the remaining globularly folded 153 amino acids of the other subunit,¹⁸³ and these 57 amino-terminal amino acids are missing in monomers from the same family. In the $(\alpha_2)_2$ tetramer of catalase from *Penicillium vitale*, the first 13 amino-terminal amino acids of one subunit are threaded through a large loop of 39 amino acids bulging out of the surface of its symmetric twin and vice versa to form a dimer in which each subunit is hooked to the other.¹⁸⁴

The ultimate expression of cyclic and dihedral symmetry is erythrocrucorin. Erythrocrucorin from *Lumbricus terrestris* is an $\{[(\alpha\beta)(\gamma\delta)]_3\}_{12}\epsilon_{36}$ oligomer of 180 folded polypeptides with a total of 29,916 aa arranged with dihedral symmetry of point group $622(D_6)$.¹⁸⁵ The core of the protein, which confers the dihedral symmetry, is a hexamer of dimers of trimers. Each of the 36 ϵ subunits (240 aa) of this core is first assembled into a homotrimer with cyclic symmetry. Along the 3-fold rotational axis of symmetry of the trimer, the amino-terminal 50 aa of each subunit forms a parallel coiled coil of three α helices holding the three subunits together. These coiled coils then combine in pairs to form dimers of trimers. Six of these dimers of trimers assemble around a central 6-fold rotational axis of dihedral symmetry in a splayed array, the interfaces of which are formed between the coiled coils of α helices. This structure displays the 12 globular

trimers of the carboxy-terminal domains (200 aa) of the ϵ subunits directed outward in upper and lower rings of six.

The globin subunits of the protein, each containing a heme, come in four isoforms (α , 151 aa; β , 145 aa; γ , 153 aa; and δ , 142 aa). They first pair as $\alpha\beta$ dimers and $\gamma\delta$ dimers with cyclic pseudosymmetry of point group $2(C_2)$. An $\alpha\beta$ dimer and a $\gamma\delta$ dimer then assemble around a molecular 2-fold rotational axis of pseudosymmetry, but their own local 2-fold rotational axes of pseudosymmetry intersect the central 2-fold rotational axis of pseudosymmetry of this tetramer at angles of 54° ¹⁸⁶ instead of 90° , as they would in a tetramer of dihedral pseudosymmetry. Nevertheless, the structure is closed not because of steric exclusion but because the subunits are not identical. The δ subunits of three copies of this asymmetric tetramer then associate with each other through three identical interfaces around a 3-fold rotational axis of symmetry to produce a symmetric $[(\alpha\beta)(\gamma\delta)]_3$ trimer of asymmetric tetramers. One of these trimers of tetramers then attaches to each of the 12 globular trimers directed outward from the dihedral core of ϵ subunits to produce the final molecule containing 36 ϵ subunits and 144 globin subunits.

The strategy employed to assemble erythrocrucorin provides a way of assembling more than 100 folded polypeptides into an enormous structure by a hierarchy of symmetries. It is also possible to accomplish the same goal even more dramatically with hexagonally expanded icosahedral symmetry.

- (I) Align this sequence with the sequence of amino acids 49–177 of the protein from *E. coli*. The most conserved region in these two sequences is PCGX-CRQ, which contains amino acids from the active site of cytidine deaminase. Aligning these two regions from the two proteins will give you a start in the alignment. Put in gaps and try to get the best alignment.
- (J) For your alignment, what is the percentage of identity and how many gaps are there? In calculating the percentage of identity, assume that the length of the aligned region is the average of the lengths of the two aligned sequences.
- (K) Which are more closely related, the two sequences from *E. coli* or the sequence from *E. coli* and the sequence of cytidine deaminase from *B. subtilis*?
- (L) Does cytidine deaminase from *B. subtilis* contain a segment homologous to the segment from Alanine 154 to Leucine 176 in cytidine deaminase from *E. coli*? Why is this of interest in deciding how these two proteins evolved?
- (M) What would you guess is the quaternary structure of cytidine deaminase from *B. subtilis*?

Problem 9-8: Hemocyanin from *Sepia officinalis* is a decamer with dihedral symmetry of point group $522(D_5)$.¹⁹⁰ The ten subunits form a ring that can be divided into five segments. As required by this point group, each of these segments is identical to the other four and has a 2-fold rotational axis of symmetry running through its center, and each segment is formed from two of the subunits of the protein. The portion of each subunit forming one of these segments of the cylinder is a folded polypeptide with six internally repeating domains. Consequently, the ancestral segment of the cylinder must have been formed from 12 identical sub-

units. Arrange 12 identical subunits around local molecular rotational axes of symmetry, including the global 2-fold rotational axis of symmetry of the dihedral point group, to produce a segment composing one fifth of a cylinder.

Problem 9-7

Isometric Oligomeric Proteins

Aside from tetramers with symmetry of point group $222(D_2)$, protomers arranged with circular and dihedral symmetry form structures in which they are arranged cylindrically. There are three other point groups, however, in which asymmetric protomers can be arranged to form oligomers that are **isometric structures** (Table 9-3). These three point groups are the only remaining ones in which asymmetric objects can be arranged. They are the tetrahedral point group $23(T)$, the octahedral point group $432(O)$, and the icosahedral point group $532(I)$. In these three point groups, the centers of mass of the protomers are arrayed systematically over the surface of a sphere centered on the point of intersection of the rotational axes of symmetry around which the protomers are positioned.

As with proteins the subunits of which are arranged with either cyclic symmetry or dihedral symmetry, it is only the rotational axes of symmetry and their relative

Table 9–3: Isometric Arrangements of Identical Asymmetric Objects¹⁹¹

symmetry	Hermann-Mauguin	Shönflies	rotational axes of symmetry ^a	angles between axes (degrees) ^b	number of asymmetric units
tetrahedral	23	<i>T</i>	three 2-fold four 3-fold	90 70.53	12
octahedral	432	<i>O</i>	six 2-fold four 3-fold three 4-fold	63.43 70.53 90	24
icosahedral	532	<i>I</i>	15 2-fold 10 3-fold six 5-fold	36 41.81 63.43	60

^aA rotational axis or symmetry is a line passing through the center of the oligomeric structure. Because it is a line, it extends in both directions from the center. As a result, each axis of symmetry passes out of the oligomeric structure at two opposite points, and at each of these two points there is a symmetric arrangement of asymmetric objects on the surface of the structure. ^bThese are the angles between the immediately adjacent axes of the same fold.

orientations, not the ultimate shape of a particular oligomer, that define its point group. Nevertheless, there are three **regular polyhedra**¹⁹² that have, respectively, tetrahedral, octahedral, and icosahedral symmetries and that illustrate the types of rotational axes of symmetry in each of these three point groups and their orientations in space. These are Kepler's rhombic dodecahedron (Figure 9–21A), the triangular expansion of Kepler's rhombic dodecahedron (Figure 9–21B), and the triangular expansion of Kepler's rhombic triacontahedron (Figure 9–21C).^{*} The Platonic solids that are the namesakes for each of these three point groups are the tetrahedron, the octahedron, and the icosahedron, respectively. The other two Platonic solids, the cube and the dodecahedron, have octahedral and icosahedral symmetry, respectively. None of the five Platonic solids, however, is an adequate representative of its point group because each of them is formed from rotationally symmetric faces (equilateral triangles, squares, or regular pentagons) that are centered on axes of symmetry. In Kepler's three polygons all of the rotational axes of symmetry lie between the faces, just as in an oligomeric protein all of the rotational axes of symmetry must pass between its necessarily asymmetric protomers.

In the **tetrahedral point group 23(*T*)**, 12 identical protomers are arranged about four isometrically spaced 3-fold rotational axes of symmetry (at 70.53° to each other) and three orthogonal 2-fold rotational axes of symmetry that all intersect at a common origin (Figure 9–21A). When 12 protomers of protein are assembled in the tetrahedral point group 23(*T*), they do not fit into the neat geometrical boundaries of any polyhedron.

^{*} The unexpanded rhombic triacontahedron of Kepler, although constructed from 30 faces arrayed around rotational axes of symmetry, cannot accommodate 30 asymmetric objects. Consequently, it does not represent a point group.

Figure 9–21: Regular polyhedra that have isometric symmetries:¹⁹² (A) the rhombic dodecahedron with tetrahedral symmetry of point group 23(*T*), (B) the tetracosahedron that is the triangular expansion of the rhombic dodecahedron and that represents octahedral symmetry of point group 432(*O*), and (C) the hexacontahedron that is the triangular expansion of a rhombic triacontahedron and that has icosahedral symmetry of point group 532(*I*). Kepler derived the rhombic triacontahedron from the intersection of the dodecahedron and octahedron by connecting the vertices at the 5-fold and 3-fold axes of symmetry with lines. In each of the figures, rotational axes on the circumference are labeled with the number of their fold.

Nevertheless, they are arrayed around the proper 2-fold and 3-fold rotational axes of symmetry. 3-Dehydroquinase dehydratase from *Mycobacterium tuberculosis* (Figure 9-22)¹⁹³ is a protein in which the 12 folded polypeptides, each 146 aa long, are arranged with tetrahedral symmetry. In this particular protein, the most extensive interfaces are those producing the four trimers, each of which sits on its own 3-fold rotational axis of symmetry. As with the 2-fold rotational axes of symmetry in the dihedral point groups of odd fold, the two ends of each of the 3-fold axis of symmetry in point group $23(T)$ are different. Each of the four trimers in 3-dehydroquinase dehydratase is at one end of a 3-fold rotational axes of symmetry, while the other end of each 3-fold rotational axis of symmetry is surrounded by the other three trimers. The monomers in a trimer are superposed by one end of a 3-fold rotational axis of symmetry, while the other three trimers are superposed upon each other by the other end of that same axis.

Several of the proteins with tetrahedral symmetry are such **tetramers of trimers**. In dilute solutions of guanidinium chloride, 3-dehydroquinase dehydratase dissociates into its constituent trimers.¹⁹⁴ Phaseolin from *P. vulgaris* is a trimeric protein¹³⁹ that associates to form a dodecamer¹⁹⁵ with tetrahedral symmetry¹³⁹ below pH 4.5. The self-rotation function of the asymmetric unit of crystals of catabolic ornithine carbamoyltransferase from *Pseudomonas aeruginosa* has the maxima consistent with an oligomer with tetrahedral symmetry,¹⁹⁶ and when the protein is cross-linked the major covalent species are trimer, hexamer, nonamer, and dodecamer, a result consistent with the trimer being the fundamental unit.¹⁹⁷

In contrast to these three dodecamers, the dodecamer of protocatechuate 3,4-dioxygenase from *P. aeruginosa* is a structure in which six dimers, each formed by an extensive interface centered on a 2-fold rotational axis of symmetry, are arrayed around the 3-fold axes of symmetry of its tetrahedral point group by less extensive interfaces.⁸ The interfaces forming the constituent dimers of bromoperoxidase from *Corallina officinalis* are also more extensive (105 nm² interface⁻¹) than those forming the tetrahedral dodecamer (32 nm² interface⁻¹) from six of those dimers.¹⁹⁸ Consequently, there are both tetramers of trimers and **hexamers of dimers** with tetrahedral symmetry.

In the **octahedral point group 432(O)**, the 24 identical asymmetric objects of the tetracosamer are arranged about three orthogonal 4-fold rotational axes of symmetry, four isometrically spaced 3-fold rotational axes of symmetry at 70.53° to each other, and six isometrically spaced 2-fold rotational axes of symmetry at 63.43° to each other (Figure 9-21B). Again, the 24 protomers of a protein with octahedral symmetry only have to be arranged about the rotational axes of symmetry; they do not have to assume any particular geometric shape. As long as the interfaces among the protomers

Figure 9-22: Tetrahedral symmetry of point group $23(T)$. An α -carbon diagram of 3-dehydroquinase dehydratase from *M. tuberculosis* is drawn from the crystallographic molecular model.¹⁹³ The protein crystallized in the space group F23, and an individual subunit of 146 aa is the crystallographic asymmetric unit. Consequently, all rotational axes of symmetry are exact. Each of the four trimers is drawn with line segments of different thickness or shading, and each subunit is labeled with a letter. The molecule is drawn in the orientation of the rhombic dodecahedron in Figure 9-21A. This drawing was produced with MolScript.⁴⁸⁵

position them in space around those rotational axes of symmetry, the oligomer will be a closed, octahedral, isometric structure. In point group $432(O)$, unlike in point group $23(T)$, identical sets of interfaces are found at the two ends of each of the rotational axes of symmetry.

Heat shock protein 16.5 from *Methanococcus jannaschii* (Figure 9-23)¹⁹⁹ is a tetracosameric protein in which subunits of 147 aa are arranged with octahedral symmetry to form a hollow spherical shell that has sizeable holes at the 3-fold rotational axes of symmetry and at the 4-fold rotational axes of symmetry. The most

Figure 9-23: Octahedral symmetry of point group 432(*O*). An α -carbon diagram of the heat shock protein 16.5 from *M. jannaschii* is drawn from the crystallographic molecular model.¹⁹⁹ The protein crystallized in the space group *H*3 with one of the molecular 3-fold rotational axes of symmetry coinciding with a crystallographic 3-fold rotational axis of symmetry and eight subunits in the crystallographic asymmetric unit. The two subunits in each dimer are given different shading. Each dimer is centered on one of the 2-fold rotational axes of symmetry. The molecule is drawn in the orientation of the regular tetracosahedron in Figure 9-21B.

extensive interfaces are those between monomers paired as dimers around the 2-fold rotational axes of symmetry. The second most extensive set of interfaces are the groups of four dimers arrayed around each of the 4-fold rotational axes of symmetry, so the structure is a trimer of tetramers of dimers. The four symmetrically arrayed interfaces among the four monomers around a 4-fold rotational axis of symmetry, one from each dimer, incline those four dimers relative to each other to form a jagged cup with the proper curvature so that three of these cups

fit together to form the final spherical structure. Coincidentally, the protein crystallizes in the space group *H*3 with one of these octameric cups as the asymmetric unit.

In the **icosahedral point group 532(*I*)**, 60 identical asymmetric objects are arranged about 31 rotational axes of symmetry (Figure 9-21C; Table 9-3) to produce the oligomer. Each of the 31 rotational axes of symmetry intersects all of the others at the center of the structure. In every icosahedral arrangement, the relative angular dispositions of these axes is always the same. Although there are 31 rotational axes of symmetry in this point group, it can be generated from one protomer by four successive rotations around specified axes in a given sequence. 6,7-Dimethyl-8-ribityllumazine synthase from *B. subtilis*²⁰⁰ and the protein coat of satellite panicum mosaic virus (Figure 9-24)²⁰¹ are oligomeric proteins in each of which 60 identical subunits are arranged with icosahedral symmetry of point group 532(*I*) to form a spherical shell.

The **protein coat of a virus** such as satellite panicum mosaic virus is a thick, continuous, spherical layer of protein that serves the purpose of enclosing and protecting the viral nucleic acid. This nucleic acid encodes the genetic information necessary for the virus to control the host parasitically and divert the purpose of the host from its own growth and replication to the growth and replication of the virus. These requirements can be satisfied only by a fairly large molecule of nucleic acid, and it all must fit within the protein coat so that it can be protected from the environment. A viral protein coat is made from 60 identical, or almost identical,^{202,203} protomers. In a spherical virus, these protomers are arranged about the icosahedral rotational axes of symmetry to produce spherical shells that can enclose the nucleic acid. In the case of satellite panicum virus, the protomer is a single folded polypeptide.

Again, it is not any regular polygon that defines a protein built from 60 protomers arranged with icosahedral symmetry but the rotational axes of symmetry. Regardless of how intertwined or encroaching the protomers in such a protein become, the number and relative angular dispositions of the rotational axes of symmetry that dictate the positions of those protomers are permanent features of the structure. If 60 identical folded polypeptides are arranged around these rotational axes of symmetry and their shapes are so constructed as to mesh symmetrically at each of the boundaries among themselves, they will necessarily form a tightly sealed icosahedral shell.

The **interfaces among the protomers** are the fundamental determinants of the multimeric structure. In 6,7-dimethyl-8-ribityllumazine synthase, the pentamer appears to have been the unit assembled by evolution into the oligomer of 60 subunits.²⁰⁴ At each of the five equivalent outer edges of this pentamer an interface evolved, connecting the pentamer to another identical

pentamer in the usual way that two identical proteins are associated, which is around a 2-fold rotational axis of symmetry. This particular 2-fold rotational axis of symmetry, however, happened to incline the two pentamers with respect to each other so that their respective 5-fold rotational axes of symmetry both intersected the 2-fold axis of symmetry and formed the angle required to exist between the 5-fold rotational axes of symmetry in an icosahedron, which is 63° . If two interfaces, the one defining the pentamer and the other at the 2-fold rotational axis defining an angle of 63° , are built into faces on a protomer, 60 such protomers will automatically assemble into an icosahedral shell.

In the protein coat of satellite panicum mosaic virus, the interfaces holding the trimers together around the 3-fold axes of symmetry ($15.7 \text{ nm}^2 \text{ interface}^{-1}$) are more extensive than those holding together the dimers around the 2-fold axes ($12.8 \text{ nm}^2 \text{ interface}^{-1}$) or the pentamers around the 5-fold axes ($10.5 \text{ nm}^2 \text{ interface}^{-1}$).²⁰¹ If the trimer was the fundamental unit from which the protein coat arose, the evolution of two complementary faces on the trimer that formed a dimer of trimers inclining the two 3-fold rotational axes of symmetry at 42° would also automatically create the entire icosahedrally symmetric oligomer of 60 subunits.

Vertebrate ferritin is a tetracosamer the identical subunits of which are arranged with octahedral symmetry (Figure 9-25A),^{205,206} but ferritin from *Listeria innocua* is a dodecamer the identical subunits of which are arranged with tetrahedral symmetry.²⁰⁷ These are examples of **two different quaternary structures for the same species of protein**. The subunits of vertebrate ferritin and the ferritin from *L. innocua* are both antiparallel coiled coils of four α helices (Figure 9-25B) that are superposable on each other and consequently homologous to each other. In both proteins, these coiled coils of α helices associate side by side in opposite directions to form dimers around 2-fold rotational axes of symmetry, and the interfaces forming the dimers from the two proteins are homologous to each other. The dimers, in turn, in each protein combine in triplets around 3-fold rotational axes of symmetry in which the three identical interfaces around each axis are formed by the two respective ends of the monomers in one dimer butting up against the side of one of the monomers in a neighboring dimer (Figure 9-25C). These interfaces around the 3-fold axes in the two proteins are homologous to each other. Vertebrate ferritin is formed from four of these trimers of dimers; the ferritin from *L. innocua*, from two. As with any oligomer with tetrahedral symmetry (Figure 9-22), there are two different types of interfaces at the two ends of each 3-fold axis in the tetrahedral dodecamer from *L. innocua*. One of these types is the set homologous to the set of interfaces around the 3-fold axes in vertebrate ferritin (Figure 9-25C).

If one of the dimers around a 4-fold rotational axis of symmetry in vertebrate ferritin were removed (for

example, the one containing monomer V) and the creases between the remaining three dimers were made more acute, the space previously occupied by the missing dimer would close up and a new interface could form (one between dimer I/II and the side of monomer IV) now identical to the other two around the once 4-fold but now 3-fold axis of symmetry. If this transformation were performed at each end of each 4-fold axis in vertebrate ferritin, six dimers would be removed, the structure would be converted from a tetracosamer with octahedral

Figure 9-24: Icosahedral symmetry of point group 532(I). An α -carbon diagram of one hemisphere of the protein coat of satellite panicum mosaic virus is drawn from the crystallographic molecular model of the protein.²⁰¹ The protein crystallized in the space group $P4_332$ with a pentamer of subunits, each of 157 aa, in the crystallographic asymmetric unit, the smallest asymmetric unit available to icosahedral symmetry. Individual subunits have been drawn with line segments with one of three different thicknesses or shadings. Only 34 of the 60 subunits are drawn to make the structure easier to visualize. These 34 subunits form the front of the sphere that is the protein coat. The portion of the molecule drawn is in the orientation of the hexacontahedron of Figure 9-21C. This drawing was produced with MolScript.⁴⁸⁵

Reprinted with permission from ref 206. Copyright 1997 Elsevier B.V. (B) Ribbon diagram of just the central of the 12 subunits portrayed in panel A. Reprinted with permission from ref 206. Copyright 1997 Elsevier B.V. (C) Representation of the arrangement of the dimers of the subunits of ferritin on the faces of a rhombic dodecahedron (Figure 9-21A). Arrows are drawn to indicate the antiparallel orientations of the two subunits around the 2-fold rotational axes of symmetry in the center of each face. The 2-fold, 3-fold, and 4-fold rotational axes of symmetry are located as they are in Figure 9-21B.

symmetry into a dodecamer with tetrahedral symmetry, and this new dodecamer would be structurally homologous to the ferritin from *L. innocua*. The two different ends of each of the new 3-fold rotational axes of symmetry in the new tetrahedral dodecamer would be the end not affected by the transformation and the end that had been at a 4-fold rotational axis of symmetry before the transformation. Consequently, in these two different quaternary structures of ferritin, the octahedral and the tetrahedral, the homologous complementary faces on two different, but homologous, dimers must accommodate in the one case a 4-fold rotational axis of symmetry and in the other case a 3-fold rotational axis of symmetry.

Among the small heat shock proteins, there are also two different quaternary structures for the same species of protein in different species of organisms. The small

heat shock protein from *M. jannaschii* (Figure 9-23) is a tetracosamer with octahedral symmetry of point group $432(O)$, while the same protein from *Triticum aestivum* is a dodecamer with dihedral symmetry of point group $322(D_3)$.²⁰⁸ In both structures, a dimer is the fundamental unit, and the respective dimers have homologous tertiary and quaternary structures. In the protein from *M. jannaschii*, the molecular 2-fold rotational axis of symmetry of each dimer is coincident with one of the 2-fold rotational axes of the symmetry of point group $432(O)$, while in the protein from *T. aestivum*, the entire dimer is the asymmetric unit for the symmetry of point group $322(D_3)$ and its 2-fold rotational axis is local and pseudosymmetric. Nevertheless, the way in which the three dimers are arranged around the single, central 3-fold rotational axis of symmetry in the latter is the same as that in which three dimers are arranged about one of the four 3-fold rotational axes of symmetry in the former (Figure 9-23), and the fundamental unit in the two different structures is this homologous hexamer. Two of these hexamers lie back to back in the dodecamer, and four of these hexamers are each centered on the respective 3-fold rotational axes of symmetry in the tetracosamer.²⁰⁸ Presumably, because this hexamer is the fundamental unit, the dodecamer is one of symmetry of point group $322(D_3)$ rather than that of point group $622(D_6)$ as are most other dodecamers.

Dihydrolipoyllysine residue acetyltransferase, dihydrolipoyllysine residue succinyltransferase, and dihydrolipoyllysine residue (2-methylpropanoyl)transferase are closely related proteins, the sequences of which can be readily aligned with each other with greater than 30% identity.²⁰⁹ All of the dihydrolipoyllysine residue succinyltransferases and dihydrolipoyllysine residue (2-methylpropanoyl)transferases and dihydrolipoyllysine residue acetyltransferases from Gram-negative bacteria are tetracosamers of 24 identical subunits with octahedral symmetry,²¹⁰⁻²¹² while the dihydrolipoyllysine-residue acetyltransferases from Gram-positive bacteria and eukaryotes are hexacontamers of 60 identical subunits with icosahedral symmetry.^{210,213}

In both the octahedral oligomers²¹² and the icosahedral oligomers,²¹⁰ the homologous interfaces forming the trimers centered on the respective 3-fold rotational axes of symmetry (Figure 9-21A,B) are the most extensive in the structures. In the octahedral oligomers, the eight trimers at the eight 3-fold vertices are connected by 12 interfaces centered on the 2-fold rotational axes of symmetry, so that the structure is a cube with wide openings in each face at the 4-fold rotational axes of symmetry.³¹ In the icosahedral oligomers, the trimers are again joined at the 2-fold rotational axes of symmetry but by 30 interfaces, and the structure is a dodecahedron with wide openings in each face at the 5-fold rotational axes of symmetry. In the octahedral oligomers, four trimers associate with each other around 4-fold rotational axes of symmetry, while in the icosahedral oligomers, five

trimers associate with each other around 5-fold rotational axes of symmetry. The respective interfaces at the 2-fold rotational axes of symmetry between these homologous trimers that are arranged around these two different rotational axes of symmetry adapt flexibly to the dispositions of the trimers that are required by those axes.²¹⁰ In these two different quaternary structures of these homologous acetyltransferases, the octahedral and the icosahedral, the homologous complementary faces on two different, but homologous, trimers must accommodate in the one case a 4-fold rotational axis of symmetry and in the other case a 5-fold rotational axis of symmetry.

Ferritin, small heat shock protein, and dihydrolipoyllysine-residue acetyltransferase, because they each are examples of the same protein having different quaternary structures, reinforce the conclusion that quaternary structure contains no information relevant to the evolution of proteins. The examples of ferritin and dihydrolipoyllysine-residue acetyltransferase also illustrate the ability of two different subunits, formed respectively from closely related polypeptides, to assume **similar arrangements around rotational axes of symmetry of different fold**. It is this ability of interfaces to adjust flexibly to different rotational axes of symmetry that has been exploited by evolution to increase the size of viral protein coats.

Although there are a few other viruses like satellite panicum mosaic virus that have protein coats assembled from only 60 subunits arranged with 532(*I*) symmetry,^{203,214,215} the problem with such protein coats is that they are too small. In order to enclose enough DNA to accomplish a successful subversion of the host, the protein coats usually must be larger. In two instances, this problem has been solved by using an elongated homodimer as a protomer and having these homodimers arrayed as spokes around the 5-fold rotational axes of symmetry. One monomer of the dimer forms the near end of the spoke adjacent to the 5-fold axis; and the other monomer, the far end of the spoke. A local 2-fold rotational axis of pseudosymmetry relating the two elongated monomers is located in the center of the spoke. The interdigitation of these long spokes forms the protein coat. Although each is formed from copies of the same polypeptide, a monomer at the 5-fold hub is required to assume a significantly different shape from a monomer at the periphery of the spoke in order for the interdigitation to succeed and the global 3-fold and 2-fold rotational axes of icosahedral symmetry to be satisfied.^{216,217} Most viral protein coats, however, are built with a different strategy that takes advantage of quasi-equivalence and pseudosymmetry to provide a general solution to the problem of expanding the size of an icosahedral shell.^{218,219}

Quasi-equivalence²¹⁸ is the manifestation of the ability of either two or more copies of the same subunit or two or more homologous subunits to adapt flexibly in

different situations to the requirements of two rotational axes of symmetry of different fold. The respective homologous subunits in the two different quaternary structures of ferritin or in the two different quaternary structures of dihydrolipoyllysine-residue acetyltransferase are quasi-equivalent to each other, but because in each case they have different amino acid sequences, it is the differences in amino acid sequence that might explain their abilities to assume the different dispositions. Furthermore, the two rotational axes of symmetry of different fold to which they adapt are in different oligomers. In many viral protein coats, however, the several quasi-equivalent subunits are formed from folded polypeptides of the same sequence, and the quasi-equivalent subunits are found together in the same icosahedral shell.

To understand the relationships of such quasi-equivalent subunits to each other in such an oligomer, the local rotational axes within a protomer must be distinguished from the global rotational axes of icosahedral symmetry governing the entire structure. A **global rotational axis of symmetry** is an axis of symmetry around which a rotation of $360^\circ/n$ causes the entire oligomer to superpose upon itself. A global rotational axis is thus distinguished from a local rotational axis that operates only on structural units in its immediate vicinity.

The triangle from which the expanded rhombic triacontahedron (Figure 9-21C) is constructed, although formally an asymmetric object because two of its vertices lie at global 3-fold rotational axes of symmetry and one vertex lies at a global 5-fold rotational axes of symmetry and only one of its three edges lies on a global 2-fold rotational axis of symmetry, is nevertheless an equilateral triangle and locally symmetric. Were the equivalent mass of three identical folded polypeptides, related to each other by this **local 3-fold rotational axis of pseudosymmetry**, to fill this triangle, it would have three times more area than if the equivalent mass of only one folded polypeptide filled it, and the shell could then contain 3.5 times more nucleic acid. This solution requires (Figure 9-21C) that this folded polypeptide be capable of quasi-equivalence because those subunits forming the interfaces around one vertex of the triangle would have to be arrayed around a global 5-fold rotational axis of symmetry (72° for each step; complementary faces at 108°), while those subunits forming the interfaces around the other two vertices would have to be arrayed around local 6-fold rotational axes of pseudosymmetry (60° for each step; complementary faces at 120°) that each coincide with a global 3-fold rotational axis of symmetry. The requirements of this quasi-equivalence would force each of the three subunits arrayed around the rotational axis in the center of each triangle to assume a significantly different conformation, so the local 3-fold rotational axis around which they are arrayed is one of pseudosymmetry.

Quasi-equivalent subunits arrayed around rotational axes of pseudosymmetry cannot each be individ-

ual protomers, but the set of all of the quasi-equivalent subunits arrayed around a rotational axis of pseudosymmetry or several rotational axes of pseudosymmetry can be a protomer of the overall quaternary structure. Consequently, it is the three quasi-equivalent subunits arrayed around the local 3-fold rotational axis of pseudosymmetry that would form the protomer of the icosahedral array. The global rotational axes of this icosahedral array would remain true global rotational axes of symmetry for the entire structure because the asymmetry would be confined entirely within each of the protomers of the point group.

Tomato bushy stunt virus has a protein coat with just such an arrangement of subunits (Figure 9–26).²²⁰ Each of its 60 identical **pseudosymmetric, trimeric protomers** is formed from three folded polypeptides, subunits A, B, and C, each of the same sequence 386 aa in length and the tertiary structures of which, when they are in the viral protein coat, are homologous and superposable. The differences in their respective conformations permit each of them to play its required quasi-equivalent

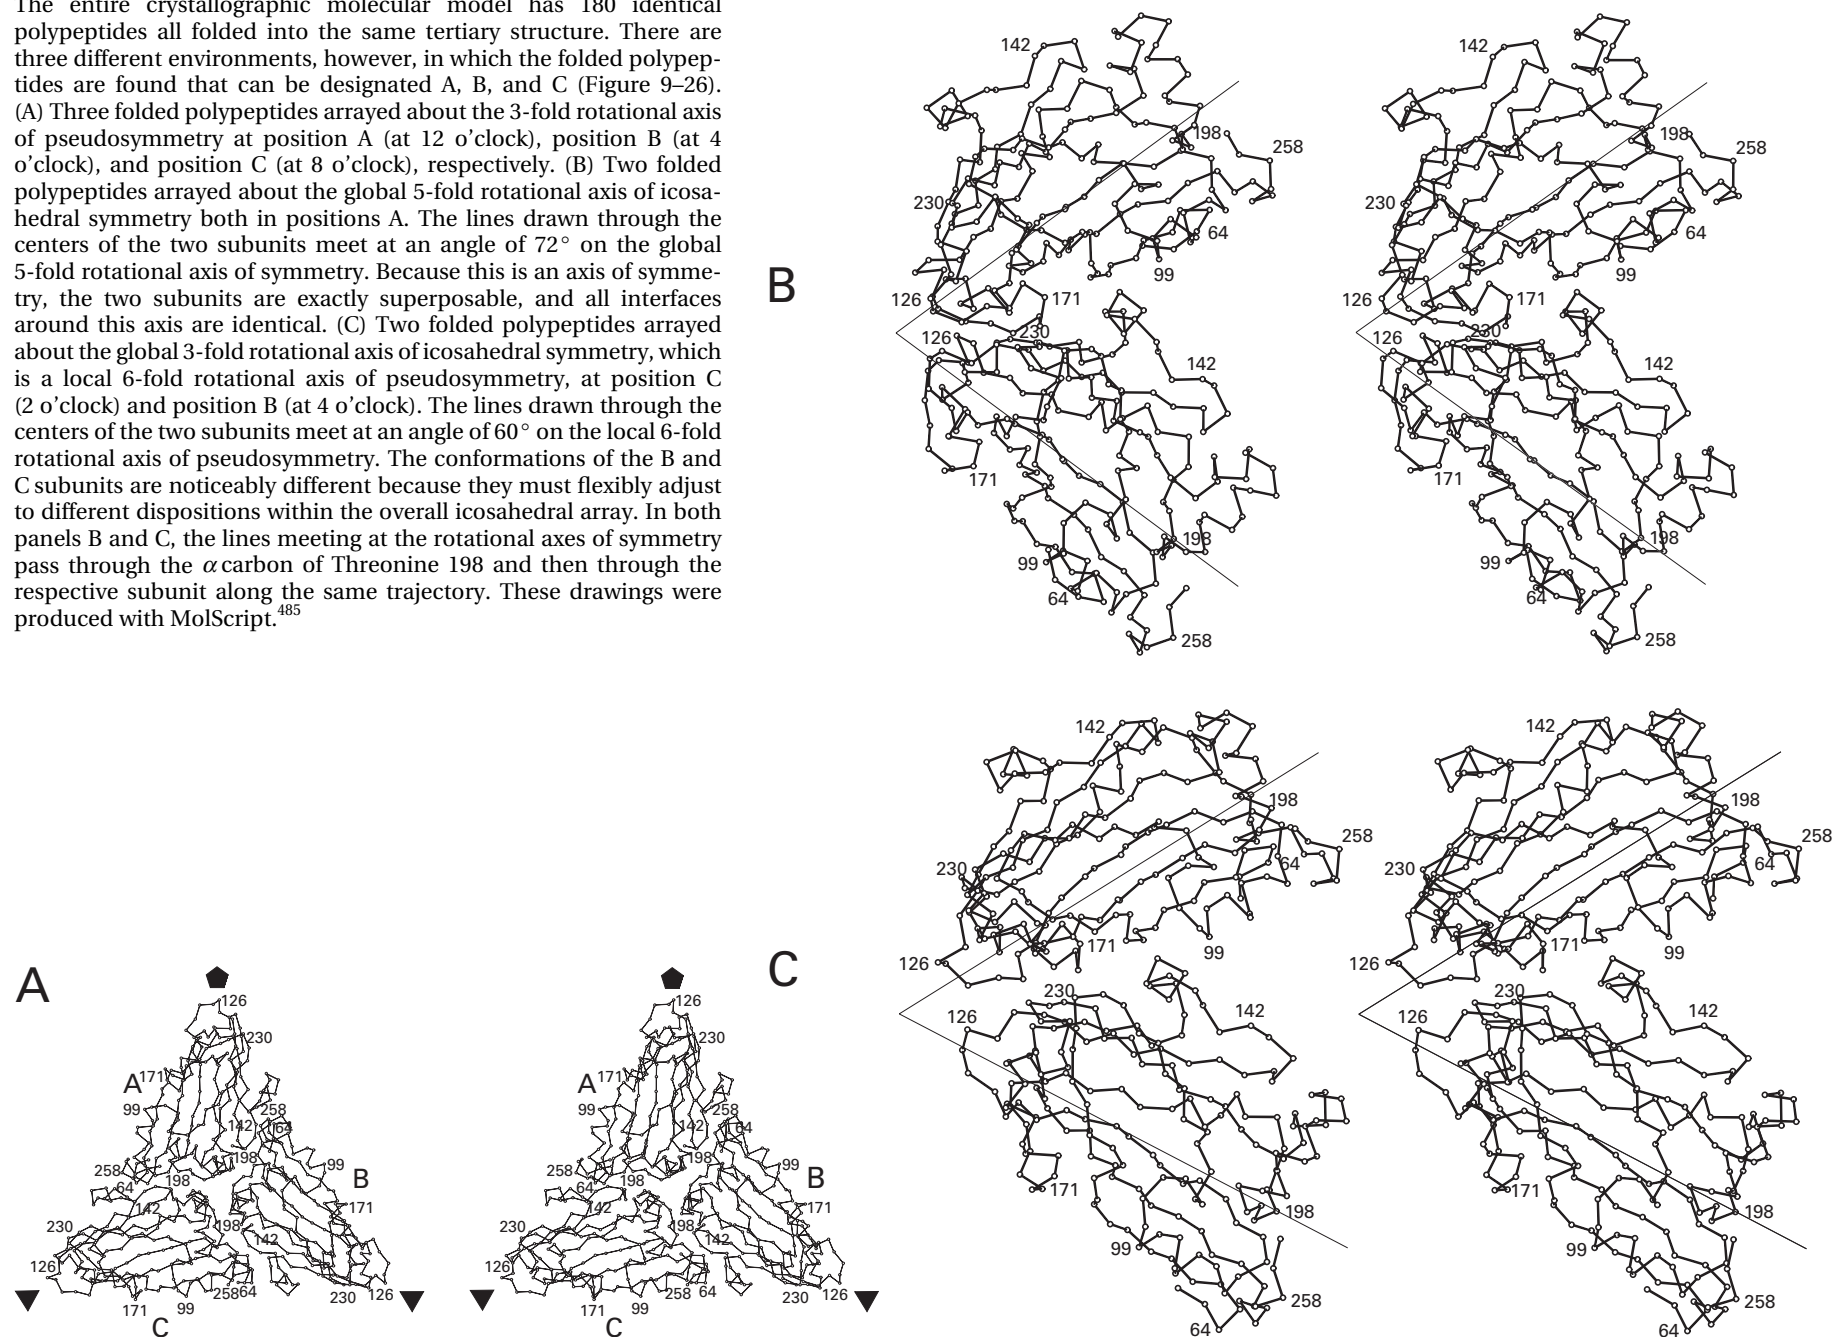

Figure 9–26: Arrangement of the 180 subunits in the protein coat of tomato bushy stunt virus.²²⁰ Each tile is a single folded polypeptide, and all of the polypeptides are identical to each other in amino acid sequence. Three folded polypeptides, designated A, B, and C, are arrayed around a local 3-fold axis of pseudosymmetry to produce the trimeric protomer of the icosahedral array. The vertex occupied by the A subunit lies at a global icosahedral 5-fold rotational axis of symmetry, and the axes occupied by the B and C subunits lie at global icosahedral 3-fold rotational axes of symmetry that are also local 6-fold rotational axes of pseudosymmetry. Global 2-fold rotational axes of symmetry relate C subunits, and local 2-fold rotational axes of pseudosymmetry relate A and B subunits. Each subunit has a protrusion that runs up its associated 2-fold rotational axis. The diagram was adapted from the crystallographic molecular model of this viral protein coat. Reprinted with permission from ref 220. Copyright 1983 Academic Press.

role. For example, only subunits C are adjacent to the global 2-fold rotational axes of symmetry. Subunits B and C must alternate around the global 3-fold rotational axes of symmetry to produce local 6-fold rotational axes of pseudosymmetry, while subunits A are distributed around the global 5-fold rotational axis of symmetry. These quasi-equivalent situations produce alterations in the structures of these folded polypeptides that are most obvious at the interfaces among the homotrimers; it is here that the strain of requiring the same protein to adapt to the different rotational axes of symmetry is the strongest.

The **packing at the quasi-equivalent interfaces** has been described in detail for the protein coat of southern bean mosaic virus,²²¹ which is closely related to tomato bushy stunt virus. The three identical but quasi-equivalently folded polypeptides, each 260 aa in length, are arranged around a local 3-fold rotational axis of pseudosymmetry (Figure 9–27A)²²¹ to create the homotrimeric protomer in which the three subunits adapt to their respective quasi-equivalent environments. The A subunits are arranged around the global icosahedral 5-fold rotational axes of symmetry (Figures 9–21C, 9–26, and 9–27B). Each of the B and C subunits uses the same vertex to form the local 6-fold rotational axis of pseudosymmetry (Figures 9–26 and 9–27C) as that used by the A subunit to conform to the global 5-fold rotational axis of symmetry. Careful inspection of Figure 9–27B,C shows that the two unique defining interfaces are similar but significantly adjusted to accommodate the differences in the angular requirements around these two axes. These adjustments, in turn, create conformational changes throughout each of the individual subunits, causing their overall structures to differ. These differences are most obvious in the angular orientations of both the pleats within the β sheets and the β sheets themselves when the three different conformations are compared.

The protein coats of tomato bushy stunt virus, southern bean mosaic virus, turnip yellow mosaic virus,²²² black beetle nodavirus,²²³ and primate calicivirus,²²⁴ among others, are all constructed from 180 identical subunits distributed among 60 identical homotrimers. Because, however, the three subunits in a trimer (A, B, and C in Figure 9–26) are not in identical environments, they need not be identical in amino acid sequence. In some icosahedral protein coats with trimeric protomers, **gene triplication** of the nucleic acid encoding the amino acid sequence of the protein forming the coat has occurred to produce three genes. The protein coats of the comoviruses, of which those of cowpea mosaic virus and beanpod mottle virus are examples, are an interesting intermediate case in this process.²²⁵ In the protein coat of these viruses, two of the subunits in the heterotrimeric protomer are internally repeating domains on the same polypeptide. This suggests that the general sequence of events has been a gene duplication

Figure 9-27: α -Carbon diagrams of the folded polypeptides composing the protein coat of southern bean mosaic virus drawn from the crystallographic molecular model of the entire viral protein coat.²²¹ The entire crystallographic molecular model has 180 identical polypeptides all folded into the same tertiary structure. There are three different environments, however, in which the folded polypeptides are found that can be designated A, B, and C (Figure 9-26). (A) Three folded polypeptides arrayed about the 3-fold rotational axis of pseudosymmetry at position A (at 12 o'clock), position B (at 4 o'clock), and position C (at 8 o'clock), respectively. (B) Two folded polypeptides arrayed about the global 5-fold rotational axis of icosahedral symmetry both in positions A. The lines drawn through the centers of the two subunits meet at an angle of 72° on the global 5-fold rotational axis of symmetry. Because this is an axis of symmetry, the two subunits are exactly superposable, and all interfaces around this axis are identical. (C) Two folded polypeptides arrayed about the global 3-fold rotational axis of icosahedral symmetry, which is a local 6-fold rotational axis of pseudosymmetry, at position C (2 o'clock) and position B (at 4 o'clock). The lines drawn through the centers of the two subunits meet at an angle of 60° on the local 6-fold rotational axis of pseudosymmetry. The conformations of the B and C subunits are noticeably different because they must flexibly adjust to different dispositions within the overall icosahedral array. In both panels B and C, the lines meeting at the rotational axes of symmetry pass through the α carbon of Threonine 198 and then through the respective subunit along the same trajectory. These drawings were produced with MolScript.⁴⁸⁵

that gave rise to two genes producing two separate polypeptides followed by a gene duplication of one of these genes producing a single polypeptide with two internally repeating domains followed by a division of the latter duplicated gene so that it then produced two smaller polypeptides, each containing the complete fold of its ancestral polypeptide. Following the triplication, each of the three genes evolved independently to produce three polypeptides, each of different sequence and each presumably incorporating changes rendering it more successful at occupying its respective quasi-equivalent position in the viral protein coat.

There are crystallographic molecular models for icosahedral protein coats of four viruses that have accomplished the complete evolutionary transition: rhinovirus,²²⁶ poliovirus,²²⁷ Mengo virus,²²⁸ and foot-and-mouth disease virus.²²⁹ The protein coats of these viruses are spherical shells (Figure 9–28A,B),²²⁷ the surfaces of which are paved with **heterotrimeric protomers** in icosahedral array (Figure 9–28C).²²⁸ That the three different folded polypeptides forming these four viral protein coats have arisen from a gene triplication follows from the fact that, in each case, the three different polypeptides folded in their native conformations are superpos-

able.^{226–229} If this is a definitive correspondence, it demonstrates that the ancestors of each of these protein coats were constructed from 180 folded polypeptides of identical sequence.

It has been shown that the single folded polypeptides composing the protomers of the protein coats of satellite panicum mosaic virus and satellite tobacco necrosis virus, another small virus the protein coat of which has only 60 subunits,^{215,230} are superposable on any one of the folded polypeptides forming the trimeric protomer of the protein coat of either tomato bushy stunt virus or southern bean mosaic virus.^{201,231} It has also been pointed out that, even though the former have 60 subunits and the latter have 180 subunits, the packing of the subunits of the protein coat of satellite panicum mosaic virus and satellite tobacco necrosis virus is similar to the packing of the subunits of the protein coats of both southern bean mosaic virus and tomato bushy stunt virus. When the global 3-fold rotational axis of symmetry in the protein coat of satellite tobacco necrosis virus is aligned with the local 3-fold rotational axis of pseudosymmetry within one of the trimeric protomers of the protein coat from one of the other viruses (Figure 9–29),²³⁰ the three global 5-fold rotational axes of symmetry in the protein coat of satellite tobacco necrosis virus coincide with one of the global 5-fold rotational axes of symmetry and two of the local 6-fold rotational axes of pseudosymmetry in the protein coat of the other virus.

It has also been observed²³² that when the first 61 amino acids of the protein coat of southern bean mosaic virus are removed, the remainder of the folded polypeptide can assemble to produce a hollow icosahedral shell

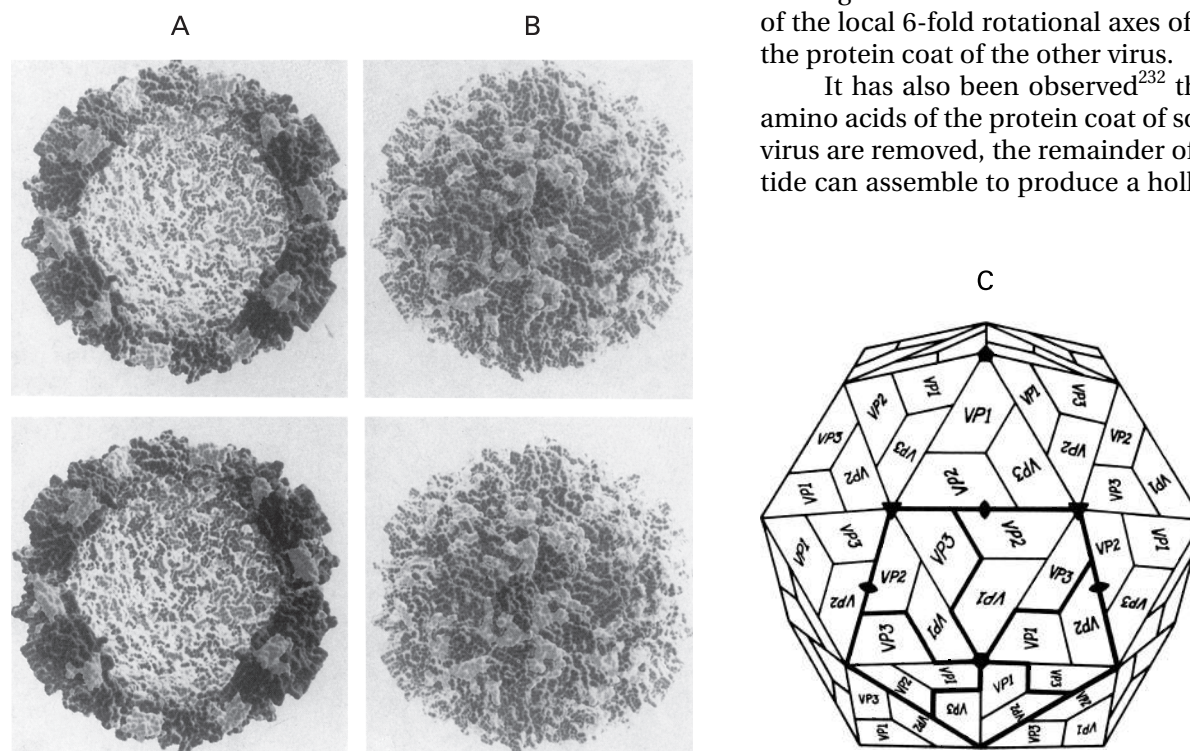

Figure 9–28: Space-filling representations of the folded polypeptides assembled into the icosahedral protein coat of poliovirus as drawn from the crystallographic molecular model of this oligomeric protein.²²⁷ (A) View into the central cavity of the viral protein coat into which the viral RNA is packed. (B) View of the surface of the viral protein coat in which the atoms contributed by each of the three different types of folded polypeptides, VP1, VP2, and VP3, have been given different shades of gray. Panels A and B reprinted with permission from ref 227. Copyright 1985 American Association for the Advancement of Science. (C) Diagrammatic representation of the surface of an icosahedral viral protein coat²²⁸ in the same orientation as panel B to illustrate the distribution of the various folded polypeptides around the rotational axes of icosahedral symmetry and local pseudosymmetry. Panel C reprinted with permission from ref 228. Copyright 1987 American Association for the Advancement of Science.

Figure 9-29: Comparison of the packing of the respective folded polypeptides in the protein coat of satellite tobacco necrosis virus (unbroken lines) and the protein coat of tomato bushy stunt virus or southern bean mosaic virus (broken lines).²³⁰ The former viral protein coat has 60 folded polypeptides in exact icosahedral symmetry; the latter have 180 folded polypeptides in $T=3$ icosahedral symmetry. The exact global 3-fold rotational axis of icosahedral symmetry for satellite tobacco necrosis virus is aligned with the local 3-fold rotational axis of pseudosymmetry (both designated as 3*) in the center of each of the protomers of the other two. This alignment causes the global 5-fold rotational axes of icosahedral symmetry at the bottom of the diagram (designated as 5) to coincide and concurrently causes the two other global 5-fold rotational axes of symmetry at the other two vertices of the three protomers from satellite tobacco necrosis virus to coincide with the two local 6-fold rotational axes of pseudosymmetry (all of these axes designated as 5*) at the other two vertices of the protomer from tomato bushy stunt virus or southern bean mosaic virus. Reprinted with permission from ref 230. Copyright 1982 Academic Press.

containing only 60 subunits instead of the usual 180. In this new oligomeric protein, the original arrangements around the global 5-fold rotational axes of symmetry have been retained and the local 3-fold rotational axes of pseudosymmetry in the centers of the protomers of the original structure have become the global 3-fold rotational axes of symmetry in the new structure (as depicted in Figure 9-29). This latter result demonstrates that these two icosahedral structures, the pseudosymmetric with 180 quasi-equivalent polypeptides and the symmetric with 60 polypeptides, are readily interconverted.

All of these results taken together indicate that the protein coats of these four viruses, tomato bushy stunt, southern bean mosaic, satellite panicum mosaic, and satellite tobacco necrosis, share a common ancestor.²³¹ The fact that satellite tobacco necrosis virus and satellite panicum mosaic virus are parasites on other viruses and the fact that viral protein coats of their size cannot carry enough nucleic acid suggests that their ancestors originally had a larger protein coat built from 60 homotrimeric protomers.

The symmetric and pseudosymmetric icosahedral protein coats of satellite tobacco necrosis, satellite panicum mosaic, tomato bushy stunt, southern bean mosaic, cowpea mosaic, beanpod mottle, Mengo, and foot-and-mouth disease viruses, black beetle nodavirus, poliovirus, and rhinovirus are all those of viruses carrying single-stranded ribonucleic acids that have positive copies of the viral messenger ribonucleic acids. These viruses infect eukaryotic cells, both animals and plants. From the descriptions that have just been given of the crystallographic molecular models of the protein coats of these viruses, it follows that the ancestors of all of these eukaryotic positive-strand RNA viruses had icosahedral protein coats constructed from 60 homotrimeric protomers, each of which was constructed from three folded polypeptides of identical sequence arranged about a local 3-fold rotational axis of pseudosymmetry. The most remarkable discovery, however, is that all of the folded polypeptides comprising the protein coats of all of these eukaryotic positive-strand RNA viruses, whether their hosts are plants or animals, are superposable.^{201,223,225-229,231} Furthermore, the single polypeptides forming the protein coats of 60 identical subunits enclosing the single-stranded DNA of the bacteriophage ϕ X174²¹⁴ and the single-stranded DNA of canine parvovirus²⁰² also have folds superposable on those of these viral protein coats that enclose single-stranded RNA. These similarities among all of these various proteins suggest that, unless convergent evolution has occurred, all of the viral protein coats they respectively compose share one **common ancestor**.*

This remarkable possibility, if it is true, would not be hard to explain. Three unique faces, each creating an independent set of repeating interfaces among the 180 identical folded polypeptides, would have had to evolve on the surface of the same monomer. The three unique interfaces produced by these three unique faces are the interface responsible for the local 3-fold rotational axis of pseudosymmetry within the protomer (Figure 9-27A), the interface responsible for the global 5-fold rotational axis of symmetry at one vertex of each subunit, and the interface responsible for the global 2-fold rotational axis of symmetry that orients the two pentagons it connects. Proteins containing molecular 5-fold rotational axes of symmetry are rare products of evolution (Table 9-1) and the 2-fold rotational axis of symmetry, though common, would be required to be located at a particular disposition relative to the 5-fold axis of symmetry. These constraints are probably not so rigid as they seem. If the

* Each of these polypeptides is folded into a 10-stranded jelly roll, antiparallel β barrel (Figure 7-19E). The same fold occurs in the subunits of the protein coat of double-stranded DNA viruses such as adenoviruses and iridoviruses. In these latter instances, however, there are substantial differences in the quaternary structures of the viral protein coats.

angles are close enough, the significant stability of such an edifice, each of whose associations strengthens all of the others, could force the interfaces to rearrange sufficiently to accommodate the icosahedral arrangement. This **cooperativity in the construction of the shell**, which should resemble the cooperativity among the supports of a building, also permits the interfaces to be weaker than interfaces that must stand alone. Nevertheless, that such a monomer, with such faces, has arisen rarely during evolution would not be a surprising fact.

There is, however, a positive-strand RNA virus, MS2, that infects bacterial hosts. It also has an icosahedral protein coat composed of 60 pseudosymmetric homotrimers, but the folded polypeptides do not appear to be related to the folded polypeptides of the coat proteins of other positive-strand RNA viruses.¹⁷³

All icosahedral viral protein coats have 60 identical protomers arrayed around the global 5-fold, 3-fold, and 2-fold rotational axes of icosahedral symmetry of point group 532(*I*). It is the identity and the number of subunits within each protomer that differ among them. The smallest protein coats have only one subunit in each protomer, those with three subunits in each protomer are somewhat larger, and those with more than three are larger still. The **number of subunits within a protomer** is designated with a capital *T*. For example, the expanded viral protein coats that have been discussed so far, in which there are three subunits in each protomer (Figures 9–26 and 9–28), have $T=3$ icosahedral symmetry. The numbers of subunits found in the protomers of the larger protein coats are those numbers that permit the subunits to assume quasi-equivalent positions around local rotational axes of pseudosymmetry and that at the same time are compatible with the global rotational axes of icosahedral symmetry. For example, in viral protein coats with $T=3$ icosahedral symmetry, the fact that a global 5-fold rotational axis of symmetry and two global 3-fold rotational axes of symmetry are arranged equilaterally (Figure 9–21C) produces the local 3-fold rotational axis of pseudosymmetry around which three subunits can be arranged within a protomer while still being compatible with those global axes of symmetry.

The viral protein coats with expanded $T=3$ icosahedral symmetry are the simplest cases of a common strategy^{218,219} used to expand the number of subunits in a protomer. Consider a **hexagonal array of cyclic hexamers** with their respective 6-fold rotational axes of symmetry normal to the plane of the array (Figure 9–30). Such a hexagonal array of hexamers automatically creates an array of global 6-, 3-, and 2-fold rotational axes of symmetry, also all normal to the plane, that operate on the entire array. In certain combinations, these global axes of symmetry have the same spacing and almost the same fold relative to each other that the global axes of icosahedral symmetry have around one of its protomers. For example, in each of the four nested quadrilaterals in

Figure 9–30A, the global 6-, 2-, 3-, and 2-fold rotational axes of hexagonal symmetry at its four vertices have the same relative spacing as the global 5-, 2-, 3-, and 2-fold rotational axes of symmetry around a quadrilateral protomer in an icosahedral array (Figure 9–30, right panel). Consequently, the array of subunits within any one of these boundaries is able to be one of the 60 protomers in an icosahedral array if the subunit at the global 6-fold rotational axis at the top vertex is able to adapt quasi-equivalently to the global 5-fold rotational axis of icosahedral symmetry. Similar compatibilities between the global axes of symmetry at the vertices and on the edges of the nested equilateral triangles of Figure 9–30B and the quadrilaterals of Figure 9–30C–E also allow the arrays of subunits within their boundaries to be one of the protomers in an icosahedral array. The nested sets in Figure 9–30A produce protomers with 4, 9, 16, and 25 subunits ($T=4$, $T=9$, $T=16$, and $T=25$); those in Figure 9–30B produce protomers with 3, 12, and 27 subunits ($T=3$, $T=12$, and $T=27$); and the skewed quadrilaterals in Figure 9–30 panels C, D, and E produce protomers with 7, 13, and 19 subunits ($T=7$, $T=13$, and $T=19$), respectively.

In each of these protomers, the three designated global rotational axes of symmetry of the hexagonal array at the vertices and the edges become global axes of icosahedral symmetry with the same fold. The global 6-fold rotational axis of symmetry of the hexagonal array at the undesignated vertex becomes a quasi-equivalent global 5-fold rotational axis of symmetry when the protomer is in the icosahedral array. The other global rotational axes of symmetry of the hexagonal array that fall within and on the edges of the boundaries become local rotational axes of pseudosymmetry in the icosahedral array, or if the protomer is large enough some of them become local rotational axes of symmetry. It was the realization of the fact that such a hexagonal array is compatible with icosahedral symmetry that allowed Fuller to design the **geodesic domes**,²¹⁹ which preceded the realization that viral protein coats are geodesic domes.²¹⁸

The protein coats of Sindbis virus²³³ and Nudaurelia ω Capensis virus²³⁴ each have 240 identical subunits arranged with **$T=4$ icosahedral symmetry**. In the protomer of $T=4$ icosahedral symmetry (Figure 9–30A), there is a local 3-fold rotational axis of pseudosymmetry (gray symbol in Figure 9–30A) equidistant from the two 2-fold rotational axes of symmetry and the upper vertex, in a position equivalent to the local 3-fold rotational axis of symmetry in the center of a protomer of $T=3$ icosahedral symmetry (gray symbol in Figure 9–30B). This local 3-fold rotational axis of pseudosymmetry is retained in the $T=4$ icosahedral shell in each protomer and is the local rotational axis of pseudosymmetry for a trimer of quasi-equivalent subunits, just as is the equivalent local 3-fold rotational axis of pseudosymmetry in a protein coat of $T=3$ icosahedral symmetry. Another copy of the same trimer necessarily occupies each position in the shell at which one of the 10 global 3-fold rotational axes

Figure 9-30: Compatibility of a hexagonal array of hexamers with icosahedral symmetry. The positions of the global axes of symmetry normal to an infinite hexagonal array of homohexamers are indicated in the distributions surrounding the two hexamers in the upper right of the array. A solid hexagon indicates a global 6-fold rotational axis of symmetry. These rotational axes of symmetry are located in the respective positions throughout the array. (A) Segments of the hexagonal array containing 4, 9, 16, and 25 subunits, respectively, that can be protomers of icosahedral symmetry. The quadrilaterals enclosing these four segments and those in C, D, and E are the protomers of an alternative icosahedral hexacontahedron (drawn to the right of the hexagonal array). In each of the protomers of this hexacontahedron, a 5-fold, a 2-fold, a 3-fold, and a 2-fold rotational axis of global symmetry are consecutively joined by line segments. (B) Segments of the hexagonal array containing 27, 12, and 3 subunits, respectively, that can be protomers of icosahedral symmetry that are each enclosed by the boundaries of the equilateral triangle connecting a global 5-fold and two global 3-fold rotational axes of symmetry as in the icosahedral hexacontahedron in Figure 9-21C. The gray global 3-fold rotational axes of symmetry of the hexagonal array in A and B become local 3-fold rotational axes of pseudosymmetry when the protomers for $T=4$ and $T=3$, respectively, are inserted into an icosahedral array (the hexacontahedron to the right of the hexagonal array and the hexacontahedron in Figure 9-21C, respectively). (C–E) Skewed segments of the hexagonal array containing 7 (C), 13 (D), and 19 (E) subunits that also can be protomers of icosahedral symmetry. The 2-fold and 3-fold rotational axes of symmetry noted at the boundary of each of the potential protomers coincide with global 2-fold and 3-fold rotational axes of symmetry of the symmetry, and the unmarked 6-fold rotational axis of symmetry becomes a quasi-equivalent 5-fold rotational axis of symmetry, when the protomer is inserted into the icosahedral array.

of symmetry emerges because that position is itself quasi-equivalent to that occupied by a trimer on one of the local 3-fold rotational axes of pseudosymmetry. Consequently, in a coat protein with $T=4$ icosahedral symmetry, there are 60 trimers located at the 60 local 3-fold rotational axes of symmetry, one in each protomer, and 20 of the same trimers located on the respective ends of the 10 global 3-fold rotational axes of symmetry.

Because the requirements placed upon the 80 trimers in $T=4$ icosahedral symmetry are similar to those placed upon the 60 trimers in $T=3$ icosahedral symmetry, there are proteins that can adopt either $T=3$ or $T=4$ icosahedral symmetry depending on the conditions,²³⁵ and within the family of alphaviruses there are protein coats with either 180 subunits ($T=3$) or 240 subunits ($T=4$).²³³

The protein coat of bacteriophage P22^{236,237} has seven identical subunits (429 aa) arranged with $T=7$ icosahedral symmetry (Figure 9-30C) in each of its 60 protomers. The subunits adapt quasi-equivalently to form the pentamers sitting on the global 5-fold rotational axes of symmetry and the hexamers sitting on the local 6-fold rotational axes of pseudosymmetry within each protomer. The mirror image of the arrangement of the

rotational axes of symmetry in each of the various skewed quadrilaterals in Figure 9-30C–E does not superpose on itself, so there are **right-handed and left-handed versions** of each of these quadrilaterals. The coat protein of bacteriophage P22 is a left-handed $T=7$ array.

The family of papilloma viruses, simian virus 40, and polyoma viruses have protein coats that are a peculiar variation on $T=7$ icosahedral symmetry.^{238–240} Each of these viral protein coats is assembled from 72 identical pentamers with cyclic symmetry the subunits of which are held together by extensive interfaces. Rather than using the same subunit to form pentamers and hexamers, both the global 5-fold rotational axes of icosahedral symmetry and the local 6-fold rotational axes within the protomer are occupied by copies of the pentamer. Consequently, dramatically different interfaces, on the same outer surfaces of identical folded polypeptides in each pentamer, must be made around the global 2-fold rotational axis of icosahedral symmetry and the local 2- and 3-fold rotational axes of hexagonal symmetry in the spaces between the homopentameric subunits. This is accomplished by forming the interfaces with flexible, structurally swapped strands of polypeptide rather than the usual rigid interfaces of interdigitated secondary structure.

Bluetongue virus²¹⁶ and reovirus²⁴¹ have protein coats with **$T = 13$ icosahedral symmetry** (Figure 9–30D). In the former, the most extensive interfaces are those holding trimers of subunits together around the global and local 3-fold rotational axes, a fact suggesting that the fundamental unit of the structure is a trimer. The trimers, however, must adapt quasi-equivalently to being arranged about both the global 5-fold rotational axes of symmetry and the local 6-fold rotational axes of symmetry.

Herpes simplex virus^{242–244} has a protein coat with **$T = 16$ icosahedral symmetry** (Figure 9–30A). Pentamers called pentons occupy the global 5-fold rotational axes of symmetry, and hexamers called hexons occupy the local 6-fold rotational axes of symmetry; but both pentons and hexons are formed from five copies and six copies, respectively, of the same folded polypeptide (1374 aa). There are 16 copies of this folded polypeptide in each protomer so each protein coat contains 1,319,040 aa.

Adenovirus²⁴⁵ has a protein coat with **$T = 25$ icosahedral symmetry** (Figure 9–30A). In this arrangement each protomer contains four hexons that occupy the local 6-fold rotational axes of pseudosymmetry, but a hexon is not a hexamer, it is a homotrimer. Each of the three identical subunits of one of these homotrimers contains two internally duplicated domains, and six domains, two from each subunit, are arranged around each local 6-fold rotational axis to produce the pseudosymmetrically displayed faces for the interfaces in which each hexon must participate with its six neighbors.²⁴⁵ Unlike those in herpes simplex virus, the pentons in adenovirus, centered on the global 5-fold rotational axes of symmetry, are formed by different folded polypeptides (571 aa) from those (967 aa) forming the hexons.

In all of these viral protein coats based on hexagonal expansion of the basic icosahedral protomer, the problem of closing the protomer arises. A hexagonal array is a potentially infinite array, yet the protomers within the boundaries of the various equilateral triangles and quadrilaterals of Figure 9–30 are finite portions of that infinite array. During the assembly of the protein coat, a mechanism for measuring out the size of that portion is required, and this role seems to be filled by proteins accessory to the subunits of the coat.²⁴⁶

The viral protein coats in which the protomer contains only a few subunits have the appearance of spheres, even though their surfaces are often quite irregular (Figure 9–28). As the number of subunits in the hexagonal array of hexamers becomes greater, there is a tendency for the structure to look polyhedral^{243,247,248} because of the tendency of the protomers to adopt the plane of the hexagonal array. In some viral protein coats, the same quasi-equivalent interface will hold its two subunits in a plane at one location, fitting into a polyhedral face, and at an angle to each other in another, forming a crease along a polyhedral edge.²²³ Usually, however, the hexagonally packed protomers are bowed out so that

their subunits end up evenly distributed over the surface of an almost spherical oligomeric protein, just as the modular units of a geodesic dome end up producing an almost spherical exploded icosahedron and for the same reason. The joints adjust to distribute uniformly the strain produced by creasing²¹⁸ the hexagonal array consequent to requiring certain of its 6-fold rotational axes of symmetry to become 5-fold rotational axes of symmetry.²¹⁹

The protein clathrin forms isometric cagelike structures that assemble around small pinocytotic vesicles as they bud inward from the plasma membrane of an animal cell. The polypeptide is 1600 aa in length, and when folded it produces a tubular protein, 45 nm in length and 2.5 nm in diameter.²⁴⁹ The protomer from which the **cages of clathrin** are formed is a trimer of these polypeptides, all three joined together at one end around a 3-fold rotational axis of symmetry to produce a triskelion with bent arms.²⁴⁹ Different numbers of these triskelia can assemble to produce intact cages of various shapes between 70 and 200 nm in diameter.²⁵⁰ The wires of the mesh forming these cages are presumed to be formed from two or more intertwined arms of the triskelia.²⁵¹ Each and every vertex in each and every cage is a junction of three wires, and each vertex must contain the local 3-fold rotational axis of symmetry at the nexus of an individual triskelion. The mesh itself is always formed of pentagons and hexagons of wire producing polyhedra with as many as 32 faces, but most of them are not based on isometric symmetries.²⁵⁰ It is the elongated and flexible nature of the subunit that permits the one protein to generate such a wide variety of oligomeric proteins.

Problem 9–9: In Figure 9–22 there are four 3-fold rotational axes of symmetry, each of which superposes four different triplets of subunits. For example, one of these axes superposes A, B, and C; J, E, and H; L, D, and G; and K, F, and I.

- (A) List the four triplets for each of the other three 3-fold rotational axes of symmetry.

In Figure 9–22 there are three 2-fold rotational axes of symmetry, each of which superposes six different twins of subunits; for example, one of them superposes A and K, B and L, C and J, D and H, E and I, and F and G.

- (B) List the six twins for each of the other two 2-fold rotational axes of symmetry.

Problem 9–10: Make a xerographic copy of Figure 9–26. On that xerographic copy designate every global 2-, 3-, 5-, and 6-fold rotational axis of symmetry. Use the standard symbols for this designation. In the same figure designate some of the local 2-, 3-, and 6-fold rotational axes of pseudosymmetry by the symbols P_2 , P_3 , and P_6 , respectively.

Problem 9–11: Kepler derived the rhombic dodecahedron from the intersection of a cube and an octahedron. Draw the intersection of a cube and an octahedron, and connect its vertices to produce a rhombic dodecahedron.

Helical Polymeric Proteins

Helical fibers formed from identical subunits of protein have useful properties, and there are many examples of them. For example, to accomplish its function of hybridizing homologous single strands of DNA, the RecA protein binds to DNA in a long helical polymeric sheath that matches the helical symmetry of the DNA. The helicity of the sheath, however, is built into the protein because it spontaneously forms a sheath with almost the same helical symmetry even in the absence of the DNA.²⁵²

Every time an interface is created by evolution between two complementary faces on the surface of copies of the same globular protein, no matter how those two faces are disposed on its surface, a distinct screw axis of symmetry is defined. Most of these screw axes would be open and generate helical polymers of the monomer, so the existing helical polymers must be the few that have escaped elimination by natural selection. The surprising fact is that there are so few helical polymeric proteins.

A single **geometric helix** can be defined by three parameters: its radius, its hand, and its pitch. The pitch of a helix is the distance it rises for each complete turn. It can also be defined by four parameters: its **radius**, its **hand**, a recurring **radial angle** dividing the helix into equal segments of arc, and the **rise** for each of these equal segments of arc. In a helical polymeric protein the second definition makes more sense because the successive subunits can be considered to be the repeating segments of arc.

An interface between two identical molecules of a protein can generate several types of helical polymers. The actin helix (Figure 9–1B,C) is an example of the simplest type in which the protomers ascend one step at a time around the screw axis. In the actin polymer, the screw axis of symmetry passes through a corner of each protomer, the helix is not much wider than the protomer (Figure 9–1C), and the radial angle between successive protomers is fairly large (-166°). It has already been

noted that the actin helix can be represented as a single helix or as a double helix.

If the generating interface creates a screw axis of symmetry where the radial angle between successive subunits is fairly small, so that there are a number of subunits in one turn of the helix, and where the rise for each subunit is just enough to cause the subunits in each turn of the helix to lie upon the subunits from the turn below it, then a **singly threaded cylinder** is formed. Because of steric problems, such a generating interface usually creates a screw axis of symmetry that is separated from the subunits themselves, rather than passing through each of them, and the threaded cylinder is hollow inside. An example of such a hollow, singly threaded helical cylinder is tobacco mosaic virus (Figure 9–31).^{253–256} In tobacco mosaic virus, the angle between successive subunits is 22.03° , and the rise for each subunit is 0.14 nm.^{255,256} These dimensions bring the subunits in the next turn of the helix into contact with the subunits in the preceding turn, and the pitch of the helix is 2.3 nm, the height of a subunit. Between two successive turns there are interfaces among the protomers. Because of the screw symmetry, each protomer provides at its lower surface the upper faces for the interfaces with the two protomers below it and at its upper surface the lower faces for the interfaces with the two protomers above it. Because every protomer is the same, each of these respective interfaces is the same and repeats along the thread every 22.03° .

The generating helix emphasized in the drawing of tobacco mosaic virus (Figure 9–31B) is a right-handed helix of pitch 2.3 nm. If the structure is examined closely, however, it can be seen that there are sets of helices of steeper pitch running through it. The subunits in tobacco mosaic virus are arranged upon a **helical surface lattice**²⁵⁷ that contains all of these other sets of helices. The helical surface lattice can be displayed in two dimensions by cutting the cylinder along a line parallel to the central axis and flattening it upon the page (Figure 9–31C). When the helical surface lattice of tobacco mosaic virus is viewed in this format, it can be seen that, in addition to the single right-handed helix of pitch 2.3 nm running through the lattice, there are also sets of 17 parallel right-handed helices and sets of 16 parallel left-handed helices (lower and upper sets of arrows, respectively, in Figure 9–31C).²⁵⁸ Any one of these sets of helices can also define the structure. A helical surface lattice can be uniquely designated by the number of parallel strands of left-handed twist (a negative number) and the number of parallel strands of right-handed twist (a positive number) for any one of the sets of each respective hand.²⁵⁷ For example, the helical surface lattice of tobacco mosaic virus can be designated $(-16, 1)$ or $(-16, 17)$. The surface lattice of the helical polymer of flagellin from *Salmonella typhimurium* also contains a singly threaded right-handed helix as well as a set of five parallel left-handed helices, a set of six parallel right-handed helices, and a set of 11 parallel left-handed helices.²⁵⁹

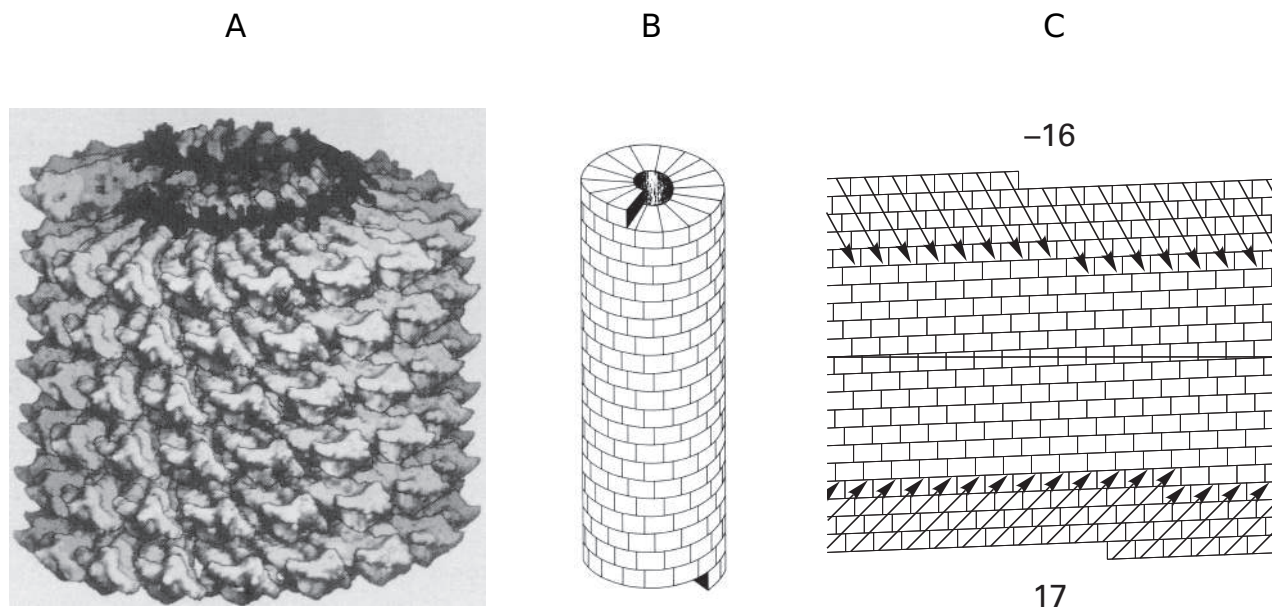

Figure 9-31: Helical surface lattice of tobacco mosaic virus. (A) Molecular model derived from a map of electron density calculated from the helical diffraction pattern of X-radiation (Bragg spacing ≥ 0.29 nm) emerging from an oriented preparation of the viruses.²⁵⁶ The diffraction from a specimen prepared in 1960 was gathered to Bragg spacing of 0.29 nm in 1982. The timing of this sequence of events illustrates how rare it is to obtain a well-aligned preparation of a helical polymeric protein. Reprinted with permission from ref 256. Copyright 1989 Elsevier B.V. (B) Diagrammatic representation of the helical surface lattice of the protein coat of tobacco mosaic virus.²⁵⁴ Individual protomers form a singly threaded helical screw that is a hollow cylinder. Each protomer has the same orientation and the successive protomers are related by a rise of 0.14 nm and a rotation of 22° along the helix. Reprinted with permission from ref 254. Copyright 1972 Federation of American Societies for Experimental Biology. (C) The surface helix of tobacco mosaic virus flattened onto the page.²⁵⁵ The hollow cylinder in panel B was split along a vertical plane passing through its wall and then flattened onto the page. The horizontal line represents a circle around the cylinder, the plane of which is normal to the central axis of the cylinder, that has been also split and flattened. It has been added to assist in counting the numbers of parallel helices in the various sets. The arrows at the upper end of the lattice indicate the set of 16 left-handed helices, and those at the lower end, the set of 17 right-handed helices that run through the lattice. These are referred to as 16 start and 17 start arrays, respectively. Reprinted with permission from ref 255. Copyright 1974 Academic Press.

A helical surface lattice does not have to have a single shallow helix of one or the other hand acting as the generating operation. The extended tail of the T4 bacteriophage is built from hexamers with cyclic symmetry. The hexamers are stacked upon each other by successive interfaces that cause them to be out of alignment in a right-handed sense by 17° .²⁶⁰ This creates a helical surface lattice that is a hexuply threaded cylinder. The $(-6, 6)$ lattice contains both a set of six parallel helices of shallow pitch with left-handed sense and a set of six parallel helices, of steeper pitch, with a right-handed sense.

The CA protein from type 1 immunodeficiency virus spontaneously forms several different sizes of helical tubes. It forms two different tubes with distinct $(-12, 11)$ and $(-11, 10)$ surface lattices, respectively, that each have a single generating helix of one strand with a left-handed pitch. The same protein, however, also forms tubes with $(-10, 13)$, and $(-8, 5)$ surface lattices.²⁶¹

The radial angle relating successive subunits to each other in a helix or each of the identical helices in a set of helices in a helical polymer is determined by the interfaces among them. It is these interfaces that produce a helical filament such as actin or a singly or multiply threaded cylinder such as tobacco mosaic virus,

flagellin, or the extended tail of the T4 bacteriophage. This **radial angle** between successive subunits that these interfaces dictate can have **any numerical value**. Technically, this means that the helix or helices never position a monomer exactly above any monomer below it in the helix. For example, tobacco mosaic virus has 49.02 subunits in three turns (22.03° subunit⁻¹), not 49.²⁵⁶ Therefore, there is no translationally repeating unit in a rigid, biological helical structure. What this means is that a helical polymeric protein has difficulty crystallizing in three dimensions, and crystals of helical polymers suitable for high-resolution crystallographic studies have not been produced. One interesting example, which is almost an exception to this uniform failure, is the protofilament running through a crystal of the protein encoded by the *mreB* gene in *E. coli*. This protein is a homologue of actin and forms filaments similar to those formed by actin (Figure 9-1B) but without the helical twist, so a filament can be incorporated into a crystal.⁶

One approach to determining the structure of a helical polymeric protein is to crystallize the monomer, construct its crystallographic molecular model at atomic resolution, and simultaneously determine the structure of the helical polymer at high enough resolution to posi-

tion crystallographic models of these monomers in the proper orientation at the locations they occupy in the polymer. Such a strategy has been applied successfully to the polymer of actin (Figure 9-1B).^{3*} The details of the structure of an intact polymer at the resolution required by this strategy can be determined by image reconstruction²⁶³ of electron micrographs.

Under appropriate circumstances, an **electron microscope** is capable of magnifying the image of a protein sufficiently that individual subunits can be distinguished and their shapes almost distinguished. A beam of collimated electrons is impinged upon the sample, and those that pass through it without being deflected sufficiently to leave the beam are then focused by electromagnetic lenses. The contrast in the image is caused by the distribution within the sample of the ability to deflect or scatter electrons from their path. The sample placed in an electron microscope usually has to reside in a chamber under high vacuum. This means that the sample has to be a solid with a low vapor pressure. In the case of molecules of protein, this requires that they be encased in a solid matrix, which also must be a **glass** to avoid the problems of the diffraction caused by crystalline solids.

To enhance contrast and provide a solid support simultaneously, the glass is often formed by drying a solution of a salt containing a heavy metal such as uranium or tungsten. Either uranyl acetate or sodium phosphotungstate, for example, will form an electron-dense glass when a film of a solution containing it is dried. This electron-dense glass will surround, encase, and support a molecule of protein that had been present in the solution from which the film was made. The glass of the salt of heavy metal encasing the molecule of protein forms a three-dimensional boundary or mold that has the shape of the molecule of protein. It is the dark image of this mold of electron-dense glass encasing the light image of the electron-translucent molecule of protein that is observed in the micrograph. This procedure is known as **negative staining**.

It is also possible to insert thin layers of **amorphous ice**, which is a glass, into a **cryoelectron microscope**, an electron microscope not with cold electrons but with a stage for the sample that is cooled to a very low temperature.^{264,265} When a molecule of protein is embedded in such a glass (Figure 9-32A),²⁶⁶ the contrast observed results from the fact that the atoms in a molecule of protein are more efficient at deflecting electrons than the molecules of water in amorphous ice. A positive image of the molecule, rather than a negative image, is observed.

The three-dimensional distribution of the ability to deflect electrons within the sample is known as the distribution of scattering density, $\theta(x,y,z)$. If a map of scat-

tering density can be produced at as high a resolution as possible, details of the structure of either the mold in which the molecule of protein is encased or the molecule of protein itself can be observed. **Image reconstruction** is any computational method that is used to calculate $\theta(x,y,z)$ from the images of molecules of proteins observed in electron micrographs.²⁶³ In all cases, the electron micrograph is the experimental data submitted to these calculations, and the electron micrograph used in a particular reconstruction must be presented to the reader so that she may appreciate the point of departure (Figure 9-32A).

A molecule of protein has a certain distribution of electron density $\rho(x,y,z)$, and when molecules of protein are arrayed in a crystal they create a periodic, three-dimensional distribution of electron density. This periodic array diffracts X-rays to produce a diffraction pattern that is also periodic. The angular dispositions of the reflections in the diffraction pattern are determined by both the angles among the axes of the fundamental unit cell and its dimensions. The dimensions and axial angles of the unit cell can be calculated from these angular dispositions. The diffraction pattern of the crystal is the Fourier transform of the periodic distribution of electron density it contains. The magnitudes and phases of the maxima in the diffraction pattern can be calculated from the distribution of electron density within the unit cell by digital Fourier transformation. Conversely, the distribution of electron density in the unit cell can be calculated from the amplitudes and phases of the diffraction maxima by digital Fourier transformation.

A helical polymer of protein in its mold of negative stain or amorphous ice has a certain **distribution of scattering density**, $\theta(x,y,z)$, which is a **periodic function** because the helix is periodic. Each protomer of the polymer is a unit cell in this helical array. The **computed Fourier transform** of this periodic array is also a periodic function. From the spatial disposition of its maxima, the angle between successive unit cells in the helix, the rise for each unit cell, and the number of helical threads in the structure can be calculated. From the amplitudes and phases of the maxima of the Fourier transform, the distribution of scattering density within the unit cell can be calculated.

The depth of focus in an electron microscope is larger than the width of a specimen containing a helical polymer, and all points in the specimen are in focus in the final micrograph. As such, the micrograph represents the projection of the three-dimensional distribution of scattering density onto a two-dimensional surface.²⁶³ The Fourier transform, $F(X,Y,Z)$, of any three-dimensional distribution of scattering density is²⁶⁷

$$F(X, Y, Z) = \iiint_{\text{object}} \theta(x, y, z) \exp[2\pi i(xX + yY + zZ)] dx dy dz \quad (9-4)$$

* A more recent crystallographic molecular model of actin²⁶² has a somewhat different structure than the one used to construct Figure 9-1B, but the differences are not significant enough to affect the choice of the orientation of the monomer within the polymer.

When $Z = 0$

$$F(X, Y, 0) = \iint \sigma(x, y) \exp[2\pi i(xX + yY)] dx dy \quad (9-5)$$

where

$$\sigma(x, y) = \int \theta(x, y, z) dz \quad (9-6)$$

The function $\sigma(x, y)$ is the projection of the three-dimensional distribution of scattering density. This set of relationships states that the two-dimensional Fourier transform of the projection of the distribution of scattering density is the **central section of the three-dimensional Fourier transform** of the unprojected distribution of scattering density. This central section of the three-dimensional Fourier transform is obtained by digitizing the optical density of the micrograph and calculating a digitized Fourier transform of the image by computer. The significant advantage of performing the Fourier transform computationally rather than by diffraction is that the computed Fourier transform comes with both **amplitudes and phases** instead of just amplitudes. The disadvantage is that there are far fewer unit cells contributing to the Fourier transform.

In the case of a helical polymeric protein embedded in negative stain or amorphous ice, the central section of its three-dimensional Fourier transform systematically intersects all of the maxima in its three-dimensional Fourier transform. In this two-dimensional central section of its Fourier transform (Figure 9-32B), the amplitudes and the associated phases of the transform (Figure 9-32C) are arrayed along **layer lines** (the horizontal lines in the figure) that arise from the repeating patterns in the helix.^{257,268} If the correct helical lattice has been assigned to the structure so that the layer lines can be properly **indexed**,²⁶⁹ the indexed amplitudes and phases distributed along the layer lines (Figure 9-32C) can be used to calculate $\theta(x, y, z)$ by a **Fourier-Bessel transform**,²⁶⁸ just as the properly indexed amplitudes and phases of the pattern of the X-rays diffracted from a crystal can be used to calculate $\rho(x, y, z)$ by a Fourier transform. Figure 9-32D presents an example of such a reconstruction from the electron micrograph of Figure 9-32A.

Image reconstruction succeeds in producing the molecular structure of a helical polymeric protein when it is able to produce an image of the helical polymer of sufficient resolution to position and orient unambiguously a crystallographic molecular model of the monomer within the polymer. In addition to the success this approach has achieved with the helical polymer of actin (Figure 9-1B),³ it has been possible to insert a crystallographic molecular model of the $\alpha\beta$ heterodimer of tubulin²⁷⁰ into image reconstructions of the micro-

tubule^{271,272} and to insert a crystallographic molecular model of flagellin into an image reconstruction of a bacterial flagellar filament.²⁷³ In the latter case, as with the protein encoded by the *mreB* gene of *E. coli*, the flagellin crystallized within a protofilament of the overall flagellar filament. Consequently, its position and orientation within the image reconstruction of the complete filament could be assigned with greater certainty.

Usually the Fourier transform of a digitized electron-microscopic image of a helical polymeric protein embedded in amorphous ice has measurable amplitudes that arise from helical spacings of 2 nm or greater,^{261,274,275} and as in crystallography, this determines the **lower limit of the resolution**. Images of tobacco mosaic virus, however, have produced Fourier transforms with terms arising from spacings of 1 nm;²⁷⁶ and images of helical tubes of acetylcholine receptor, terms arising from spacings as little as 0.5 nm.²⁷⁷

Difference maps of scattering density can also be useful. A helical polymeric protein, for example, helical fibers of tubulin, often associates with another protein, for example, kinesin, at sites on its surface, one of which is located on each of the asymmetric units in the helical lattice, for example, on each subunit of tubulin.²⁷⁸ When the helical polymer is decorated with the other protein, for example, when a helical fiber of tubulin is decorated with kinesin, the distribution of that other protein will assume the helical distribution of the underlying filament. The Fourier transform of an image of the undecorated filament is subtracted from that of a decorated filament, and the Fourier-Bessel transform of this difference is a map of scattering density arising just from the bound protein.^{266,278}

A population of **oriented helical polymeric proteins** produces **X-ray diffraction**. As a diffraction pattern is the Fourier transform of the distribution of electron density in the helical specimen, these X-ray diffraction patterns also display the layer lines seen in Fourier transforms of digitized images from electron micrographs of those same specimens. Because the reflections are produced by diffraction rather than computationally, they must be phased by multiple isomorphous replacement.²⁵⁶ This has been accomplished for oriented filaments of the protein coat of tobacco mosaic virus incorporating reflections arising from spacings to 0.3 nm to obtain a map of electron density into which a model of the polypeptide could be inserted (Figure 9-31A).^{256,279} It is also possible to use phases from electron micrographs and amplitudes from X-ray diffraction to produce a map of electron density.²⁵⁹

There are helical polymeric proteins that are constructed from long, flexible strands of polypeptide rather than globular protomers. These proteins resemble the **helical cables** that are used in the construction of suspension bridges. The smallest structural element in a cable is a **strand**. Two or more strands are twisted around each other to make a **rope**. Two or more ropes are then

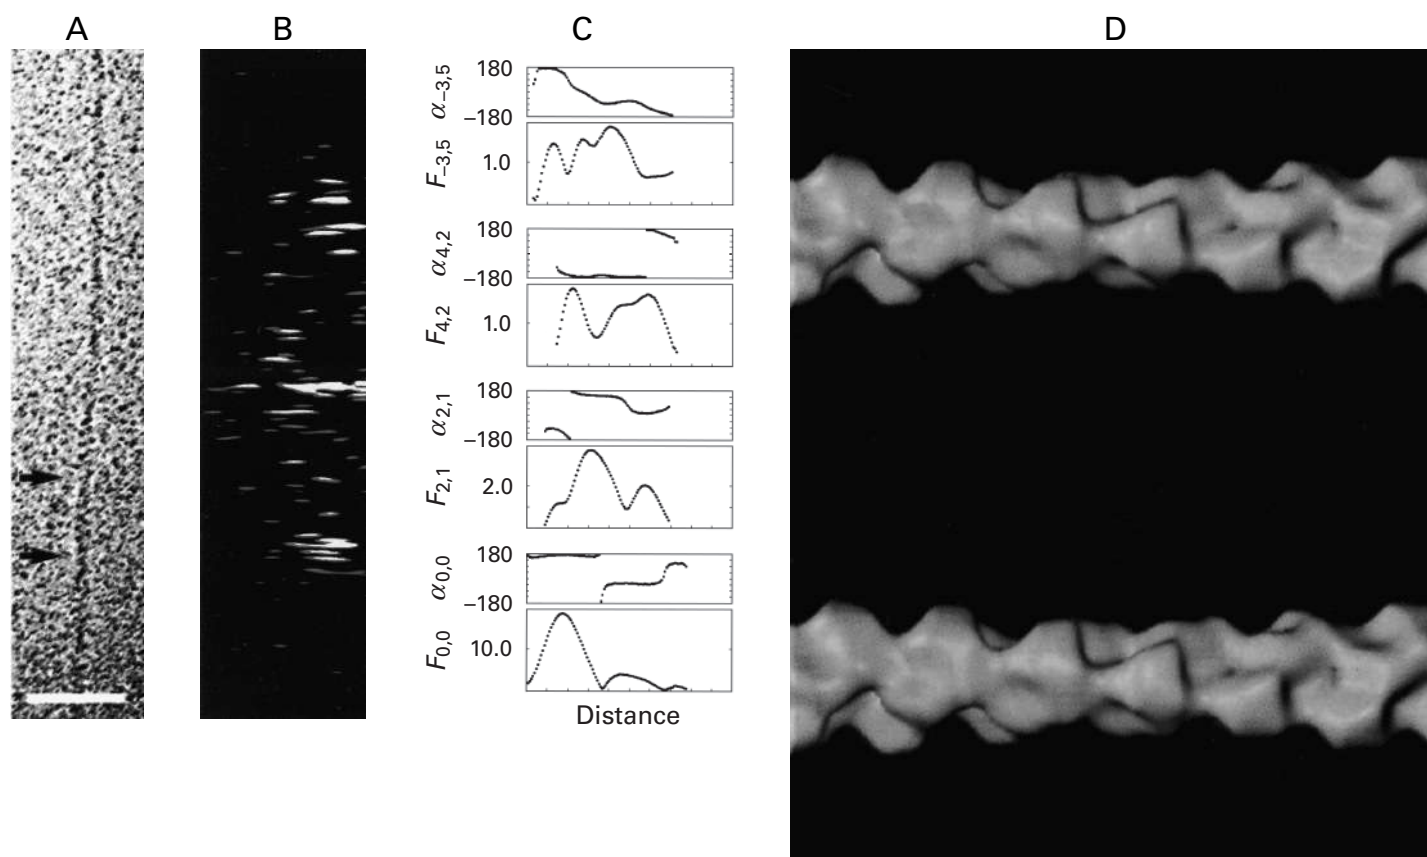

Figure 9-32: Image reconstruction of the helical array of subunits in a filament of actin.²⁶⁶ Filaments of human cytoskeletal β actin were suspended in a buffered aqueous solution. A small sample of the suspension ($4 \mu\text{L}$) was spread over a grid for electron microscopy and rapidly frozen to obtain a thin sheet of amorphous ice in which the filaments were embedded. (A) An electron micrograph ($36000\times$) of an actin filament embedded in the ice. The arrows mark points of helical crossovers. The electron micrograph was scanned and a Fourier transform of the digitized image was performed. (B) The Fourier transform (Equation 9-5) of the image in panel A is presented graphically on a two-dimensional field such that the brightness of the image is directly proportional to the amplitude of the function at that point. Because the array is helical, the maxima in the Fourier transform are found along layer lines. (C) Distribution of the amplitude and phase of the Fourier transform along several of the layer lines in panel A. Phases ($\alpha_{n,l}$; degrees) are presented in the upper plot of each pair and amplitude ($F_{n,l}$; relative units) in the lower plot. The indexing of the layer lines (n, l) designates the Bessel order (n) and the number of the layer line (l). (D) Reconstructed image in stereo resulting from a Fourier-Bessel transform of the amplitudes and phases along the properly indexed layer lines. Reprinted with permission from ref 206. Copyright 2000 Elsevier B.V.

twisted around each other to make a cable. The strands from which ropes of protein are made are polypeptides read from messenger RNA, and for this reason, each strand must have a discrete length. This in turn means that the cable is built from strands of uniform length that are overlapped to provide the necessary tensile strength.

The arrangement of the strands in the molecular rope and the ropes in the cable is elucidated by permitting a macroscopic fiber to diffract X-radiation. A macroscopic fiber, built from billions of the molecular cables, is placed in a beam of X-rays. The cables are all more or less aligned with the axis of the macroscopic fiber. The helical arrays of the strands in the ropes and the helical arrays of the segments of rope in the cable have certain regularly recurring dimensions and angles associated with them that give rise to diffraction. The dimensions and helical parameters of these arrays can be established from the angles at which the reflections emerge from the

fiber. For example, a serial set of reflections is produced by a tendon from the tail of a rat when the tendon is placed in a beam of X-rays. This serial set of reflections arises from a helical array that repeats every 67 nm ,^{280,281} and this dimension, along with others, must be incorporated into the model for the complete cable of the collagen from which the tendon is formed.

Collagen is the helical polymeric protein from which is formed the tough, flexible material composing tendons, intercellular matrix, the matrix of bone, and many strong, plastic sheets of various shapes and sizes found in animals. The basic structural element in these macroscopic structures is the fibril of collagen, which is a cylindrical thread of indefinite length, $200\text{--}800 \text{ nm}$ wide. This thread in turn is formed from molecular cables of collagen, each probably as long as the fibril, packed side by side in register.

The strand from which a molecular cable of colla-

gen is formed is a polypeptide that contains significant amounts of **4-hydroxyproline** and that has a characteristic repeating sequence in which **glycine** is every third amino acid. In humans, there are 30 different polypeptides containing segments with such a repeat. These polypeptides vary in length from 666 to 3039 aa; most of them have lengths of 1000–2000 aa. The segment with the repeating sequence can be as long as 1530 aa or as short as 15 aa. Polypeptides with segments longer than 500 aa in which every third amino acid is a glycine usually have only one continuous segment of this repeating pattern; polypeptides with segments shorter than 300 aa usually have multiple segments of different lengths. The segment or segments with the repeating sequence are usually found in the middle of the polypeptide. It is such a segment that forms the strand of the rope; the remainder of the polypeptide forms appendages to the rope usually at its two ends. If the rope forms a cable, these amino-terminal and carboxy-terminal appendages jut out from the cable at regular intervals.

Three strands of polypeptide with a repeating sequence in which every third amino acid is a glycine can wrap around each other in parallel to form a triple-helical rope (Figure 9–33).²⁸² The collagen **triple helix** is a coiled coil of three helices, each formed by one of the strands. The structure is that proposed by Rich and Crick.²⁸³ The three helices are all left-handed with the same helical parameters. Each has on average a rise of 0.29 nm aa^{-1} over an angle of $-107^\circ \text{ aa}^{-1}$, and this conformation produces a complete turn every 3.36 aa.^{282,284} Suppose each of the three helices had an angle of $-120^\circ \text{ aa}^{-1}$ instead of $-107^\circ \text{ aa}^{-1}$ so that every third amino acid in each of them would point in the same direction. They could then be brought together in a triangular bundle in which every glycine in each helix was directed into the center. As with a coiled coil of α helices, the deficit between -107° and -120° is accommodated by coiling the three individual left-handed helices around each other, but with a right-handed twist of $+13^\circ$ rather than the left-handed twist of -4° . As a result, the core of the triple helix contains only glycines along its entire length.

The three strands fit together so that they are in register. Only one of the three side chains at each level in the rope is a glycine, and the *pro-S* hydrogen of this glycine is pointed towards the center. The side chains that necessarily occupy this *pro-S* position in the other two amino acids at that level from the other two strands point away from the center of the rope. The α carbon of each glycine is snug against the acyl carbon–oxygen of the glycine in the level above. Within each level there are three amino acids arrayed cylindrically about the central axis: the glycine, an amino acid to the carboxy-terminal side of the glycine in the level above, and an amino acid to the amino-terminal side of the glycine in the level below. Traditionally, these three amino acids are designated glycine, amino acid X, and amino acid Y, respectively. The small size of the *pro-S* hydrogen of each

Figure 9–33: Triple helix of collagen. A portion of the crystallographic molecular model²⁸² of the synthetic triacontapeptide with the sequence $(\text{Pro-Hyp-Gly})_3\text{ITGARGLAG}(\text{Pro-Hyp-Gly})_4$, where Hyp is 4-hydroxyproline, is presented. The carboxy-terminal segment $(\text{Pro-Hyp-Gly})_2$ of the portion of the model that has been drawn represents the carboxy-terminal region of nucleation for a triple helix; the amino-terminal segment, $-\text{ITGARGLAG}-$, represents the bulk of the interior of the triple helix. Molecules of water are represented by white spheres attached to the structure only by hydrogen bonds. This drawing was produced with MolScript.⁴⁸⁵

glycine permits the three strands to approach each other so closely that an **interstrand hydrogen bond** forms at each level in the triple helix between the amido oxygen of amino acid X and the amido nitrogen–hydrogen of the glycine in the level below. In all of the regions of the triple helix in which the amino acids X are not prolines or 4-hydroxyprolines, there is a molecule of water hydrogen-bonded to the amido oxygen of the glycine at one level and the amido nitrogen–hydrogen of amino acid X in the level two steps below. These molecules of **water** are integral components of the structure.²⁸⁵ If amino acid Y in the same level as the amino acid X providing a donor to the molecule of water is a threonine, a serine, a 4-hydroxyproline, or an asparagine, the donor in its side chain can form a third hydrogen bond to one of these integral molecules of water.

The **carboxy-terminal regions** of each of the three polypeptides in such a triple helix are often composed of repeating sequences of prolyl-4-hydroxyprolylglycine or prolylprolylglycine.²⁸² These segments are thought to

nucleate the structure.²⁸⁶ Beyond this region of nucleation in the triple helix, the only requirement is for a glycine at every third position. In the short region of nucleation, the helix governing the conformation of a strand rises 0.28 nm aa^{-1} over an angle of $-104^\circ \text{ aa}^{-1}$ and the structure has angles ϕ and ψ of around -70° and $+160^\circ$, which are in the range of those for the polyproline helix. It is thought that these regions spontaneously form a triple polyproline helix, which then propagates into the rest of the structure.^{282,287} Synthetic peptides of the sequence $(\text{Pro-Pro-Gly})_n$ or $(\text{Pro-Hyp-Gly})_n$ spontaneously form such triple helices.^{288,289}

Many of the polypeptides containing sequences in which glycine is every third amino acid form triple helices that do not associate further to form fibrils. In some of these polypeptides the triple-helical regions are frequently interrupted by segments incompatible with a triple-helical structure.²⁹⁰ In others, the two or three triple-helical segments are of insufficient length to effect fibrillar formation.²⁹¹ In yet others, the globular domains flanking the triple-helical segments are too large to permit further association.²⁹² The polypeptides of collagen that associate further beyond the triple-helical state usually contain continuous segments of a thousand or more amino acids with uninterrupted sequences in which glycine is at every third position flanked by carboxy-terminal and amino-terminal portions of several hundred amino acids or less.²⁹⁰

The paradigm of such a **fibrillar collagen** is type I. The triple helix of type I collagen is a heterotrimer of two $\alpha 1$ polypeptides (1057 aa in the human) and one $\alpha 2$ polypeptide (1024 aa in the human) and is formed from a sequence $(\text{Gly-X-Y})_{338}$ of 1014 aa from each chain. The three chains in the triple helix are in register so the rope produced by these three strands is a finite segment, and each segment of rope has the same length. The carboxy-terminal and amino-terminal flanking portions, the telopeptides, are short ($<30 \text{ aa}$), so there is little to interfere with formation of the fibril. This type of collagen is the major component of tendon, and it is fiber diffraction from tendons that has provided the angle of 107° and rise of 0.29 nm characterizing the collagen triple helix²⁸⁴ as well as evidence for repeats of 67 and 30 nm.²⁸¹ These latter repeats arise from the cable formed from the segments of triple-helical rope.

The **segments of rope** (represented by vertical lines in Figure 9-34A)^{281,293} forming this cable are 298 nm in length ($1014 \times 0.29 \text{ nm}$) and are placed side by side in a **right-handed helical array**. In this helical array, the segments of rope are not butted up against each other, and gaps of 37 nm in which the cable has only four ropes alternate with segments of 30 nm in which it has five ropes. The radial angle between each successive protomer, each of which is an individual segment of rope, would be 72° and the helix would repeat every five protomers if the ropes were held perfectly vertical (Figure 9-34A), but they are not.

Figure 9-34: Arrangement of the triple-helical ropes of collagen in the cable-forming tendon.²⁹³ The individual segments of rope, each a triple helix formed from three segments of 1014 aa from the central regions of three collagen polypeptides, are represented by vertical lines with splayed amino- and carboxy-terminal ends. The individual segments of rope are arrayed in a right-handed helical distribution (left panel).²⁸¹ In tendon,²⁹³ the cable is twisted in a left-handed sense by one turn over its repeat of 335 nm (right panel). Because the most rigid segments of the cable are where five strands overlap, the twist occurs in the regions where only four strands overlap. The cable is twisted by -72° in each of these gap regions to give each of the five strands a left-handed helical path in these spaces. The cable is kinked as well as twisted. Two of the unit cells for the crystalline array in tendon are drawn. The cable shifts from one column of unit cells into the column of unit cells diagonally adjacent to it at each level.

The collagen in a tendon is arranged in a crystalline array the unit cell of which is triclinic (Figure 4–2)²⁹⁴ with a length of 67 nm, equal to only one-fifth of the 335 nm repeat of the cable. Consequently, the cable must be **twisted** so that its structure repeats translationally every 67 nm. This is accomplished by twisting it by -72° over each 67 nm segment of its length to produce repeating conformations that are translationally superposable on each other (Figure 9–34B).²⁹³ Because the regions with only four ropes are the most flexible, the twist is confined to them. The cable is kinked so that as it ascends at each step it shifts from one column of unit cells to the column diagonally adjacent to it. The pentagonal array of the five ropes is compressed in one dimension into a layer of two and a layer of three ropes to permit the pentamer of ropes to pack in a hexagonal array. The helix of each strand is left-handed, the superhelix of the triple helix of the three strands forming the rope is right-handed, and the twist of the cable of five ropes is left-handed. Alternating the hand of the elements in a cable increases its strength.²⁹³

As the cables enter these rather contorted arrays, they are aligned by the crystallization in register, and the crystallographic asymmetric units, each containing the equivalent of 67 nm of cable, create a **repeating pattern on the surface of the fibril** itself. This pattern can be seen in the electron microscope. It appears as alternating thickenings and thinnings along a desiccated fibril that repeat every 67 nm. These thickenings and thinnings are believed to represent the alternation in register of regions within the molecular cables five ropes in thickness and those of four ropes in thickness, respectively (Figure 9–34). Fibrils of collagen also stain positively by chelating heavy metals at specific locations on the surfaces of the ropes where there are high, unbalanced constellations of negative charge. Because the segments of rope are placed in register by the side to side crystallization of the cables, these positions to which heavy metals bind form bands across the fibrils or across sheets of collagen. The pattern of bands is quite reproducible,²⁹⁵ and it repeats every 67 nm.²⁹⁶ From an examination of the patterns in which charged amino acids occur in the amino acid sequences of the polypeptides, it can be shown that the pattern in which these bands occur on the ropes is entirely consistent²⁹⁶ with the triple-helical array of strand and pentahelical array of ropes in the hypothetical model (Figure 9–34B), the Fourier transform of which mimics the reflections in the X-ray diffraction pattern from an oriented tendon.²⁹³ All of these correlations provide independent support for this model of the structure of the cable.

Three classes of filaments can be observed within animal cells. **Thin filaments**, or microfilaments, are filaments of actin the basic structural element of which is the actin helix (Figure 9–1C). Tropomyosin, a fibrous protein that is one continuous coiled coil of two parallel α helices,²⁹⁷ lies in the grooves of the actin helix. Each of

these coiled coils of tropomyosin spans seven actins. The globular protein troponin decorates the microfilament at regular intervals. The structure of the thin filament has been elucidated by image reconstruction.^{298–300} In transmission electron micrographs, thin filaments appear to be about 8 nm wide. **Microtubules** are hollow cylinders,³⁰¹ constructed from the globular protein tubulin. They are about 20 nm in width. **Intermediate filaments** are the third class of filament. In transmission electron micrographs, they appear to be about 10 nm wide, intermediate between thin filaments and microtubules.

Intermediate filaments were originally considered to be a heterogeneous class of polymeric proteins grouped together only because they were similar in width. Within this class are tonofilaments, neurofilaments, cellular keratin filaments, desmin filaments, glial filaments, and vimentin filaments. Each of these subclasses occurs in a different set of tissues, and they form intermediate filaments that often seem quite different in their appearance and their distribution through a cell (Figure 9–35).³⁰² It is now known, however, that all of these filaments are constructed from polypeptides that are homologous in sequence (Figure 9–36)³⁰³ and thus necessarily share a common, superposable structure. That an intermediate filament can be constructed from one of these polypeptides all by itself has been demonstrated by reassembling filaments from a pure homogeneous preparation of a given polypeptide.³⁰⁴ These polypeptides form helical cables of indefinite length.

One of these intermediate filaments, keratin, composes the fibers in the composite material that forms skin, hair, and horn. For example, the quill of a porcupine represents a large array of more or less aligned keratin cables. Diffraction of X-radiation from such specimens³⁰⁵ provides dimensions of the helical arrays in these cables.³⁰⁶ Meridional reflections representing a repeat of 0.51 nm are strong features of such diffraction patterns, and this demonstrates that these cables are built from **coiled coils of α helices**.

The strand from which an intermediate filament is constructed is a polypeptide folded into an α helix. Two α helices twist around each other in a left-handed coiled coil (Figure 6–29) to produce the rope.^{307,308} The **heptad repeat** permitting the formation of this rope can be noticed in those regions of the sequences that are involved in its formation when sequences from several of these polypeptides are aligned (Figure 9–36).³⁰³ The amino acids in the heptad positions at which the side chains are directed into the core of the coiled coil are not always nonpolar, but at four of the positions where they are not, remarkable conservation is displayed.

As in collagen, the sequences producing the rope are found in the central portions of the polypeptides. In each of the amino acid sequences from this central region, there are three consecutive segments of heptad repeat, about 30, 100, and 130 aa in length,³⁰⁹ separated by short segments (about 20 aa in length) lacking the

Figure 9-35: Distribution of intermediate filaments of vimentin (A) and keratin (B) in animal cells.³⁰² Hamster Nil-8 cells (A) or kangaroo rat PtK-2 cells (B) were grown on glass cover slips. The cells were fixed with methanol, rinsed with acetone, and dried in the air. Antiserum raised in guinea pigs to either vimentin (A) or epidermal prekeratin (B) was then applied to the respective cells. After the antiserum was rinsed away, those antibodies bound to the intermediate filaments could be visualized by adding fluorescein-labeled immunoglobulins specific for guinea pig immunoglobulin. The covalently attached fluorescein causes the intermediate filaments to which it is bound to fluoresce. Reprinted with permission from ref 302. Copyright 1978 National Academy of Sciences.

Figure 9-36: Alignment of portions of the amino acid sequences of the polypeptides composing various intermediate filaments.³⁰³ The aligned segments come from different locations in the amino acid sequences of the various polypeptides. The numbers indicate the sequence positions in the various polypeptides at which the alignment on that line commences. The proteins are isoform 5 of human type II cytoskeletal keratin, isoform 7c of ovine type II microfibrillar keratin, isoform 8c1 of type I keratin from intermediate filaments of ovine wool, isoform 14 of human type I cytoskeletal keratin, desmin from *Gallus gallus*, vimentin from *Cricetulus griseus*, glial fibrillary acidic protein from murine astrocytes, triplet M protein from porcine neurofilaments, and triplet H protein from human neurofilaments. The pattern of the heptad repeat is highlighted in boldface type. The highlighted amino acids are those the side chains of which are directed into the cores of the coiled coils.

repeat. The approximately 300 aa strand⁻¹ should produce an interrupted rope 35–45 nm long. On either side of this rope are amino-terminal domains (100–200 aa) and carboxy-terminal domains (100–1600 aa) that must either be incorporated into the body of the cable or pro-

trude from its sides. These protrusions presumably cause each type of intermediate filament to have a different width and a different tissue-specific function. An intermediate filament is a cable formed from these ropes. The filament is a helical polymeric protein

that has a $(-1, 3)$ surface lattice. In the cables of keratin in a fiber of wool, the rise for each step of the left-handed single-stranded helix generating the structure is 6.7 nm,³¹⁰ and each step is -111° from the preceding one.³¹¹ The measured mass of protein in each nanometer of an intermediate filament indicates that its cross section contains about 30 strands of α -helical polypeptide³¹² and that each rope is a coiled coil of two parallel α helices. Adjacent ropes are antiparallel to each other and staggered, and in the resulting staggered pattern there are two different alignments, one in which the ropes are staggered by half their length and the other in which they are side by side, unstaggered.^{307,308} The precise arrangement of the ropes within the helical lattice of the cable, however, is as yet unknown.

In all of the cables that have been discussed, the faces and interfaces can be divided into three groups. There is a continuous interface between or among the strands, containing within itself the central axis of the rope and twisting around that axis with the twist of the rope. Between the ropes in the cable there are interfaces, but they are formed from faces on each rope composed of small regions of surface on each strand alternating between or among the strands as the rope is ascended (Figure 9–33). The cables themselves may have faces on them to promote side to side associations, and these faces are composed of small regions of surface on strands from the same or different ropes that are encountered in turn as the cable is ascended (Figure 9–34).

There is a class of polymers that form extracellularly during the progress of systemic amyloidosis, maturity-onset diabetes, Alzheimer's disease, and spongiform encephalopathy, which are diseases affecting mammals. The diffraction of X-radiation by these fibers shows reflections arising from a repeat of 0.48 nm along the axis of the fiber.^{313–315} This dimension is the spacing between the strands of a continuous β sheet (Figure 6–9) with individual β strands perpendicular to the axis of the fiber. The β sheets in these polymers can be either parallel β structure³¹⁵ or antiparallel β structure.³¹³ The length of each strand in one of the continuous β sheets forming these polymers varies from 2.5 nm (7 aa) to 3.5 nm (10 aa) depending on the protein forming the fiber. This length determines the width of the ribbon formed by each of the continuous β sheets. Several of these **ribbons of continuous β sheet** are packed against each other about 1 nm apart, a spacing determined by the interdigitations of the side chains (Figure 6–32) to create a fibril about 3–4 nm in width. The β sheets can twist as they usually would (Figure 6–9) to give a helical twist to the ribbons that are packed together,³¹⁵ and hence to the fibril, or they can be untwisted.³¹³

Heterologous Oligomeric Proteins

The oligomeric proteins described so far, with a few exceptions, have been homooligomers of identical subunits. There are many proteins in which the subunits are not identical to each other but are homologous, such as the α and β subunits of hemoglobin or the VP1, VP2, and VP3 subunits of the protein coat of poliovirus (Figure 9–28). In such cases, the **homologous subunits** are arrayed around rotational axes of pseudosymmetry that are the descendants of the rotational axes of symmetry of their homooligomeric ancestral proteins. For example, there are seven distinct β subunits, each with a unique sequence and each present in two copies, in the 20S multicatalytic endopeptidase complex from *S. cerevisiae*. Although they have distinct sequences, their tertiary structures are all homologous and the 14 β subunits in the oligomer are arranged at the center of the protein with dihedral pseudosymmetry of point group $722(D_7)$.³¹⁶ In the homologous complex from *Thermoplasma acidophilum*, representing the ancestor of the complex from *S. cerevisiae*, the 14 β subunits are all identical to each other, homologous to those from *S. cerevisiae*, and also arranged with the same dihedral symmetry.¹¹⁶ Often the homologous subunits in a heterooligomer are interchangeable with each other, as are those in fructose-bisphosphate aldolase (Figure 8–18) or those in the dimer of creatine kinase.³¹⁷ In all of these uncertain heterooligomers, there is no significant difference between the **pseudosymmetric arrangement** of their subunits and the symmetric arrangement of the identical subunits in their homooligomeric siblings or homooligomeric ancestors.

There are also **heterooligomeric proteins** formed from two or three distinct, unrelated subunits each present in equal numbers of copies and held together by heterologous interfaces. A **heterologous association** is the association between two folded polypeptides of unrelated sequence and unrelated tertiary structure. A **heterologous interface** is the interface between two unrelated subunits in heterologous association. The heterologous association between two unrelated subunits produces the protomer of aspartate carbamoyltransferase.

Aspartate carbamoyltransferase (Figure 9–37A)³¹⁸ is a hexamer with dihedral symmetry of point group $322(D_3)$ in which each protomer contains two different subunits, a catalytic α subunit and a regulatory β subunit. There are three types of interfaces holding the protein together, six interfaces among the six α subunits of the two trimers, three interfaces between each of the three pairs of β subunits, and six heterologous interfaces,

Figure 9-37: Heterologous interface in aspartate carbamoyltransferase.^{318,319} (A) α -Carbon skeletal drawing of the protomers of aspartate carbamoyltransferase arranged around the molecular axes of symmetry. The drawing was made from the crystallographic molecular model of this heterododecameric protein. The six folded α polypeptides, each with 310 aa, are drawn with gray line segments; the six folded β polypeptides, each with 152 aa, are drawn with black line segments. The view is down the 2-fold rotational axis of dihedral symmetry that passes through the center of the β_2 dimer in the rear. The two other 2-fold rotational axes of dihedral symmetry pass through the centers of the other two β_2 dimers, one to the left and one to the right. The 3-fold rotational axis of symmetry is vertical, in the center of the molecule, and in the plane of the page. The front α subunit of the upper α_3 trimer forms its heterologous interface with the upper subunit of the β_2 dimer to the right to produce one of the protomers of the overall molecule. The participants in each of the other heterologous interfaces, and hence each of the other protomers, can be related to this one by rotations around the axes of symmetry. (B) Detailed view of the heterologous interface between a β subunit and an α subunit. The participants are drawn in exactly the same orientation as those in the interface between the upper β subunit in the β_2 dimer on the left and the α subunit to the back left of the upper α_3 trimer in panel A. Two segments from the β subunit, from Proline $\beta 109$ to Valine $\beta 120$ and from Leucine $\beta 135$ to Phenylalanine $\beta 144$, are drawn with thick line segments; and six segments from the α subunit, Threonine $\alpha 87$ to Aspartate $\alpha 90$, Proline $\alpha 107$ to Leucine $\alpha 114$, Glycine $\alpha 130$ to Glutamine $\alpha 133$, Leucine $\alpha 163$ to Lysine $\alpha 178$, Aspartate $\alpha 190$ to Methionine $\alpha 201$, and Arginine $\alpha 234$ to Aspartate $\alpha 236$, are drawn with thinner line segments. Side chains in all of the segments are drawn with the thinnest line segments. A Zn^{2+} cation is represented by the gray sphere shown covalently bound to three of its four surrounding cysteines. It stabilizes the long, otherwise conformationally uncertain loops from the β subunit. These drawings were produced with MolScript.⁴⁸⁵

one between each α subunit and each β subunit within each of the six protomers. The trimers of α subunits have only limited contacts with each other.

In a molecule of aspartate carbamoyltransferase, each α subunit is associated with a β subunit at a paradigmatic heterologous interface (Figure 9-37B).³¹⁹ One face of the interface is formed from two long loops of random meander from the β subunit stitched in place by a Zn^{2+} ion (gray sphere in Figure 9-37B). These two loops are surrounded by a complementary face created from six segments of the folded α polypeptide: the amino-terminal end of an α helix ($\alpha 87$ to $\alpha 89$); three loops of random meander and β turn ($\alpha 108$ to $\alpha 114$, $\alpha 130$ to $\alpha 133$, and $\alpha 163$ to $\alpha 174$), each between the carboxy-terminal end of a β strand and the amino-terminal end of an α helix; and two loops of random meander ($\alpha 190$ to $\alpha 197$ and $\alpha 234$ to $\alpha 236$), each between two α helices. Consequently, this interface serves as an example of the fact that most intersubunit interfaces, both homologous and heterologous, are formed from loops of random meander and β turns on the surfaces of the respective subunits, while interfaces within a subunit are usually between α helices, β sheets, or an α helix and a β sheet

Figure 9-38: Heterologous associations in the $(\alpha_2)_4\beta_8$ heterohexamer of ribulose-bisphosphate carboxylase from *S. oleracea*.^{41,321} The drawing was made from the crystallographic molecular model of the protein. Four α_2 dimers of 2×473 aa (drawn with thin line segments in front and gray line segments behind) are held together at top and bottom by monomeric β subunits of 123 aa (drawn with thick line segments) to produce an oligomer with dihedral symmetry of point group $422(D_4)$. Each β subunit inserts two long loops of random meander, most readily observed to the right and to the left above and below, into the space between two α subunits. This drawing was produced with MolScript.⁴⁸⁵

(Figures 6-23 through 6-35) in its interior. Because it incorporates a lysine, a histidine, and four glutamates, this heterologous interface in aspartate carbamoyltransferase also reemphasizes the fact that interfaces between subunits incorporate twice as many charged side chains as do interfaces between secondary structures within a subunit.

The heterologous interface between an α subunit and a β subunit of aspartate carbamoyltransferase is formed from two **continuous faces**, one on the surface of each subunit, that fit together as a casting in a mold. The

heterologous interface between elongation factor Tu and elongation factor Ts from *E. coli*, however, incorporates 27 amino acids from the latter protein and 22 amino acids from the former, but they are situated in four **separate clusters**, one of which is formed by the carboxy-terminal α helix of elongation factor Ts that reaches over to sit in a groove on the surface of elongation factor Tu.³²⁰

In ribulose-bisphosphate carboxylase from *Spinacia oleracea* (Figure 9-38),^{41,321} heterologous interfaces between its constituent monomeric β subunits and α_2 dimers hold together the $(\alpha_2)_4\beta_8$ complex around the rotational axes of its dihedral symmetry of point group $422(D_4)$. Unlike the situations in aspartate carbamoyltransferase and the complex of elongation factors Tu and Ts, each β subunit connects two α subunits from two different α_2 dimers around the 4-fold rotational axis of symmetry. Consequently, each β subunit has **two distinct faces** on its surface, one that forms a heterologous interface with one α subunit from one dimer and one that forms a different heterologous interface with another α subunit from another dimer. The majority of each of these two distinct faces on each β subunit is formed by two long loops of random meander sandwiched between the two respective α subunits (Figure 9-38). The loop that is most detached from the β subunit and closest to the center of the heterooligomer has a conserved sequence and is required for proper assembly of the complete protein.³²² One side of each of these two loops associates with one of the α subunits, and the other side of each of these two loops, which necessarily is completely different, associates with the other of the α subunits. The four respective copies of the two different interfaces alternate with each other around the 4-fold rotational axis of symmetry. The protein from *Rhodospirillum rubrum*, which lacks the gene for the β subunit, is an α_2 dimer.³²³

Steric exclusion and mismatched symmetry are complications that can arise whenever an oligomer contains both heterologous associations between different, unrelated subunits and molecular rotational axes of symmetry relating subunits homooligomerically. **Steric exclusion** is the blocking of a face for heterologous association on one subunit of a homooligomer by the association of one of the heterologous subunits with the copy of that face on another subunit of the homooligomer. For example, the binding of a face on the extracellular domain of the immunoglobulin ϵ receptor to one of the two identical, symmetrically displayed, complementary faces on the homodimeric Fc domains of immunoglobulin E sterically blocks the other face on that molecule of immunoglobulin E from associating with another molecule of the receptor.³²⁴

Transthyretin is an $(\alpha_2)_2$ tetramer with dihedral symmetry. Its sole function is to bind retinol-binding protein. The four symmetrically arrayed faces for association with retinol-binding protein are in two adjacent pairs situated on opposite sides of transthyretin. The two

identical faces in each adjacent pair, however, are too close to the 2-fold rotational axis of symmetry around which their two respective subunits are arrayed for each to bind to a retinol-binding protein simultaneously. When a retinol-binding protein binds to one face of a pair on one side of transthyretin, the other face of that pair cannot bind another retinol-binding protein because there is not enough room for it.³²⁵ Because of this steric exclusion, only two of the four identical faces for associating with retinol-binding protein, one on each side of transthyretin, can be occupied at a time, and the complex is a closed $\beta(\alpha_2)_2\beta$ heterohexamer. During the evolution of this heterologous association, the face for binding retinol-binding protein just happened to arise on the surface of a subunit of transthyretin at this site. The realization of the resulting heterologous interface accomplished the function of the protein even though to an intelligent designer it has been accomplished inelegantly.

Mismatched symmetry occurs when the rotational axis of symmetry relating two or more identical faces on one oligomer is of a different fold from or does not coincide with the rotational axis of symmetry relating the two or more identical complementary faces on a different oligomer during the formation of the heterologous association between the two oligomers.

The 2-oxoglutarate dehydrogenase complex provides an example of mismatched symmetry. It is the multienzymatic complex responsible for the oxidative decarboxylation of 2-oxoglutarate. Three different proteins combine together in the complex to accomplish this oxidative decarboxylation: dihydrolipoyllysine-residue succinyltransferase, oxoglutarate dehydrogenase (succinyl-transferring), and dihydrolipoyl dehydrogenase. The octahedral core of the complex is formed from the 24 identical subunits of dihydrolipoyllysine-residue succinyltransferase arranged in octahedral symmetry. Oxoglutarate dehydrogenase (succinyl-transferring) is a symmetric homodimer, and dimers of this protein adorn the outer surface of the central octahedral core. They must each be attached to the core through heterologous interfaces formed between a face on the core and a face on the respective dimer. Because each of the dimers is built around a 2-fold rotational axis of symmetry, it necessarily has two identical faces, each complementary to a face on the core. Because the core is octahedral, it necessarily has 24 identical faces, each complementary to a face on a dimer of oxoglutarate dehydrogenase (succinyl-transferring). The two identical faces on each dimer are arrayed about its 2-fold rotational axis of symmetry; the 24 faces on the core are each arrayed about its octahedral rotational axes of symmetry.

Careful examination of electron micrographs of complexes containing one tetracosamer of dihydrolipoyllysine-residue succinyltransferase but only two dimers of oxoglutarate dehydrogenase (succinyl-transferring)³²⁶ showed that a dimer of the dehydrogenase is

bound to a site on the succinyltransferase midway between one of its 2-fold rotational axes of symmetry and one of its 4-fold rotational axes of symmetry (Figure 9–21B). Therefore only one interface, formed from one face on the dimer and one face on the core, can attach each molecule of oxoglutarate dehydrogenase (succinyl-transferring) to the core because if the two identical faces on the dimer of oxoglutarate dehydrogenase (succinyl-transferring) were both occupied with complementary faces on the dihydrolipoyllysine-residue succinyltransferase, the one 2-fold rotational axis of symmetry of the dehydrogenase would have to coincide with one of the 2-fold rotational axes of symmetry of the succinyltransferase rather than being displaced from it. Only in this arrangement would the two identical faces on the oxoglutarate dehydrogenase (succinyl-transferring) be able to associate with two complementary faces on the dihydrolipoyllysine-residue succinyltransferase. The symmetry-related face on an attached dimer of the dehydrogenase finds itself empty because it is sterically inaccessible to a complementary face on another subunit of the succinyltransferase. This arrangement is a result of the fact that, as might be expected, the complementary faces on the heterologous partners, the octahedral core and the dimer, happened to evolve with no concern for their positions relative to the axes of symmetry. Consequently, their symmetries were mismatched.

In addition to this mismatch of symmetry, the complex between dihydrolipoyllysine-residue succinyltransferase and oxoglutarate dehydrogenase (succinyl-transferring) also displays steric exclusion. For each of the 24 equivalent faces on the octahedral tetracosamer of dihydrolipoyllysine-residue succinyltransferase that is occupied by a dimer of oxoglutarate dehydrogenase (succinyl-transferring), the three other identical faces arrayed around the respective 4-fold rotational axis of symmetry (Figure 9–21B) remain empty³²⁶ because the complementary face on the octahedral succinyltransferase to which a face on the dimer of the dehydrogenase attaches is too close to a 4-fold rotational axis of symmetry and the dimer is too large to permit more than one dimer to bind to the four identical faces around this axis. In the saturated complex between oxoglutarate dehydrogenase (succinyl-transferring) and dihydrolipoyllysine-residue succinyltransferase, there are six heterologous interfaces joining 12 polypeptides of the former and 24 polypeptides of the latter. These **nonstoichiometric ratios of subunits** are dictated by both mismatched symmetry and steric exclusion. Because there are only six heterologous interfaces connecting these two proteins together, only six of the 12 subunits of the dehydrogenase are directly attached to the succinyltransferase, and 18 of the faces on the succinyltransferase and six of the complementary faces on the dimers of the dehydrogenase remain unoccupied.

There are other examples within the family of oxoacid dehydrogenase complexes in which the stoichiome-

Figure 9-39: Heterologous associations among the α subunit of human HLA class I histocompatibility antigen A-2 (HCA α), β_2 microglobulin (β_{2mic}), the α subunit of the B7 isoform of human T-cell receptor (TCR α), and the β subunit of the B7 isoform of human T-cell receptor (TCR β). The skeletal drawing is from the crystallographic molecular model of this complex.^{332,333} The three extracellular amino-terminal domains of the α subunit of human HLA class I histocompatibility antigen A-2 (Glycine 1 to Alanine 90, Glycine 91 to Threonine 182, and Aspartate 183 to Glutamate 275) are drawn with thick line segments. The first two domains of this protein form the oblate disk in the center of the complex, and the carboxy-terminal domain of the three domains is the immunoglobulin modular domain (Table 7-7) at the top left of the drawing. An entire molecule (99 aa) of β_2 microglobulin, which is the β subunit of the histocompatibility antigen, is drawn with thin line segments. This single immunoglobulin modular domain is in the upper right of the drawing. The amino-terminal immunoglobulin modular domain (Leucine 1 to Arginine 111) of the α subunit of isoform B7 of the human T-cell receptor is drawn with thin line segments and is situated in the lower left of the drawing. The amino-terminal immunoglobulin modular domain (Glycine 3 to Leucine 114) of the β subunit of isoform B7 of the human T-cell receptor is drawn with line segments of intermediate thickness and is situated in the lower right of the drawing. At the center of the complex is the nonapeptide LLFEYVYV, drawn with the thickest line segments. This peptide is essential for the formation of the complex. This drawing was produced with MolScript.⁴⁸⁵

try between two different oligomers and the number of interfaces formed in the heterologous complex between the two are dictated by steric exclusion. In the pyruvate dehydrogenase complex from *Bacillus stearother-*

mophilus, only one of the two symmetrically displayed faces on dimeric dihydrolipoyl dehydrogenase is able to associate with the icosahedral dihydrolipoyllysine-residue acetyltransferase because these faces are located too close to the 2-fold rotational axis of symmetry on the dimer to accommodate two of the complementary faces on dihydrolipoyllysine-residue acetyltransferase simultaneously.³²⁷ In the pyruvate dehydrogenase complex from *S. cerevisiae*, only one molecule of E₃-binding protein can bind to each pentagonal face of the icosahedral dihydrolipoyllysine-residue acetyltransferase even though each pentagonal face must have five identical sites for associating with E₃-binding protein.³²⁸ That this low stoichiometry results from steric exclusion follows from the fact that when the pentagonal face is made less crowded by truncating the dihydrolipoyllysine-residue acetyltransferase, more molecules of E₃-binding protein can associate with it.

The stoichiometry of the heterologous association of one homooligomer with another can also be affected by **conformational changes** resulting from the association itself. Only one low-affinity immunoglobulin γ Fc region receptor can associate with the symmetrically dimeric Fc fragment of immunoglobulin G. Its association induces an asymmetric conformational change in the Fc fragment. This conformational change distorts the other face on the Fc fragment so that it cannot assume the conformation required to associate with a receptor even though it is not sterically blocked from doing so by the already bound molecule of the receptor.³²⁹

Most heterooligomeric proteins display no discernible symmetry, but often there are **vestiges of symmetry**, such as the rough 2-fold rotational axis of pseudosymmetry in the complex between growth hormone and its receptor^{330,331} and the local 2-fold rotational axis of pseudosymmetry in the complex between human HLA class I histocompatibility antigen A-2 and human T-cell receptor B7 (Figure 9-39).^{332,333} This latter complex contains four different proteins held together with several asymmetric and pseudosymmetric heterologous interfaces. There are the central heterologous interfaces between the first two domains of the histocompatibility antigen and the α and β subunits of the T-cell receptor, a heterologous interface between β_2 microglobulin and the α subunit of the histocompatibility antigen, and heterologous interfaces between the α and β subunits of the T-cell receptor. The α and β subunits of the T-cell receptor are homologous, and the interface between the two respective domains presented in the figure contains a 2-fold rotational axis of pseudosymmetry. The two amino-terminal domains of the histocompatibility antigen arose from an internal duplication, and they are related by a 2-fold rotational axis of pseudosymmetry. Both of these 2-fold rotational axes of pseudosymmetry coincide so the lower half of the complex in Figure 9-39 has two halves, right and left, that are related by an overall 2-fold rotational axis of pseudosymmetry.

Many heterooligomers are complexes between two proteins held together by **transitory heterologous associations** rather than permanent heterologous associations. These transitory complexes dissociate and associate during the lifetimes of their constituent proteins as required by their function. For example, when 3',5'-cyclic AMP is bound by the regulatory β subunits of cyclic AMP-dependent protein kinase, the catalytic α subunits dissociate from them.^{334,335} The complex between the HLA class I histocompatibility antigen A-2 and the B7 isoform of the T-cell receptor forms only after the histocompatibility antigen has bound a short peptide of a sequence recognized by the T-cell receptor (Figure 9-39).

Many asymmetrical heterooligomers, both those that are permanent and those that are transitory, contain folded polypeptides composed of multiple copies of **modular domains** (Tables 7-7 and 7-8). For example, both the nidogen and the laminin in the permanent equimolar complex between these two proteins³³⁶ contain multiple copies of EGF modular domains among others. Both the HLA class I histocompatibility antigen A-2 and the T-cell receptor are composed of internally repeating domains, most of which are immunoglobulin modular domains (Figure 9-39).

One of the main functions of modular domains is to participate in heterologous associations.³³⁷ For example, the carboxy-terminal EF hand of α actinin forms a complex with the seventh Z-repeat of titin in which the former (see Figure 7-17) wraps around the single α helix that comprises the latter.³³⁸ The WW modular domain of dystrophin forms a complex with the proline-rich motif on β -dystroglycan in which a segment of the latter 5 aa long lies in extended conformation within a complementary groove on the former.³³⁹ The fifth and sixth EF hands of thrombomodulin form a complex with the globular protein α -thrombin through an interface that is formed from two complementary faces, one including surfaces from both of the EF hands and the other a flat continuous surface on the α -thrombin.³⁴⁰

It is their lack of exact symmetry, their transitory nature, and their modularity that distinguishes asymmetric heterooligomers held together entirely by heterologous associations from homooligomers.

The **interfaces producing heterologous associations**, either permanent ones between two unrelated subunits or transitory ones between two unrelated proteins, are as variable in their structure as the interfaces between two identical subunits. They can be almost planar interfaces between two flat faces, as is the interface between T-cell receptor and HLA class I histocompatibility antigen (Figure 9-39),³³³ they can involve terminal segments from one subunit that embrace the body of the other subunit, as in the interface between the α subunit and β subunit in nitrile hydratase from *Rhodococcus*,³⁴¹ or they can be a coiled coil of α helices, one from each of the participants, as in the complex

between syntaxin-1A, synaptobrevin-II, and SNAP-25B.³⁴² In the interface between protein G from *Streptococcus* and murine immunoglobulin G, three β strands from the immunoglobulin and four β strands from the protein G (each six amino acids long) form a continuous, paradigmatic antiparallel β sheet.³⁴³ In the heterologous association between the interleukin-1 receptor and interleukin-1 β , the three consecutive immunoglobulin modular domains of the receptor wrap around the interleukin, surrounding it on three sides.³⁴⁴ The leucine-rich repeats of ribonuclease inhibitor wrap around ribonuclease, also surrounding it on three sides,³⁴⁵ as do 13 of the 18 HEAT repeats of karyopherin β 2 that wrap around GTP-binding nuclear protein RAN.³⁴⁶

An examination³⁴⁷ has been made of the composition of heterologous interfaces that form transitorily between two proteins during the performance of their normal function. The fraction of the accessible surface area of such a transitory interface formed by nonpolar atoms (0.56) is somewhat lower than that in the interfaces holding together permanent oligomers (0.65) and is indistinguishable from that on the solvent-accessible surface of a small globular protein (0.57). The fractions formed by polar but uncharged atoms (0.24) and polar and charged atoms (0.19) are consequently somewhat higher than those in the interfaces of permanent oligomers (0.22 and 0.13, respectively). The same elevation in the fraction of arginine that is observed in the interfaces of permanent oligomers is also observed in the interfaces of transitory oligomers (0.10 of the amino acids in the interfaces) and the same decreases in aspartate and glutamate, but the transient interfaces also show a significant elevation in tyrosine (0.09), a hydrophilic hydrophobe, and significant decreases in valine (0.04) and leucine (0.05), both hydrophobic hydrophobes, relative to the composition of permanent interfaces (0.05, 0.07, and 0.11, respectively). An extreme example of the **elevation in the fraction of charged side chains** in transitory interfaces is the interface between human HLA class I histocompatibility antigen Cw3 and killer cell immunoglobulin-like receptor 2DL2 in which there are five arginines, three aspartates, three glutamates, and two lysines.³⁴⁸

The elevation in the polarity of transitory interfaces is in keeping with the fact that these interfaces are not permanent features; and consequently, the complementary faces on the two proteins must be exposed to the aqueous phase through much of their lives. Within the transitory, heterologous interface between α -thrombin and thrombomodulin, however, most of the side chains are hydrocarbon. In this instance, the problem of the solubility of the separated proteins is solved by surrounding the hydrophobic patch forming the face on α -thrombin with a high density of positively charged side chains and the hydrophobic patch on thrombomodulin with a high density of negatively charged side chains.³⁴⁰ Only five of

these charged side chains actually participate in the interface itself.

A common strategy for heterologous association is the specific **binding of a disordered, structureless segment of polypeptide** within one protein by a structured binding site on another. Upon the binding of the structureless partner to the structured partner, the structureless segment of polypeptide assumes a structure complementary to the structured site.³⁴⁹ In this type of heterologous association, it is only the amino acid sequence of the disordered segment and not its conformation that is recognized by the structured binding site. Consequently, the structureless partner can be mimicked by a synthetic peptide of the proper sequence. For example, the association between troponin I and troponin C can be **blocked by a synthetic peptide** with a sequence only 12 aa in length from the center of troponin I.³⁵⁰ In such a situation, each of the members of a set of overlapping synthetic peptides comprising the complete sequence of the protein providing the structureless partner for the interface can be assayed for its ability to inhibit the heterologous association of the intact protein in order to identify the segment that participates in the association.³⁵¹

Importin- β associates with importin- α by binding the structureless, highly charged (50% arginine, lysine, aspartate, and glutamate) amino-terminal segment (40 aa) of importin- α . The amino-terminal 876 aa of importin- β form 19 internally repeating, modular HEAT domains (46 aa), each consisting of a hairpin of two α helices. In the crystallographic molecular model, the 38 α helices of these 19 internally repeating, modular domains wrap in a spiral around a synthetic peptide of 44 aa with the amino acid sequence of the amino-terminal segment of importin- α . The formation of the complex induces the carboxy-terminal 28 amino acids of the otherwise structureless synthetic peptide to form an α helix aligned with the 38 α helices from importin- β ,³⁵² in a structure resembling a thick section from the trunk of a palm. In the natural heterologous association between importin- α and importin- β , the amino-terminal segment of importin- α , represented by the synthetic peptide in the crystallographic molecular model, is inserted into the middle of the spiral formed by importin- β to form a strong complex between the two proteins.

There are a large number of examples of such heterologous associations mediated by structureless sequences of amino acids. The structureless segment can be located anywhere in the amino acid sequence of a protein. Annexin II associates with protein p11 by binding its amino-terminal 12 amino acids.³⁵³ Tumor necrosis factor receptor-associated factor 2 is a globular trimer, each subunit of which has a binding site for a sequence of six amino acids in the structureless carboxy-terminal portion of the CD40 tumor necrosis factor receptor.³⁵⁴ PDZ Domains can bind to a structureless sequence located either at the carboxy terminus of

another protein or in a portion of polypeptide in the interior of its sequence of amino acids that loops out from its surface.³⁵⁵ Nuclear localization signals are short structureless sequences (5–20 aa) containing several lysines and arginines³⁵⁶ on the surfaces of proteins destined for the nucleus of a cell. Such structureless segments are recognized by being bound to a structured domain of the nuclear import factor karyopherin α , composed of 10 internally repeated armadillo modular domains.³⁵⁷ The Eps15 homology domains are modular domains that bind short segments of polypeptide containing the sequence -Asn-Pro-Phe-³⁵⁸ and in this way produce heterologous associations between a protein containing an Eps15 homology domain and a protein containing a structureless segment of this sequence within its folded polypeptide.

Historically, homooligomers with globular subunits, all arranged around rotational axes of symmetry, accounted for most of the proteins initially purified and studied. There are several reasons for this fact. Most of the proteins present at high concentrations in the cytoplasm and most of the proteins that have enzymatic activity, and hence for which there are obvious assays, are globular homooligomers. Globular homooligomers are also compact, sturdy, and resistant to degradation by endopeptidases. Consequently, globular, homooligomeric enzymes were the easiest proteins to purify.

Proteins the sole function of which is to participate in heterologous associations are more difficult to purify. Such proteins are often assembled by those associations into **large, heterogeneous polymeric matrices**, and until recently, identifying the partners involved in a particular heterologous association has been difficult. Proteins the enzymatic activities of which are **regulated by transient heterologous associations** with other proteins or the substrates of which are other proteins are difficult to assay because several components must be mixed together in the proper ratio. Proteins that **control the enzymatic activities** of the classical enzymes are present in much lower concentrations than those enzymes. Nevertheless, it is proteins engaging in heterologous associations that form large macromolecular structures within the cell and between cells, that control the metabolism carried out by the classical enzymes, and that regulate the expression of genes. Recently, proteins involved in such functions have been purified, identified, and expressed in amounts high enough to be studied functionally and structurally.

These **new proteins** (Table 9–4) are new only because they are present normally in low concentrations, are difficult to assay, or for some other reason are difficult to purify. In addition to their novelty, however, they all seem to share the property of participating in heterologous associations, either among their unrelated subunits or with other proteins. Most of these new proteins are peculiar to eukaryotic cells and the tissues of multicellular organisms. Now that complete genomes are

available for a number of eukaryotes, it has become clear that most of the proteins encoded by the genes in those genomes are new proteins. The examples listed in Table 9–4 illustrate various properties of these new proteins.

One of the most unfortunate features of these new proteins is the **chaos of their nomenclature**. Often the same protein from two different species of organisms will have completely unrelated names. Often the proteins are designated by a number that either derives from the initial genetic screen or from the initial, invariably inaccurate estimate of the length of their constituent polypeptide by electrophoresis on gels cast in solutions of dodecyl sulfate. Often the heterologous subunits of one of these proteins will each have its own peculiar name and the complex between them has another, unrelated name. One has the suspicion that such confusion is intended to discourage individuals outside the narrow field of investigators interested in one or the other of these proteins from learning about them or even realizing that they are normal, unremarkable proteins.

Most of the new proteins contain **internally repeating domains** or widely distributed modular domains⁴⁶⁴ or both of these types of domains. The sole function of many of the modular domains, such as the SH2 domain of proto-oncogene tyrosine-protein kinase ABL1, is to form heterologous associations with other proteins.

Many of these proteins, such as laminin $\alpha 1\beta 1\gamma 1$, integrin $\alpha 2\beta 1$, and guanine nucleotide binding protein G(s), are **heterooligomers**. The $\beta 1$ and $\gamma 1$ subunits of laminin are homologous, but the $\alpha 1$ subunit is unrelated to the others. The subunits of the integrin are unrelated to each other, as are those of the guanine nucleotide binding protein. The heterologous associations between the subunits of integrin $\alpha 2\beta 1$ are permanent, as are those between the subunits of laminin, but the heterologous associations between the α , β , and γ subunits of guanine nucleotide binding protein G(s) are transitory, and they dissociate and reassociate during its normal operation.

Almost all of these new proteins are participants in extensive, intricate **networks of heterologous associations** among many proteins.^{465,466} Each of these networks is responsible for a global function such as the production of the extracellular matrix or controlling the growth and multiplication of the cell. Proteins such as SHC transforming protein 1 form heterologous associations with many different partners and act as hubs in these networks. Proteins such as gelsolin associate with only one or two proteins at the dead ends in a network, while proteins such as α actinin 1 and guanine nucleotide binding protein G(s) link one protein to the next protein within the spokes radiating from the hubs. Some of these proteins can connect one network to another network. Integrin $\alpha 2\beta 1$ connects the network of heterologous associations forming the extracellular matrix to the networks for the cytoskeleton and for cellular regulation through protein kinases. Nucleoporin Nup214 connects the network of heterologous associations forming the

nuclear pore to networks for nuclear import and for cellular regulation.

Many of these proteins are responsible for shifts in the steady state of the cell such as changes in metabolism or the initiation of growth. Consequently, they must detect changes and respond to change by altering the heterologous associations in which they participate. Proteins such as SHC transforming protein 1 and proto-oncogene tyrosine-protein kinase ABL1 form heterologous associations with some proteins only when particular tyrosines on the surfaces of those proteins have been phosphorylated. In this way, they recognize changes produced by intracellular signalling. The heterologous associations in which cyclin participates are permanent, but their status is transitory, changing systematically as the cyclin is rapidly degraded and then more is synthesized. Protein kinases form specific, transitory heterologous associations with their substrate proteins in order to phosphorylate specific serines, threonines, or tyrosines on their surfaces.

Some of the heterologous associations, such as those between α actinin and actin or between laminin and nidogen, are exclusive. Others, such as those between ankyrin and various proteins embedded in the plasma membrane serving as sites of attachment for the cytoskeleton or those between the SH2 modular domains on proto-oncogene tyrosine-protein kinase ABL1 or SHC transforming protein 1 and an array of proteins containing phosphorylated tyrosines signalling changes in the regulatory status of the cell, are **promiscuous**. Transcription initiation factor TFIID recognizes TATA boxes that precede many different genes and then initiates the assembly of the large complex of different proteins responsible for initiating transcription.

Proteins involved in these networks of interactions responsible for particular functions are often identified and assigned a role on the basis of the heterologous associations themselves. There are several ways to detect a heterologous association between two proteins. A complex between two native proteins can be detected by their coelectrophoresis.⁴⁵⁹ A complex between two proteins can be immunoprecipitated with immunoglobulins specific for one of the two, and the fact that the other coprecipitates demonstrates the existence of the complex. Glutathione transferase can be fused to a protein during its expression, and any proteins that participate in heterologous associations with that protein can be identified after isolation of the complex by affinity adsorption with a solid phase to which glutathione has been attached.⁴⁶⁷

It is also possible to screen a library by **phage display**⁴⁶⁸ for a cDNA or a gene encoding a protein that participates in a heterologous interaction with a protein of interest. Fragments of cDNA or genomic DNA are inserted at a particular position in the gene encoding the coat protein pIII of the f1 or M13 bacteriophage. A population of *E. coli* is then infected with these bacteriophage.

Table 9–4: Examples of New Proteins

protein (length of human version)	stoichiometry of subunits	modular domains and internal repeats ^a	function	heterologous associations
E-cadherin ³⁵⁹ (728 aa)	α_2	cadherin modular (5) serine-rich modular (1)	cellular adhesion	integrin $\alpha E\beta 7$, ³⁶⁰ β -catenin, ³⁶¹ other molecules of E-cadherin ^{362,363}
integrin $\alpha 2\beta 1$ ³⁶⁴ (1152 aa, 778 aa)	$\alpha\beta$	von Willebrand factor type A modular (2), cysteine-rich repeat (4), FG-GAP repeat (7)	attaches cell to extracellular matrix	collagen, ³⁶⁵ laminin, ³⁶⁶ chondroadherin, ³⁶⁷ interstitial collagenase, ³⁶⁰ filamin, ³⁶⁸ α actinin, ³⁶⁹ skelemin, ³⁷⁰ integrin cytoplasmic associated protein I, ³⁷¹ receptor 1 for activated protein kinase C, ³⁷² paxillin, ³⁷³ focal adhesion kinase, ³⁷³ integrin-linked kinase, ³⁷⁴ calnexin ³⁷⁵
laminin $\alpha 1 \beta 1 \gamma 1$ ^{376,377} (3058 aa, 1765 aa, 1576 aa)	$\alpha\beta\gamma$	laminin G modular (5), EGF modular (41), laminin modular (2), laminin amino-terminal modular (3)	extracellular matrix	nidogen, ³⁷⁸ integrin $\alpha 2\beta 1$, ³⁶⁶ thrombospondin ³⁷⁹
vitronectin ^{380–382} (459 aa)	α	hemopexin modular (2)	protein in serum and extracellular matrix	integrin $\alpha V\beta 1$, ^{383–385} proteoglycan, ³⁸⁶ plasminogen activator inhibitor type 1 ³⁸⁷
ankyrin 1 ^{388,389} (1880 aa)	α	ankyrin repeat (23), death modular (1)	cytoskeleton	anion exchanger, ³⁹⁰ spectrin, ³⁹¹ Na ⁺ , K ⁺ -exchanging ATPase, ³⁹² Na ⁺ channel, ³⁹³ neuroglian, ³⁹⁴ CD44 antigen ³⁹⁵
α actinin 1 ³⁹⁶ (892 aa)	α_2	calponin modular (2), spectrin modular (4), calcium-binding EF-hand modular (2)	cytoskeleton	actin, ³⁹⁶ vinculin, ^{397–399} titin ^{338,400,401}
gelsolin ^{402,403} (755 aa)	α	gelsolin repeat (6)	sculpts actin	actin, ⁴⁰² caspase-3 ⁴⁰⁴
synaptotagmin 1 ^{405,406} (422 aa)	α	C2 modular (2)	controls traffic of synaptic vesicles	neurexin, ⁴⁰⁷ syntaxin, ⁴⁰⁸ clathrin assembly protein 2 ⁴⁰⁹
nucleolin ^{410,411} (706 aa)		Asp/Glu-rich repeat (3), RNA-binding modular (4), nucleolin repeat (8)	nucleolar component ⁴¹²	chromatin, ⁴¹³ preribosomal particles, ⁴¹⁴ insulin receptor substrate I, ⁴¹⁵ nucleophosmin ⁴¹⁶

nucleoporin Nup214 ⁴¹⁷ (2090 aa)		Pro/Ser/Thr-rich region (1), coiled coil (2), nucleoporin FG repeats (40)	component of nuclear pore	other nucleoporins, mitogen-activated protein kinase, ⁴¹⁸ nuclear RNA export factor 1, ⁴¹⁹ CRM1 protein, ⁴²⁰ CREB-binding protein ⁴²¹
HLA type I histocompatibility antigen A-2 ^{422,423} (341 aa, 99 aa)	$\alpha\beta$	immunoglobulin modular (4)	mediates immune response	T-cell receptor ³³³
cyclin A2 ⁴²⁴ (432 aa)			control of cell cycle	cyclin-dependent kinase 2, ⁴²⁵ cell division control protein 2 homologue, ⁴²⁶ protein CDC20, ⁴²⁷ β 3 endonexin ⁴²⁸
SHC transforming protein 1 ⁴²⁹ (583 aa)		phosphotyrosine interaction domain (1), SH2 modular (1)	intracellular signalling	activated receptors for growth factors, ^{429,430} proteins phosphorylated at tyrosine, ^{431–433} Grb2 protein, ⁴³⁴ mPAL protein, ⁴³⁵ phosphotyrosine phosphatase-PEST, ⁴³⁶ Gads protein ⁴³⁷
proto-oncogene protein-tyrosine kinase ABL1 ^{438–441} (1130 aa)		eukaryotic protein kinase modular (1), SH3 modular (1), SH2 modular (1), Pro-rich domain (1)	intracellular signalling, protein tyrosine kinase	protein substrates, proteins phosphorylated at tyrosine, EphB2 protein tyrosine kinase, ⁴⁴² Wiskott–Aldrich syndrome protein family member 1, ⁴⁴³ actin, ⁴⁴⁴ Abl interactor protein 2b, ⁴⁴⁵ proteins with proline-rich segments ^{446,447}
myosin light chain kinase ⁴⁴⁸ (1914 aa)		protein kinase modular (1), flbronectin type III modular (1), immunoglobulin C2 modular (1), myosin light chain kinase repeats, type I (5) and type II (6)	intracellular signalling, protein serine/threonine kinase	calmodulin, ⁴⁴⁹ myosin regulatory light chain 2
CD45 protein-tyrosine phosphatase ⁴⁵⁰ (1281 aa)		flbronectin type III modular (2), tyrosine-protein-phosphatase modular (2)	intracellular signalling	proteins phosphorylated at tyrosine, semaphorin 4D, ⁴⁵¹ protein CD2, ⁴⁵² protein p56lck ⁴⁵³
guanine nucleotide-binding protein G(s) ^{454,455} (394 aa, 340 aa, 75 aa)	$\alpha\beta\gamma$	G-protein β WD-40 repeat (7)	intracellular signalling	adenylate cyclase, ⁴⁵⁴ β -adrenergic receptor ⁴⁵⁶
transcription initiation factor TFIID ⁴⁵⁷ (339 aa)		polyglutamine domain (1), transcription factor TFIID repeat (2)		TATA box on DNA, ⁴⁵⁷ transcription initiation factor TFIIA, ^{457,458} transcription initiation factor TFIIB, ^{459,460} negative cofactor 1, ⁴⁶¹ negative cofactor 2, ⁴⁶² general transcription factor II-I ⁴⁶³

^aAs listed in the SwissProt data base (www.expasy.ch). Numbers in parentheses are the numbers of each type of domain in the protein.

Each of the resulting bacteriophage that carries an insert has pIII coat proteins on its surface, all of which display the segment of amino acids encoded by that insert. Because the point of insertion was chosen to be within an exposed loop in the coat protein, the segment of amino acids displayed is accessible to the solution and capable of interacting with the protein of interest. The protein of interest is covalently attached to a solid phase to produce an affinity adsorbent, and bacteriophage that carry segments of amino acids with which it associates can be purified by successive rounds of affinity adsorption.⁴⁶⁹ The bacteriophage purified by the affinity adsorbent can be plated, plaques can then be individually replicated, and the particular inserts that they carry can be sequenced. The method, however, that has been used most widely to catalogue heterologous associations between large sets of proteins has been the **yeast two-hybrid assay** (Figure 9–40).^{470–472}

At various points on the chromosomal DNA of *S. cerevisiae*, in the vicinities of the genes encoding enzymes involved in the metabolism of galactose, there are sequences of 17 base pairs that are recognized by the regulatory protein GAL4, which activates transcription of these genes when the cell is grown in the presence of galactose or an oligosaccharide containing galactose.⁴⁷¹ These upstream activating sequences for galactose metabolism can be anywhere from 100 to 400 base pairs away from the sites at which transcription of the gene is initiated, and yet binding of regulatory protein GAL4 still activates transcription.

Protein GAL4 contains a domain that binds to the upstream activating sequence in the DNA and a domain that acts at the site of initiation.⁴⁷³ These two domains are connected flexibly so that either the short or the long distances between the binding site on the DNA and the site of initiation can be spanned. The domain of regulatory protein GAL4 that binds to the upstream activating sequence in the DNA is fused to protein X or a portion of protein X. If the domain of regulatory protein GAL4 that activates transcription is fused to protein Y or a portion of protein Y that normally forms a heterologous association with protein X, the heterologous association between protein X and protein Y or the portions of these two proteins will usually be sufficient to position the activating domain effectively when the DNA-binding domain associates with an activating sequence on the DNA. The activation is effective because the requirements of the complex are so flexible that the only property required is a physical connection between the two domains of regulatory protein GAL4. Even a complex in which two other proteins form a noncovalent bridge that then connects protein X and protein Y is sufficient for activation.⁴⁷⁴

When β -galactosidase from *E. coli* is inserted into the DNA of *S. cerevisiae* under the control of a site for the initiation of transcription normally activated by regulatory protein GAL4, the normal version of regulatory

Figure 9–40: Yeast two-hybrid system for detecting heterologous associations.⁴⁷⁰ (A) Regulatory protein GAL4 from *S. cerevisiae* binds to a palindromic sequence of 17 base pairs (the consensus sequence for which is shown)⁴⁷¹ through its DNA-binding domain⁴⁷² and then activates the transcription of a gene, the initiation site for which is from 100 to 400 base pairs away, through the action of its activating domain, which is thought to be flexibly tethered to the DNA-binding domain. When a portion of the GAL1 gene, which is normally activated by regulatory protein GAL4, is fused to the *lacZ* gene from *E. coli*, which encodes β -galactosidase, the activation of the GAL1 gene by regulatory protein GAL4 causes high levels of β -galactosidase to be produced by the yeast cell (as indicated by the arrow). (B) Protein X, the partners of which in normally occurring heterologous associations are being sought, is fused to the DNA-binding domain of regulatory protein GAL4. When this fusion protein is expressed alone in a cell that is lacking regulatory protein GAL4, the GAL1 gene is not activated and β -galactosidase does not accumulate. (C) Protein Y, which participates in a normal heterologous association with protein X, is fused to the activating domain of regulatory protein GAL4. When it is coexpressed with the fusion protein between the DNA-binding domain and protein X, protein X and protein Y associate with each other, the activating domain of regulatory protein GAL4 is reassociated with its DNA-binding domain, the GAL1 gene is activated, and the cell fills with β -galactosidase.

protein GAL4 is replaced by the two pieces linked to protein X and protein Y, respectively, and the cell is grown on galactose, β -galactosidase, a protein for which there is an assay producing a bright blue color, will accumulate. Any colonies of cells containing two hybrid GAL4 domains, the respective proteins X and Y of which associate with each other, become blue when the assay is performed, but any colonies containing hybrid GAL4 domains the proteins X and Y of which do not associate do not turn blue.

The yeast two-hybrid assay is performed by choos-

ing one protein or a portion of one protein and fusing its complementary DNA in phase with the DNA encoding the domain of regulatory protein GAL4 that binds to the DNA. This acts as the bait. It is then possible to fuse DNA encoding the domain responsible for activation to fragments of genomic DNA at random. If a protein that associates heterologously with the bait happens to be encoded by the DNA in one of these fragments, it will be caught, the colony containing that fragment will turn blue, and the DNA in the fragment can be sequenced to identify the protein it encodes.⁴⁷⁵

This assay has been automated and applied to discover large numbers of heterologous associations. For example, in one of these **large screenings**, 957 heterologous associations involving 1004 different proteins were identified.⁴⁶⁶ Usually, however, the fishing is for the partners of a particular protein of interest to the investigator. For example, when cDNA for human cyclin A (Table 9–4) was used as the bait and fragments of the yeast genome as the fish, three positive colonies were identified.⁴²⁸ One of the proteins identified in this way was cyclin-dependent kinase inhibitor 1, a protein already known to form complexes containing cyclin A, but the other two, protein CDC20 and $\beta 3$ endonexin, represented novel associations. Once candidates for heterologous association have been identified with the yeast two-hybrid system, the validity of the associations must be established in more extensive studies of the two isolated proteins, as was done for the associations between cyclin A and $\beta 3$ endonexin⁴²⁸ and between cyclin A and protein CDC20.⁴²⁷

To establish the strength of the heterologous association between two proteins, its **dissociation constant** can be measured. As with any measurement of a dissociation constant, the molar concentration of the complex is followed as a function of the molar concentrations of the two unassociated proteins (Problem 5–7). The complex between the proto-oncogene protein c-fos and transcription factor AP-1 could be identified by the quenching of a fluorescent functional group on proto-oncogene protein c-fos by a fluorescent functional group on transcription factor AP-1, and a dissociation constant of 20 nM could be calculated from the changes in fluorescence as a function of the concentrations of the two proteins.⁴⁷⁶

The heterologous interfaces between two proteins are often probed by **cross-linking**^{477,478} or by **site-directed mutation**. To make sense of either of these types of experiments, a crystallographic molecular model of at least one of the participants must be available. In the case of site-directed mutation, changes are made at particular sites on the surface of the model, and the effects of these mutations on the strength of the association between the two proteins are assessed.⁴⁷⁹ It has also been possible to identify neighbors across the interface by discovering mutations in one of the proteins that compensate for mutations in the other protein that weaken the association by restrengthening it.⁴⁸⁰

Such experiments often identify a cluster of amino acids on the surface of the crystallographic molecular model of the protein, and this cluster is then assumed to represent the face participating in the interface holding the two proteins together. The heterologous interface between human somatotropin and human somatotropin receptor was probed by site-directed mutation of the somatotropin.^{481,482} Sixty-six side chains, located consecutively in three segments of the overall amino acid sequence of somatotropin, were mutated one by one to alanine, and the effect of each of these mutations on the association between somatotropin and its receptor was quantified by measuring the dissociation constant of the complex. Fourteen of these mutations produced what were judged to be significant increases in the dissociation constant, and those 14 side chains were found to form a cluster on the surface of the crystallographic molecular model of somatotropin, which was available at that time. In the crystallographic molecular model of the complex between human somatotropin and its receptor that became available subsequently, seven of those 14 side chains were found to be located within one of the interfaces.³³⁰

The difficulty in evaluating such sets of site-directed mutations is that often the change in the strength of the interaction produced by each individual mutation is not large,^{479,483} so a distinction between a mutation within the interface and one without the interface is difficult to make. When an amino acid critically involved in an interface is mutated, changes as large as 500-fold in the dissociation constant have been observed,⁴⁸⁴ so it is difficult to evaluate changes of less than 10-fold. For example, those 14 mutations judged to have a significant effect on the association of somatotropin with its receptor increased the dissociation constant by factors of only 4–20, while 14 of the mutations judged to be insignificant nevertheless increased the dissociation constant by factors of 2–3. The distinction appears to be arbitrary. Another problem is that during the formation of an interface of any kind, a conformational change may be required to occur in a portion of one or the other of the proteins in order for the proper fit between the faces to be achieved. Any mutation that hinders this conformational change will disrupt the association even if it is not in a side chain that ends up within the interface. In the case of somatotropin, four of the mutations to side chains that are not incorporated into the interface, but which nevertheless did increase the dissociation constant between somatotropin and its receptor by factors of 4–15, are to side chains that are located in a segment of random meander in free somatotropin that becomes ordered upon its association with the receptor.

Chapter 10

Chemical Probes of Structure

Although there are systematic programs to crystallize as many of the available proteins as possible, crystallographic molecular models have been obtained so far for only a minority of the proteins that have been purified. This is not only a problem of time. There are a number of technical problems associated with the crystallographic method, and these have proved baffling in many instances. Often a purified protein has not been crystallized. Often the crystals of protein deteriorate too rapidly in the beam of X-rays. Often the space group is too complex to permit a ready solution. Often the crystals of a particular protein are microscopically disordered. Often usable isomorphous replacements have not been obtained.

There are indications that many of these problems will be solved eventually. It seems that the extensive purifications required for proteins that are naturally present in low concentrations produces unnoticed alterations leading to undetected heterogeneities in the final preparation that interfere with crystallization. When such a protein is produced at high concentrations in an appropriate expression system so that only a few steps of purification are required, attempts to crystallize that protein become significantly more successful. Crystals of membrane-spanning proteins, a class of proteins that are quite difficult to crystallize, have been obtained more and more frequently and used successfully for high-resolution crystallography. The development of charge-coupled detectors, which permit a complete data set to be gathered in a short period of time, has decreased the required length of exposure to the beam. Changing the conditions of crystallization¹ or the species from which the protein has been purified² can sometimes give crystals that have a different space group or are more ordered. As more reagents containing heavy metals become available, the odds against finding a suitable set of isomorphous replacements decrease. Yet it still seems possible that the majority of the proteins that have been or will be purified may never yield high-resolution maps of electron density.

In the absence of a map of electron density, the molecular structure of a protein is studied by a diverse collection of techniques. These approaches can be conveniently divided into three classes: the use of chemical probes, the use of immunochemical probes, and the use of physical measurements.

Covalent Modification

Several types of amino acids in a molecule of protein are susceptible to covalent modification. As most of the reactive functional groups in a protein are **nucleophiles**, the reagents used to modify proteins are usually **electrophiles**. Serine and threonine contain nucleophilic oxygens, but they are indistinguishable from those of the water and cannot be easily modified. The amino acids possessing nucleophilic sites that can be conveniently modified are cysteines, methionines, lysines, histidines, tyrosines, glutamates, aspartates, arginines, and tryptophans. The electrophilic reagents that are used to modify these amino acids couple the electrophile covalently to them. In the process, the ability of the amino acid to act as an acid, a base, or a donor or acceptor of a hydrogen bond is usually lost because an atom of the electrophile, usually a carbon, forms a covalent bond to the conjugate base of the central heteroatom. The proton that previously occupied the conjugate acid of the conjugate base, which is the smallest possible atom, is replaced with the whole molecular structure of the electrophile, and this also increases the size of the side chain dramatically. After its modification, the amino acid is no longer able to participate in any particular role it might have had in the function of the protein and is no longer able to fit into the same space. Accordingly, the function or the structure of the protein or both is usually disrupted.

Chemical modifications of amino acids in a protein are used for many different purposes. Most of the uses are designed imaginatively to answer a particular question about a particular protein, so it is impossible to give an exhaustive list of the reasons for covalently modifying amino acids in proteins. A few examples, however, will indicate why such experiments are so common.

The most common purpose for using covalent modification is to demonstrate that a particular type of amino acid is involved in the **function** of the protein. For example, fibrinogen, upon activation, polymerizes to form long helical polymers that produce a clot. The initial polymerization is noncovalent, but the polymer is then strengthened by posttranslational cross-links. When the lysines of fibrinogen were modified by amidination, the initial noncovalent polymer could form normally, but the covalent cross-links could not.³ This evidence was the basis for the prediction that the posttranslational cross-links were amides between gluta-

mates and lysines. The most common use of covalent modification to study the function of a protein is the observation of the inactivation of an enzyme by covalent modification of amino acids in its active site. For example, the chemical modification of Lysine 116 in spinach ferredoxin-NADP⁺ reductase inactivates the enzyme.⁴

There are, however, many other purposes for covalently modifying proteins. Covalent modification can be used to **dissociate the subunits** of a protein. For example, succinylation of its lysines caused the hemerythrin of *Goldfingia gouldi* to dissociate into its eight identical subunits.⁵ Covalent modification can also be used to change the electrophoretic mobility of a protein by converting, for example, positively charged lysines into negatively charged carboxylates.⁶ When such a modification is performed reversibly, the protein will travel with a different electrophoretic mobility before the modification has been reversed than after it has been reversed. Covalent modification of a protein can be used to prevent endopeptidolytic enzymes, for example, trypsin, from digesting that protein at particular amino acids, for example, arginine.⁷ Covalent modifications are also used to **introduce foreign functional groups** into proteins. For example, functional groups that absorb visible light⁸ or have strong fluorescence⁹ may be introduced so that their spectral properties can be used in physical studies.

When a protein is modified covalently, either the modification is performed under conditions that produce a **high yield** of the desired product, and this is used in further experiments, or the chemical reaction itself between the protein and the reagent is monitored, and its **kinetics** are used to make arguments about the properties of a particular amino acid in the native protein. For example, the dependence of the rate of the modification of a particular amino acid on the pH of the solution can be used to estimate the pK_a of that amino acid in the native protein.^{10,11} Differences in rate constants for the reaction of amino acids of a particular type with the same electrophile can be used to assess differences in their accessibility to the solution in the native structure of the protein.¹²

In all of these experiments, the possibility that the covalent modification itself disrupts the **global conformation** of the protein must always be kept in mind. If this happens, effects of the modification on the function of the protein might be attributed to local changes around the specific amino acid that has been modified when they actually result from the disruption of the entire structure of the protein. The modified protein should always be examined to rule out this possibility. For example, it could be shown by following electrophoretic mobility, sedimentation rate in the ultracentrifuge, and optical rotation that exhaustive amidination of the lysines in either serum albumin or immunoglobulin G had no measurable effect on the structures of these proteins.¹³

In designing an experiment that involves the covalent modification of a protein, the usual desire is that the reagent chosen react with only one type of amino acid. Because cysteines, methionines, lysines, histidines, and tyrosines are similarly reactive nucleophiles, this is not a simple task. The issue of **specificity** is best addressed by examining the reaction of a simple alkylating agent, such as iodoacetamide, with the nucleophiles present in a protein.

Iodoacetamide has been shown to alkylate cysteines, lysines, histidines, and methionines.¹⁴ The four reactions are

When a protein is exposed to iodoacetamide, all four of these amino acids disappear from amino acid analyses of the reaction mixtures, at **rates that depend on the pH**,¹⁵ and the carboxymethyl products^{16,17} appear in concert. The first three reactions require that the amino acid be in the form of its **conjugate base**.

The rate of the reaction between **lysine and iodoacetamide** can be described by

$$\frac{d[\text{Lys}]_{\text{TOT}}}{dt} = -k_{\text{Lys}} [\text{iodoacetamide}] [\text{RH}_2\text{N}^\ominus] \quad (10-5)$$

where $[\text{Lys}]_{\text{TOT}}$ is the total concentration of unmodified lysine (both protonated, RNH_3^+ , and unprotonated, $\text{RH}_2\text{N}^\ominus$) at a particular time, t . Substitution of the appropriate terms into Equation 10-5 leads to

$$\frac{d[\text{Lys}]_{\text{TOT}}}{dt} = - \left(\frac{k_{\text{Lys}} K_{\text{aLys}}}{K_{\text{aLys}} + [\text{H}^+]} \right) [\text{iodoacetamide}] [\text{Lys}]_{\text{TOT}} \quad (10-6)$$

where K_{aLys} is the acid dissociation constant for lysine. If the concentration of iodoacetamide is so large that it remains constant throughout the reaction and the pH does not change, Equation 10-6 describes a pseudo-first-order reaction. The pseudo-first-order rate constant, k'_{Lys} , governing the disappearance of lysine with time is

$$k'_{\text{Lys}} = \left(\frac{k_{\text{Lys}} K_{\text{aLys}}}{K_{\text{aLys}} + [\text{H}^+]} \right) [\text{iodoacetamide}] \quad (10-7)$$

and

$$\frac{d[\text{Lys}]_{\text{TOT}}}{dt} = -k'_{\text{Lys}} [\text{Lys}]_{\text{TOT}} \quad (10-8)$$

When this is rearranged

$$\frac{d[\text{Lys}]_{\text{TOT}}}{[\text{Lys}]_{\text{TOT}}} = -k'_{\text{Lys}} dt \quad (10-9)$$

and integrated from $t = 0$ to $t = t$

$$\int_{[\text{Lys}]_{0,\text{TOT}}}^{[\text{Lys}]_{\text{TOT}}} \frac{d[\text{Lys}]_{\text{TOT}}}{[\text{Lys}]_{\text{TOT}}} = \int_0^t -k'_{\text{Lys}} dt \quad (10-10)$$

where $[\text{Lys}]_{0,\text{TOT}}$ is the initial concentration of unmodified lysine

$$\ln \frac{[\text{Lys}]_{\text{TOT}}}{[\text{Lys}]_{0,\text{TOT}}} = -k'_{\text{Lys}} t \quad (10-11)$$

It follows that

$$\ln [\text{Lys}]_{\text{TOT}} = \ln [\text{Lys}]_{0,\text{TOT}} - k'_{\text{Lys}} t \quad (10-12)$$

and

$$[\text{Lys}]_{\text{TOT}} = [\text{Lys}]_{0,\text{TOT}} \exp(-k'_{\text{Lys}} t) \quad (10-13)$$

As in all **first-order reactions**, the rate constant k'_{Lys} is estimated either by fitting the disappearance of unmodified lysine to Equation 10-13 by nonlinear least-squares analysis or from the slope of the line obtained when $\ln [\text{Lys}]_{\text{TOT}}$ is plotted against time.

The other two of the first three reactions (Reactions 10-1 through 10-3) have a formally equivalent mechanism, and the **pseudo-first-order rate constants** of each of them, k'_{Cys} and k'_{His} , are of the same form as k'_{Lys} (Equation 10-7) with the appropriate rate constants, k_{Cys} or k_{His} , and acid dissociation constants, K_{aCys} or K_{aHis} , substituted for k_{Lys} and K_{aLys} , respectively. The variation in each of these rate constants can be presented graphically (Figure 10-1).¹⁵

At values of pH greater than the $\text{p}K_{\text{a}}$ of lysine ($[\text{H}^+] < K_{\text{aLys}}$), almost all of the primary amine is the conjugate base, the rate constant k'_{Lys} is equal to k_{Lys} (Equation 10-7), and the rate of the reaction of lysine with iodoacetamide is independent of pH. At values of pH below $\text{p}K_{\text{aLys}}$ ($[\text{H}^+] > K_{\text{aLys}}$), the concentration of the unprotonated conjugate base of lysine, and hence the rate of its reaction with iodoacetamide (Equation 10-7), decreases by a factor of 10 (1 logarithmic unit) for each decrease of 1 unit in pH (Figure 2-6).

The rate of the reaction of the unprotonated conjugate base of **histidine with iodoacetamide**, which is governed solely by k_{His} (Reaction 10-3), is correlated to the rate of the reaction of the unprotonated conjugate base of lysine with iodoacetamide, k_{Lys} (Reaction 10-2), through the Brønsted relationship:

$$\log \left(\frac{k_{\text{His}}}{k_{\text{Lys}}} \right) = -\beta \log \left(\frac{K_{\text{aHis}}}{K_{\text{aLys}}} \right) \quad (10-14)$$

Figure 10-1: Variation with pH of the logarithm of the pseudo-first-order rate constants, k'_i , for the reaction between a fully accessible and unperturbed methionine, cysteine, histidine, or lysine in a protein with iodoacetamide. The first-order rate constants are on a relative scale with the rate constant of cysteinate anion arbitrarily assigned a value of 1.0. The individual lines were drawn according to the respective forms of Equation 10-7 with values of the pK_a of 6.6 for histidine, 8.7 for cysteine, and 10.5 for lysine. The relative vertical positions of the lines were fixed by assuming that methionine reacts 10 times more slowly than cysteine at pH 5.5, histidine reacts 30 times more slowly than cysteine at pH 5.5, methionine reacts at the same rate at pH 5.5 and 8.5, lysine reacts 2.5 times more quickly than methionine at pH 8.5, and histidine reacts 2 times more slowly than methionine at pH 8.5.¹⁵ The rate of the reaction with cysteine below pH 4 is assumed to be invariant with pH, as is the rate of the reaction with methionine, but with a rate constant less than that of methionine.

In the case illustrated, below pH 8, histidine reacts more rapidly than lysine, while above pH 8, lysine reacts more rapidly than histidine. Such an **inversion in reactivity** occurs because β is usually between 1.0 and 0. If β were 0, the unprotonated conjugate bases of both histidine and lysine would react at equal rates with iodoacetamide ($k_{\text{His}} = k_{\text{Lys}}$), and the curves for lysine and histidine would coincide at values of pH above the pK_a of lysine. If β were equal to 1.0 (Equation 10-14), the rate constants for the modification of both lysine, k'_{Lys} , and histidine, k'_{His} (Equation 10-7), would be equal at low pH and the lines for histidine and lysine in Figure 10-1 would coincide at values of pH less than $pK_{a\text{His}}$. In any case, at values of pH below the pK_a of histidine, the pseudo-first-order rate constant, k'_{His} , for its reaction with iodoacetamide decreases by a factor of 10 for each decrease of 1 unit in pH. At low pH, therefore, the rates of the reactions of both lysine and histidine with iodoacetamide decrease in concert and remain in constant ratio to each other.

The rate constant, k_{Cys} , for the reaction of the unprotonated conjugate base of **cysteine with iodoacetamide** is significantly greater than that of unprotonated lysine. Because sulfur is an element from the third row and nitrogen is an element from the second row of the periodic table, cysteine is more nucleophilic than

lysine, even though the pK_a (8.7) associated with its lone pair of electrons is less than the pK_a (10.5) associated with the lone pair of electrons on lysine.* With the appropriate substitutions, Equation 10-7 governs the behavior of the rate of the reaction of cysteine with iodoacetamide as a function of pH at values of pH above and below the pK_a of cysteine. Cysteine (Reaction 10-1), however, unlike lysine (Reaction 10-2) and histidine (Reaction 10-3), retains two nucleophilic lone pairs of electrons after its protonation and can react with iodoacetamide as the conjugate acid in a reaction analogous to that of methionine (Reaction 10-4).

The reaction of **methionine with iodoacetamide** is invariant with pH because its acid dissociation constant ($pK_{a\text{Met}} = -9$) is below accessible ranges of pH. The rate constant for the reaction of protonated cysteine with iodoacetamide should be lower than the rate constant, k_{Met} , for the reaction of methionine because of hyperconjugation. At low pH, the rate of the reaction of cysteine with iodoacetamide should level off at a value lower than k_{Met} and also should become invariant with pH because the concentration of neutral cysteine is invariant with pH.

The individual behavior of each of the reactions determines the specificity of iodoacetamide. At the lowest values of pH, methionine is the most reactive amino acid. As the pH is increased, into the range where the concentration of the thiolate anion becomes sufficiently large, cysteine becomes the most reactive amino acid at all higher values of pH. As the pH is increased, histidine becomes as reactive as methionine because the lone pair of electrons of its neutral base ($pK_{a\text{His}} = 6.6$) is so much more basic than those of methionine ($pK_{a\text{Met}} = -9$). At even higher values of pH, lysine becomes more reactive than histidine. All of these consequences determine which amino acid reacts most rapidly with iodoacetamide at a particular pH.

The reagent used to modify the amino acids of a protein may itself also be affected by alterations in pH. Methyl acetimidate is an imidoester that modifies lysines with high specificity (Figure 10-2).¹⁸ The specificity results in part from the fact that while the product of the reaction with lysine is a stable amidine, the analogous products with cysteine, methionine, glutamate, aspartate, tyrosine, and histidine are unstable derivatives of acetate and decompose as quickly as they are produced. The effect of pH on the rate of the reactions between amines and imidoesters has been explained mechanistically (Figure 10-2)¹⁸ with the assumption that the reactive form of the lysine is the free base and the reactive form of the imidoester is the cationic conjugate acid. For methyl acetimidate,¹⁹ $pK_{a\text{AI}} = 7.5$, and the concentration of cationic imidoester should be decreasing as the pH is

* The Brønsted relationship does not apply when the central atoms of the two acid-bases differ.

Figure 10-2: Mechanism for the reaction between the free base of lysine and the cationic conjugate acid of methyl acetimidate.¹⁸ The products of the modification can be either the amidine of one lysine, the acetamide of one lysine, or the amidine of two lysines. The latter reaction produces cross-links within the protein but rarely occurs.

raised above pH 7, while that of the free base of lysine should be increasing.

At the higher values of pH where K_{aTV} has little effect, the rate of the reaction between lysine and methyl acetimidate is governed by the equation

$$\frac{d[\text{Lys}]_{\text{TOT}}}{dt} = -k_{\text{AI}} [\text{R}'=\text{NH}_2^+] [\text{RH}_2\text{N}\ominus] \quad (10-15)$$

from which it follows that

$$\frac{d[\text{Lys}]_{\text{TOT}}}{dt} = - \left[\frac{k_{\text{AI}} K_{\text{aLys}} [\text{H}^+]}{(K_{\text{aAI}} + [\text{H}^+])(K_{\text{aLys}} + [\text{H}^+])} \right] [\text{AI}]_{\text{TOT}} [\text{Lys}]_{\text{TOT}} \quad (10-16)$$

where $[\text{AI}]_{\text{TOT}}$ is the total concentration of methyl acetimidate, both conjugate acid, $\text{R}'=\text{NH}_2^+$, and conjugate base, $\text{R}'=\text{NH}$.

If $[\text{AI}]_{\text{TOT}}$ were high and constant throughout the course of the reaction and the pH did not change, Equation 10-16 would describe a pseudo-first-order reaction. The pseudo-first-order rate constant, k'_{AI} , governing the disappearance of lysine with time would be

$$k'_{\text{AI}} = \left[\frac{k_{\text{AI}} K_{\text{aLys}} [\text{H}^+]}{(K_{\text{aAI}} + [\text{H}^+])(K_{\text{aLys}} + [\text{H}^+])} \right] [\text{AI}]_{\text{TOT}} \quad (10-17)$$

When $\text{p}K_{\text{aAI}} < \text{p}K_{\text{aLys}} < \text{pH}$

$$k'_{\text{AI}} = \frac{k_{\text{AI}} [\text{H}^+]}{K_{\text{aAI}}} [\text{AI}]_{\text{TOT}} \quad (10-18)$$

and k'_{AI} would decrease by a factor of 10 for each increase of 1 unit in pH. Between the two acid dissociation constants, when $\text{p}K_{\text{aAI}} < \text{pH} < \text{p}K_{\text{aLys}}$, Equation 10-17 predicts that

$$k'_{\text{AI}} = \frac{k_{\text{AI}} K_{\text{aLys}}}{K_{\text{aAI}}} [\text{AI}]_{\text{TOT}} \quad (10-19)$$

and the rate of the reaction should be almost invariant with pH, and when $\text{pH} < \text{p}K_{\text{aAI}} < \text{p}K_{\text{aLys}}$

$$k'_{\text{AI}} = \frac{k_{\text{AI}} K_{\text{aLys}}}{[\text{H}^+]} [\text{AI}]_{\text{TOT}} \quad (10-20)$$

and k'_{AI} should decrease by a factor of 10 for every decrease of 1 unit in pH. While the reaction of amines with ethyl benzimidate is more complicated than this simple picture,¹⁸ in the case of the reaction of methyl acetimidate with the lysines in unfolded aldolase,¹⁹ the plateau between $\text{p}K_{\text{aAI}}$ and $\text{p}K_{\text{aLys}}$ is observed as predicted by Equation 10-19, and the decrease in the rate of amidination does not occur until below pH 8.0.

The fact that the modification of a protein is usually performed in **aqueous solution** limits the reagents that can be used. On the one hand, problems of solubility of the electrophile often arise, thereby restricting its useful

range of concentrations. On the other hand, because water is itself a nucleophile, decomposition of the reagent through hydrolysis often occurs. Methyl acetimidate, unlike iodoacetamide, reacts quite readily with water. Between pH 6.8 and 8.4, the rate constant for its hydrolysis at 20 °C is 0.02 min^{-1} .¹⁹

When the reagent chosen for a particular modification decomposes rapidly, measurements of its rate of reaction with the protein are complicated by this **decomposition**. In the case of methyl acetimidate, the situation can be represented by the kinetic mechanism

In this situation, where hydrolysis is occurring coincidentally with modification, it can be shown²⁰ that

$$f_{\text{amidine}} = 1 - \exp\left(-\frac{k_1 [\text{AI}]_{0,\text{TOT}}}{k_2}\right) \quad (10-22)$$

where $[\text{AI}]_{0,\text{TOT}}$ is the initial total molar concentration of methyl acetimidate and f_{amidine} is the fraction of the lysine that has been modified when all of the methyl acetimidate has been consumed either by reaction with lysine or by hydrolysis. From Equation 10-22 it follows that

$$\ln\left(\frac{1}{1 - f_{\text{amidine}}}\right) = \frac{k_1}{k_2} [\text{AI}]_{0,\text{TOT}} \quad (10-23)$$

In effect, this relationship allows the reaction to be studied more leisurely. A series of mixtures containing the protein are prepared with increasing concentrations of methyl acetimidate at constant temperature and pH. The reaction is allowed to reach completion. The various fractions of the lysine modified are assessed. From these results and Equation 10-23, estimates of the ratio $k_1 (k_2)^{-1}$ can be determined. If the rate constant k_2 has been measured in a separate experiment under identical conditions, k_1 can be obtained directly.

Alkyl imidoesters, such as **methyl acetimidate**, react specifically and in high yield with **lysine** in proteins. In the case of myoglobin, for example, the two major products of the reaction with methyl acetimidate were proteins amidinated either at every primary amine except Lysine 77 or at every primary amine except the amino terminus.²¹ An amidine ($\text{p}K_{\text{a}} = 12.5$) is positively charged at pH 7, and as a result, no change in the charge of the protein occurs during the amidination of its lysines. The lysines, however, are no longer nucleophilic, and the size of the side chain has increased significantly.

Another way to direct the modification exclusively to lysines is to take advantage of the fact that primary amines such as lysine are the only functional groups on a protein that react with **aldehydes** to form imines (Figure 10-3). The conjugate acid of the resulting imine can then be reduced with sodium borohydride or sodium cyanoborohydride to produce the secondary amine. Both formaldehyde²² and pyridoxal 5'-phosphate²³ have been used as the aldehyde. The former is a more reactive aldehyde and produces much higher yields of alkylated lysine; the latter is more selective and under the proper conditions will modify only the most accessible and nucleophilic lysines in a protein.

Isothiocyanates are also specific for the primary amino groups of lysines, as well as the amino terminus (Figure 3-1), of a protein:

The products of the modification are *N,N'*-dialkylthioureas. Presumably, isothiocyanates are specific for lysine because the products they would form with the other nucleophilic amino acids are unstable under the

Figure 10-3: Reaction of lysine with an aldehyde to form an iminium cation, which can be reduced to the secondary amine with sodium borohydride (NaBH_4) or the less reactive sodium cyanoborohydride (NaCNBH_3). If tritiated sodium borohydride (NaB^3H_4) or tritiated sodium cyanoborohydride (NaCNB^3H_3) is used, tritium is incorporated into one of the alkyl carbons of the secondary amine.

reaction conditions. A similar reaction occurs with **isocyanates**:

The products are *N,N'*-dialkylureas. Alkyl and aryl isocyanates react with cysteine and tyrosine as well but produce products that can be hydrolyzed back to the unmodified amino acids under alkaline conditions,²⁴ to leave only the lysines modified.

A large collection of **acylating agents** react with lysine and also acylate other nucleophilic amino acids.

Figure 10-4: Acylation of lysine with any one of a number of acylating agents in which the acyl carbon is activated by attaching a good leaving group. In the tetra-valent intermediate, the leaving group is expelled, in preference to the nitrogen of the lysine, to produce the derivative of the carboxylic acid that is the acylating agent are the carboxylic acid itself to form the anhydride, *N*-hydroxysuccinimide to form the *N*-hydroxysuccinimide ester, azide anion to form the acyl azide, ethyl carbonic acid to form the acyl ethyl carbonate, imidazole to form the acyl imidazole, or a thiol to form the thioester.

The general reaction performed by these reagents is acyl transfer (Figure 10-4). As in synthetic organic chemistry, the appropriate reagent is chosen on the basis of its electrophilicity. The properties of the leaving group X determine both the electrophilicity and the rate at which the reagent will modify the lysines in a protein. Because the leaving group departs from a Lewis acid, the tetra-valent intermediate, the tendency for the leaving group to depart from a proton will reflect its tendency to depart from the tetra-valent intermediate (Figure 10-4). Therefore, the larger the acid dissociation constant K_{aLG} of the conjugate acid of the leaving group X, the more reactive will be the reagent. If the leaving group is the carboxylic acid itself, the reagent is an anhydride such as trifluoroacetic anhydride ($pK_{aLG} = 0.2$) or acetic anhydride²⁵ ($pK_{aLG} = 4.8$). Other leaving groups on acyl derivatives that have been used in the modification of lysine are azide²⁴ ($pK_{aLG} = 4.7$), *N*-hydroxysuccinimide²⁶ ($pK_{aLG} = 6.0$),²⁷ imidazole²⁵ ($pK_{aLG} = 7.0$), ethyl carbonate²⁸ ($pK_{aLG} = 7$), and ethanethiol²⁹ ($pK_{aLG} = 10.5$).

All of these acylating agents react as readily with cysteine, tyrosine, and histidine as they do with lysine to form the respective *S*-, *O*-, or *N*-acyl derivatives. Unlike the *S*-, *O*-, or *N*-alkyl derivatives formed during the reaction with an alkylating reagent such as iodoacetamide (Reactions 10-1 through 10-4), these acyl derivatives of cysteine, tyrosine, and histidine are unstable and decompose spontaneously or can be decomposed intentionally under conditions that leave the lysines in the modified form. For example, *O*-acetyltyrosine can be hydrolyzed back to tyrosine by treatment with hydroxylamine.³⁰ Often an acylating agent the structure of which causes the undesired derivatives to be particularly unstable can be chosen. For example, the ethoxycarbonyl group is added to tyrosine and histidine as well as lysine when one uses the carbonic acid anhydride, diethyl pyrocarbonate:

(10-26)

The ethoxycarbonyl group, however, can be removed from the histidine and tyrosine by treatment of the modified protein with hydroxylamine.²⁸

Cyclic anhydrides such as succinic anhydride

are frequently used to modify the lysines in a protein. They replace the positively charged primary ammonium cation of lysine with a negatively charged carboxylate. The acylation at lysine can be reversed to regenerate the lysine when maleic anhydride (2,3-dehydrosuccinic anhydride), citraconic anhydride,³¹ or 3,4,5,6-tetrahydrophthalic anhydride is used.⁶

Fluorosulfonic acids are general electrophilic reagents that modify lysine, by *N*-sulfonation, and tyrosine, by *O*-sulfonation. The paradigm for these reagents is 5-(dimethylamino)naphthalene-1-sulfonyl fluoride (dansyl fluoride):

which is a fluorescent reagent for the covalent modification of proteins.³²

Both 2,4-dinitrofluorobenzene (FDNB) and **2,4,6-trinitrobenzenesulfonate** (TNBS)³³

modify lysine by nucleophilic aromatic substitution. The former compound reacts with every nucleophilic amino acid.³⁴ The latter can be confined to react with only cysteine²⁴ and lysine by the proper choice of pH;³³ but the derivative formed with cysteine is unstable, so in the end only lysine is modified. In situations in which particular lysines in a protein are more nucleophilic than the others, modification of the protein even by as promiscuous a reagent as 2,4,6-trinitrobenzenesulfonate can be confined to those few sites. For example, at pH 8.0, only Lysine 332 of the α subunit of ribulose-bisphosphate carboxylase from *Spinacia oleracea* reacts significantly with this otherwise nonspecific arylating reagent.³⁵

As noted previously, alkylating agents such as iodoacetamide and other alkyl halides are electrophiles that react with every nucleophilic amino acid to yield stable products. Informed or uninformed manipulation of the pH can affect the distribution of alkylated products. At low pH, alkylating agents can be used to produce stable derivatives of **methionine** specifically.¹⁷ For example, at slightly acidic values of pH, benzyl bromide alkylates methionine in fumarase quite selectively.³⁶

The reagent that has shown the greatest selectivity for **histidine** is **diethyl pyrocarbonate** (Equation 10-26).²⁸ Usually this selectivity is obtained by running the reaction at a pH slightly below the pK_a for histidine, where the greatest discrimination in favor of histidine, relative to lysine (Equation 10-26), should be manifested (Figure 10-1). Histidine is also susceptible to **photooxidation** in the presence of dyes such as methylene blue or rose bengal.³⁷ Under carefully controlled conditions such photooxidation can be confined to histidine,^{37,38} but usually several other amino acids are destroyed simultaneously.³⁷

One of the most readily modified amino acids in a protein is **cysteine**. At slightly alkaline pH, in the vicinity of its pK_a (Figure 10-1), cysteine is preferentially alkylated by alkyl halides such as iodoacetamide and iodoacetate (Equation 3-17), but one must remain aware of the fact that other nucleophilic amino acids can also be modified. ***N*-Ethylmaleimide** (NEM) is another reagent often used to modify cysteine.³⁹

This reaction is an example of nucleophilic addition to an α,β -unsaturated acyl compound. **2-Vinylpyridine**⁴⁰ is selective for modification of cysteine in a similar reaction. The specificity of these alkylating agents for cysteine depends both upon the fact that sulfur is more nucleophilic than either nitrogen or oxygen and upon the use during the reaction of a pH just below the pK_a of cysteine (Table 2-2) so that modification of lysine is suppressed (Figure 10-1). The possibility of alkylation at other nucleophiles such as lysine⁴¹ must always be considered. For example, the inactivation of spinach ferredoxin-NADP⁺ reductase by *N*-ethylmaleimide results from alkylation of a lysine rather than a cysteine.⁴

Organic mercurials, such as ***p*-chloromercuribenzoate** (PCMB),³⁹ are usually specific for cysteine:

The sulfur-mercury bond, because it is a bond between a soft metal and a soft Lewis base, is significantly covalent and is particularly stable, but it is usually not stable enough to survive subsequent digestion of the protein and chromatography of the peptides.

Cysteine can be converted to *S*-(2-aminoethyl) cysteine by modification with **aziridine** (ethyleneimine):⁴²⁻⁴⁵

The modified side chain is isosteric with the side chain of a lysine and has become a site for tryptic digestion.⁴⁶

5,5'-Dithiobis(2-nitrobenzoate)

participates readily in disulfide interchange with a cysteine (Figure 3-20). The reagent contains a disulfide that is particularly electrophilic⁴⁷ because the nitrothiobenzoate dianion is such a good leaving group ($pK_a < 5$). This causes the equilibrium to lie in favor of mixed disulfides between the cysteines on the protein and 5-thio-2-nitrobenzoate. Unfortunately, these mixed disulfides are also electrophilic. Consequently, the pH of the solution should be well-buffered to prevent further reaction of the mixed disulfide with nucleophiles such as hydroxide ion. The nitrothiobenzoate dianion released during the disulfide interchange between cysteine and 5,5'-dithiobis(2-nitrobenzoate) (**10-2**) is brightly colored ($\epsilon_{412} = 13,600 \text{ M}^{-1} \text{ cm}^{-1}$), and its absorbance can be used to follow the reaction. The situation is complicated, however, by the possibility of side reactions with other nucleophiles releasing extrastochiometric nitrothiobenzoate that increases the absorbance of the solution and by the reaction of the nitrothiobenzoate itself with oxygen that decreases the absorbance of the solution. Well-buffered solutions should be used in the absence of atmospheric oxygen, and the absorbance should be measured continuously. The ease with which this reaction can be followed has led to its wide application to proteins.

Tyrosine is frequently alkylated, acylated, arylated, or sulfonylated inadvertently during modification reactions designed to be restricted to lysines. It can be modified specifically, however, by taking advantage of its elevated susceptibility to **electrophilic aromatic substitution**. As a *p*-alkylphenol, it is activated toward substitution, which is directed to its ortho positions by the

electron-releasing hydroxyl. A simple example of this susceptibility is the facile **iodination** of tyrosine:

Iodide ion is used as the source of the iodine, and it is oxidized to I_2 , IOH, or ICl either chemically⁴⁸ or enzymatically.⁴⁹ Histidine is also iodinated under similar conditions but not so readily as tyrosine.⁴¹ A particularly advantageous method for activating I^- chemically uses *N*-chlorosulfamylphenyl groups covalently incorporated into a solid phase by the *N*-chlorosulfamylation of polystyrene beads.⁵⁰ The covalently attached *N*-chlorosulfamylphenyl groups produce ICl from I^- in a reaction identical to that performed by *N*-chlorobenzenesulfonamide in free solution:

The ICl iodinate tyrosines in the protein, and the attachment of the chlorinating agent to a solid phase inhibits its ability to chlorinate the protein. The most advantageous enzymatic method uses lactoperoxidase. This enzyme converts I^- and H_2O_2 to OI^- and H_2O . Either the OI^- remains bound to the iron of the heme on the enzyme, where it can iodinate a tyrosine on the surface of another protein that has been bound by the lactoperoxidase, or it is released as HOI, which can iodinate a tyrosine on the surface of another protein free in the solution.⁵¹ Iodination is usually used to introduce the radioactive isotope of iodine, ^{125}I , into the protein to make it radioactive.

Diazonium salts also participate in the electrophilic aromatic substitution of tyrosine. 5-Diazonium-1-hydrotetrazole⁵² is a diazonium salt producing a product with tyrosine that absorbs strongly at 550 nm.⁴¹

It reacts readily with histidine as well, but at low pH histidine will be mainly protonated, and the imidazolium cation is inert to electrophilic aromatic substitution.

Tetranitromethane is the reagent used most frequently to modify tyrosine:

The nitration that produces the *o*-nitrotyrosine proceeds by a free radical mechanism.⁵³ The *o*-nitrotyrosine produced absorbs strongly at 428 nm as the nitrophenolate anion. It can be reduced to *o*-aminotyrosine with dithionite.⁵⁴ The hydroxyl of *o*-aminotyrosine has a uniquely low pK_a (4.8), and this fact can be exploited to direct further modification to this location in the protein.⁵⁴ Unlike *O*-acylation and *O*-alkylation, which require the tyrosine to be anionic to react as a nucleophile, the reaction with tetranitromethane proceeds with the neutral tyrosine.

Tryptophan is susceptible to electrophilic aromatic substitution because of its similarity to aniline. For example, tritium can be incorporated specifically into tryptophan in a protein under strongly acidic conditions:⁵⁵

Sulfonyl halides such as 2,4-dinitrobenzenesulfonyl chloride participate in a formal electrophilic aromatic substitution at carbon 2 of tryptophan.⁵⁶

The most peculiar position in tryptophan is the π bond between carbons 2 and 3. This bond displays the properties of an olefin during **bromination** with mild brominating reagents (Equation 3-1) by participating in addition rather than substitution. Under mild conditions a relatively inert brominating agent, 2-[(2-nitrophenyl) sulfonyl]-3-methyl-3'-bromoindolenine (BNPS-skatole), oxidized the tryptophan in micrococcal nuclease to the oxindole,⁵⁷ presumably through an intermediate halo-hydrin:

Only methionine was oxidized at the same time, and it could be regenerated readily by reduction. The use of addition reactions to the olefin in tryptophan to incorporate nucleophiles other than water might be feasible. The bromination, however, often results in cleavage of the polypeptide at the tryptophan (Equation 3-1).

Arginine is modified specifically by **vicinal diones**:

Reagents normally used are diphenylethanedione ($R_1 = R_2 = \text{phenyl}$), *p*-nitrophenylethanedione ($R_1 = \text{C}_6\text{H}_4\text{NO}_2$; $R_2 = \text{H}$), 4-(oxoacetyl)phenoxyacetic acid ($R_1 = \text{C}_6\text{H}_4\text{OCH}_2\text{COOH}$; $R_2 = \text{H}$), and 1,2-cyclohexanedione ($R_1 = \text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_2 = R_2$). In all cases the initial product is the cyclic adduct **10-5**^{7,58} that then dehydrates:

When the reagent is diphenylethanedione, this dehydrated adduct is the final product;⁵⁹ when the reagent is *p*-nitrophenylethanedione⁶⁰ or 4-(oxoacetyl)phenoxyacetic acid, the hydrogen (R_2) permits a Cannizzaro rearrangement that produces iminoimidazolidone **10-6**⁶¹

and when the reagent is cyclohexanedione, a similar rearrangement produces iminoimidazolidone **10-7**.⁶²

The modification of arginine by vicinal diones can also yield products that incorporate additional molecules of the dione. 2,3-Butanedione (**10-4**, $R_1 = R_2 = \text{CH}_3$) under appropriate conditions self-condenses to dimers and trimers that both react with arginine to yield poorly characterized, heterogeneous mixtures of products containing about 3 mol of dione for every mole of arginine.⁶³ Phenyl glyoxal (**10-4**, $R_1 = \text{phenyl}$, $R_2 = \text{H}$) reacts with arginine to produce a product containing 2 mol of dione for every mole of arginine.⁵⁸

The earliest modifications of arginine, with either diphenylethanedione⁶⁴ or 1,2-cyclohexanedione,⁶² were performed at alkaline pH (0.2 M NaOH), and the products were quite stable. The conditions, however, were too harsh to avoid destruction of the polypeptide. It was subsequently noted that the addition of **borate** during the reaction of a protein with 2,3-butanedione accelerated the rate of the reaction at neutral pH and rendered the modification irreversible as long as the borate was present.⁶⁵ The initial product of the reaction of 1,2-cyclohexanedione and arginine, presumably diol **10-5**, could also be stabilized significantly by the addition of borate.⁷ Borate is known to add to vicinal diols, such as sugars, to form cyclic borate diesters:

The addition of borate to cause the reaction with diones to be irreversible under mild conditions has permitted the isolation of modified peptides from proteins modified by 1,2-cyclohexanedione.⁶⁶

Glutamates and **aspartates** are modified with **carbodiimides** (Figure 10-5).⁶⁷ The carbodiimides used can be either hydrophobic, such as dicyclohexylcarbodiimide (DCCD; $R_1 = R_2 = \text{cyclohexyl}$), or hydrophilic and water-soluble, such as *N*-ethyl-*N'*-[3-(dimethylamino)propyl]carbodiimide [EDC; $R_1 = \text{C}_2\text{H}_5$, $R_2 = (\text{CH}_3)_2\text{NHC}_3\text{H}_6$]. The initial product of the

Figure 10-5: Outcomes of the reactions of carbodiimides with aspartate or glutamate. The *O*-acylurea is formed by the direct addition of the carboxylate anion to the protonated carbodiimide. In a rigid, isolated, aprotic environment, the *O*-acylurea might be the final product, but there are two other possible outcomes. If a nucleophile (usually an amine) has been added, or if there is an adjacent nucleophile in the protein (usually a lysine), the *O*-acylurea is an activated carboxylic acid derivative capable of acylating that nucleophile in an acyl exchange reaction ① to give the *N,N'*-dialkylurea as the leaving group and the acyl derivative (usually the amide) of the glutamate or aspartate with either the added nucleophile or the lysine in the protein. If there is no accessible nucleophile, the *O*-acylurea can rearrange, by intramolecular acyl exchange ②, to the *N*-acylurea. Pathway ① is initiated by the attack of the extraneous nucleophile on the activated carboxyl group, and pathway ② is initiated by intramolecular attack of the unprotonated urea nitrogen on the acyl carbon.

reaction is an *O*-acylurea⁶⁷ in which the acyl carbon of the original glutamate or aspartate has been activated by forming an acyl derivative, the leaving group of which is an excellent one because it is the oxygen of an *N,N'*-dialkylurea ($pK_a = 1$).

Four fates await this ***O*-acylurea**. First, if it is buried in a nonnucleophilic environment within the protein and sterically constrained, it will remain as the *O*-acylurea until the protein is unfolded, at which point it will usually hydrolyze back to the unmodified glutamate or aspartate. Second, if it is somewhat buried in a polar environment, but not sterically constrained, the *O*-acylurea will rearrange to the *N*-acylurea, which is stable (pathway ② in Figure 10-5). Dicyclohexylcarbodiimide is often incorporated into a protein in this way. It usually reacts with buried carboxylic acids because it is so hydrophobic, and the buried *O*-acylurea usually survives long enough to rearrange as the protein sits around after the investigator believes the reaction has finished; but the reaction rarely proceeds in high yield. Third, if there is a nucleophilic amino acid in the

protein, for example a lysine, in the vicinity of the *O*-acylurea, an intramolecular adduct, for example an amide, between that amino acid and the glutamate or aspartate will form (pathway ① in Figure 10-5).⁶⁸ Fourth, if an external amine, such as the methyl ester of glycine, has been added in high concentration to the solution, it can react with the *O*-acylurea as it is formed, if it is sterically accessible, and produce the amide between the external amine and the glutamate or aspartate.⁶⁷ In this way, a defined covalent modification of the carboxylate can be made. If the external nucleophile is ammonia, glutamates and aspartates are converted to glutamines and asparagines, respectively.⁶⁹

The practical outcome of each of these four fates is unique. In the first, the native protein is modified by the carbodiimide at glutamate or aspartate but loses the modification upon unfolding. In the second, a stable derivative between the protein and the carbodiimide is formed. In the third, the glutamate or aspartate is stably modified by being intramolecularly cross-linked,⁶⁸ but neither the carbodiimide nor an external amine is incor-

Figure 10-6: Formation of an ethyl carbonic anhydride (Figure 10-4) at a glutamate or aspartate by *N*-(ethoxycarbonyl)-2-ethoxy-1,2-dihydroquinoline. The 2-ethoxy group leaves as the alcohol when the reagent reverts in water to the aromatic *N*-(ethoxycarbonyl)iminium cation. The iminium cation reacts with the carboxylate of a glutamate or an aspartate. The adduct that is formed undergoes an intramolecular, cyclic rearrangement involving an acyl exchange at one end with quinoline as the leaving group and the expulsion of an ester from its adduct with an iminium cation at the other end.

porated into the protein. In the fourth, an external amine but not the carbodiimide is incorporated. Often, regardless of the intentions of the investigator, a combination of all of these outcomes occurs, and the complex mixture of products that results defies any attempt at quantification.

Another reagent used to activate the carboxylates of glutamates and aspartates is *N*-(ethoxycarbonyl)-2-ethoxy-1,2-dihydroquinoline (EEDQ). It activates the carboxylate (Figure 10-6) by forming a mixed ethyl carbonic anhydride ($pK_{aLG} = 7$),⁷⁰ which is an acylating agent (Figure 10-4) that is somewhat less reactive than an *O*-acylurea ($pK_{aLG} = 1$) but capable of the same types of intramolecular or intermolecular reactions with nucleophiles such as a lysine on the same protein or another protein⁷¹ or an amine that has been added to the solution.

***N*-Ethyl-5-phenylisoxazolium-3'-sulfonate** (Woodward's reagent K)⁷² activates glutamates and aspartates⁷³ by forming an enol ester:

In this intermediate enol ester, the acyl carbon of the aspartyl or glutamyl side chain is activated sufficiently to react readily with nucleophiles elsewhere on the protein or with nucleophiles such as amines that have been purposely added to the solution, as does the *O*-acylurea that is the intermediate in the reactions of carbodiimides (Figure 10-5). The acyl group that has been activated with *N*-ethyl-5-phenylisoxazolium-3'-sulfonate is also reactive enough to be reduced with **borohydride ion**, (BH_4^-) to convert the side chain of the aspartate or glutamate to the respective alcohol,⁷⁴ just as an ester can be reduced to the corresponding alcohol by AlH_4^- ion.

Compounds that serve as precursors to nitrenes or carbenes through **photolytic reactions** are reagents that display even less specificity than alkylating agents in the modification of the amino acids in a protein. The fact that they are generated photolytically permits an added level of control over the reaction. The reagent can be equilibrated with the protein and then activated.

Aryl azides, such as phenyl azides or nitrophenyl azides, are the usual precursors for nitrenes. A nitroaryl azide produces a nitroaryl nitrene upon photolysis:

A convenient, widely used reagent for attaching a nitrophenyl azide to other compounds (the R in Reaction 10-41) by nucleophilic aromatic substitution is 4-azido-

2-nitrofluorobenzene. Aliphatic azides have also been observed to insert photolytically into proteins.⁷⁵

A **nitrene** is a nitrogen the four valence orbitals of which are occupied by only six valence electrons. Therefore, it is dramatically electron-deficient and electrophilic. In a **singlet nitrene**, three of these orbitals are occupied by pairs of electrons and one orbital is vacant. In theory, a singlet nitrene, because of its vacant orbital, has a higher preference for insertion into nitrogen–hydrogen or oxygen–hydrogen bonds than carbon–hydrogen bonds because atoms of oxygen or nitrogen attached to carbon are electron-rich. In a **triplet nitrene**, two of the orbitals on nitrogen are each occupied by only one unpaired electron and the other two are occupied by two pairs of electrons. Consequently, a triplet nitrene is a diradical. Theoretically, triplet nitrenes should be able to modify proteins by hydrogen abstraction followed by rebound of the two adjacent monoradicals.⁷⁶ Because hydrogen is usually more easily abstracted from carbon than from oxygen or nitrogen, triplet nitrenes should abstract hydrogen more readily from carbon–hydrogen bonds than either nitrogen–hydrogen or oxygen–hydrogen bonds.

When light is absorbed by an aryl azide, which itself is a singlet, the excited state is initially a singlet excited state that must produce a singlet nitrene because N_2 is a singlet molecule. If the singlet excited state lasts long enough, it can convert to a triplet excited state by **inter-system crossing**. The triplet excited state produces a triplet nitrene and singlet N_2 . The yield of triplet excited state can be increased by adding a triplet sensitizer.⁷⁷ Singlet nitrene itself can turn into triplet nitrene if it survives long enough. In the absence of a sensitizer, only about 10% of the nitrene produced by photolysis of phenyl azide is triplet.⁷⁸

Although it is widely believed that **aryl nitrenes**, such as the phenyl nitrenes or the 3-nitro-4-(alkylamino)phenyl nitrenes usually employed in the modification of proteins, should insert into carbon–hydrogen bonds, a reaction that would require significant yields of the triplet state, the chemistry of such nitrenes belies this belief. In ideal situations, such as the intramolecular insertion in the vapor phase of an aryl nitrene into a tertiary carbon–hydrogen bond four carbons away, a reasonable yield of the *N*-alkylaniline (50%)⁷⁹ is obtained. When, however, phenyl nitrene is generated in cyclohexane by photolysis, no insertion (<30%)⁷⁸ into the solvent is observed, and most of the reaction proceeds with either dimerization of the nitrene itself or the production of aniline by two successive hydrogen abstractions by the triplet. Phenyl nitrene generated by photolysis under the same conditions in hydroxylic solvents such as methanol or propanol inserts into those solvents in high yield (80%).⁷⁸ The products of the photolytic reactions of 4-substituted phenyl nitrenes with water, methyl alcohol, or diethylamine as solvent are the lactams **10-9** (60–90% yield), the 2-methoxy-3-hydroazepines **10-10** (40–80% yield), or the 2-di-

ethylamino-3-hydroazepines **10-11** (90–100% yield), respectively:⁸⁰

The products of the photolytic reaction of 4-methylamino-3-nitrophenyl nitrene with methanol as solvent or 1% diethylamine in methanol are aniline **10-12** (40% yield) and aniline **10-13** (40% yield) or aniline **10-12** (30% yield) and aniline **10-14** (70% yield), respectively:⁸⁰

These products can be explained as the results of nucleophilic addition of solvent or solute to the two electrophilic species engaged in the following equilibrium:

Consequently, the majority of the products from the reaction of an aryl nitrene with a protein should result from reaction with nucleophilic functional groups.

The identity of the amino acids modified by aryl nitrenes are consistent with these general considerations. The modification of rabbit glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) by a *p*-amino-*m*-nitrophenyl nitrene produces the sulfenamide of Cysteine 149 (**10-15**)⁸¹

which, however, could have arisen from either the triplet or the singlet. The photolytic modification of rat phosphoenolpyruvate carboxykinase (GTP) with 8-azidoguanosine 5'-triphosphate produces an intramolecular disulfide between two cysteines in the protein,⁸² presumably arising from the nucleophilic displacement of the 8-aminoguanosine from the initially formed sulfenamide (**10-16**) by an adjacent cysteine. In addition to cysteine, tyrosine and lysine have usually been identified as the reactants with aryl nitrenes, but a leucine, two alanines, and a phenylalanine have also been reported to be modified.^{76,83,84} Singlet aryl nitrenes can insert intramolecularly by electrophilic aromatic substitution into phenyl rings,⁷⁷ and this reaction would explain the modification of phenylalanine.

Carbenes, like nitrenes, have only six valence electrons on one atom, but they are distributed around a carbon instead of nitrogen. The carbenes generally used for the modification of proteins are on secondary carbons. They can be singlets or triplets, and relatively stable examples of both of these electronic states for carbenes have been synthesized.^{85,86} Again, the singlet is the first product and has a significant preference for **insertion into nucleophilic locations** such as nitrogen-hydrogen or oxygen-hydrogen bonds⁸⁷ and, in an aqueous solution of protein, probably reacts before much triplet is formed. The carbene of adamantane, formed by photolysis of adamantyldiazirine, is entirely (>99.9%) singlet and reacts as a strong electrophile to form ylides with the nitrogen of pyridine (Equation 10-43) and the sulfur of thiophene.⁸⁸

The singlet adamantyl carbene can also be protonated on its lone pair of electrons to produce the carbocation

that reacts readily with nucleophilic heteroatoms in reactions analogous to S_N1 substitutions.

Most aliphatic carbenes are prone to **intramolecular rearrangements** that are more rapid than their intermolecular reaction with other molecules in solution.⁸⁸ Reagents must be designed to avoid such rearrangement. The compounds that have proven to be the most efficient and uncomplicated precursors of carbenes unsusceptible to rearrangement are derivatives of 1-trifluoromethyl-1-phenyldiazirines:⁸⁹

The carbene is generated by photolysis. Prior to the advent of these reagents, α -diazoketones, α -diazoacetyl esters, and ethyldiazomalonyl esters were used as precursors of carbenes:⁷⁶

The first application of a carbene as a reagent for the modification of a protein used a diazoacetyl ester of Serine 195 in α chymotrypsin to increase the chances of insertion into other amino acids in the protein. Modifications of a cystine,⁹⁰ a serine other than Serine 195,⁹¹ an alanine,⁹² and a tyrosine⁹¹ were observed. Carbenes have usually been found to display a preference for insertion into oxygen-hydrogen and nitrogen-hydrogen bonds in proteins. They have been observed to modify lysines,⁷⁶ tyrosines,⁸⁷ tryptophans,⁹³ glutamic acids,⁹⁴ and aspartic acids,⁸⁷ but incorporation has also been noted into valine⁸⁷ and glycine.⁷⁶

Two remarkable illustrations of the **preference of carbenes for nitrogen-hydrogen and oxygen-hydrogen bonds** can be found in the use of these reagents to modify amino acids found in polypeptides that in the cell span membranes of phospholipid. In both instances, several precursors for the carbene were used that should have placed it at different respective locations along the polypeptide crossing the phospholipid bilayer; yet in each of the two experiments, the several different carbenes reacted respectively with the same amino acid, in one case a tryptophan⁹³ and in the other case a glutamic acid.⁹⁴ Other amino acids, with readily abstracted hydrogens at tertiary carbons, must have been more accessible

to at least some of these carbenes than the respective tryptophan or glutamic acid into which they eventually inserted. These results demonstrate that carbenes, like nitrenes, are not so promiscuous in their choices of reactants as they are often thought to be.

The products of the reactions between nitrenes and carbenes and proteins have rarely been characterized. In part, this is due to the **low yields** encountered in most of these reactions, presumably because of the tendency of the singlet carbene or singlet nitrene and its rearranged products to insert into water,⁹⁵ the inescapable solvent.

There are other compounds that can be photoactivated to form reactive species that modify proteins. For example, a 5-bromouracil was inserted in place of a thymine within the DNA sequence recognized by general control protein GCN4. When the complex between the protein and the modified DNA was irradiated with ultraviolet light ($\lambda_{\text{max}} = 254 \text{ nm}$), Alanine 238 of the protein had been covalently modified in low yield.⁹⁶ Vanadate anion binds specifically to proteins such as rabbit myosin⁹⁷ and isocitrate lyase from *Escherichia coli*.⁹⁸ Upon photolysis of these complexes, serines in the sites at which the vanadate had bound were photooxidized to products that could be converted by reduction with $\text{Na}[\text{}^3\text{H}]\text{BH}_4$ to $[\text{}^3\text{H}]\text{serine}$.⁹⁷ The incorporated tritium tagged the specific serines modified.

Oxidative cleavage is used to modify the **polyamide backbone** of a protein. In the presence of reducing agents such as ascorbate or dithiothreitol, complexes between Fe^{2+} or Cu^+ and chelators such as tetracycline, *N,N,N',N'*-tetracarboxymethyl-1,2-diaminoethane (EDTA), phenanthroline, or the protein itself convert O_2 or H_2O_2 into reactive species capable of cleaving peptide bonds.⁹⁹⁻¹⁰¹ The products of this cleavage that have been identified so far suggest that several different reactions can bring it about, so no unique mechanism seems to predominate.¹⁰² When the chelated metal is attached in some way to the protein, the cleavages that occur are confined to a few peptide bonds rather than being widely distributed along the polypeptide,^{103,104} an observation suggesting that the reactive species responsible for the cleavage either remain bound to the metallic cation or cannot diffuse very far without being discharged.

The **chelating ligand** surrounding the **metallic cation** is usually attached purposefully to a defined location on the surface of the protein to be modified. The activated products of the reaction cleave a peptide bond immediately adjacent to the place where the cation ends up. For example, the polypeptide in the vicinity of the site with which tetracycline associates on the tetracycline repressor was identified by the oxidative cleavage of the protein produced by the complex between tetracycline and Fe^{2+} .¹⁰³ In this case, the major targets for cleavage were the peptide bonds between positions 103 and 104 and positions 104 and 105. Lower yields of cleavage were observed between positions 55 and 56 and positions 135 and 136 and even lower yields between positions 143 and

144 and positions 146 and 147. If the protein itself has a site at which a structural metallic cation is bound, oxidative cleavage induced by the appropriate cation can map the polypeptide surrounding that site.¹⁰⁴ One advantage of oxidative cleavage of the polypeptide is that it can be readily detected by submitting complexes between dodecyl sulfate and the protein and its fragments to electrophoresis. Mass spectrometry of the resulting fragments can be used to locate the exact points of cleavage.¹⁰³

Site-directed mutation^{105,106} produces the covalent modification of a protein by converting one particular amino acid in its sequence into another of the 20 amino acids. It is also possible to delete amino acids from the sequence of a polypeptide or insert extra amino acids at a particular location with similar techniques. A common goal of both chemical modification and site-directed mutation is to correlate the structure of the protein with its function. An assessment of the effects of either type of modification on the normal function of the protein provides information about the role of the modified amino acid in that function. In order for either approach to place that side chain in a structural context, a crystallographic molecular model of the protein is required to define the location of the modified amino acid.

A strategic distinction, however, exists between covalent modification with chemical reagents and covalent modification by site-directed mutation. In the former procedure, the protein of interest is modified, and the effects of the modification on the function of the protein are assessed before the outcome of the reaction is defined by digesting the protein and then identifying the modified peptides either by mass spectrometry or by chromatographic separation and sequencing. In the latter procedure, any amino acid in the sequence of the protein can be chosen, and this particular modification is then performed before the results are assessed by the effect of the modification on some property of the protein. In the former procedure, the selectivity of the chemical modification is determined by the accessibility and the inherent nucleophilicity of the side chains that are potential targets, properties controlled by the protein and not by the investigator, so the results often contain unexpected information about the relationship between structure and function. In the latter, modification can be performed at any site selected by the investigator with absolute specificity, but the choice of which amino acid to modify and which of the 19 mutations to perform at that site relies on his intuition. Because the intuition of the investigator is usually fallible, informative experiments using site-directed mutation usually require that a crystallographic molecular model be already available to assist in the choice of the site to be modified.

It is also possible to decide to focus one's attention on the **nucleophilicity of a particular side chain** in the sequence of a protein on the basis of the location of that side chain in a crystallographic molecular model, its

position relative to specific features in the sequence, or its identification as an important structural or functional site from other experiments, just as one would choose a particular amino acid in the sequence of a protein for site-directed mutation. To assess its role in the function of the protein, the rate of the reaction of this one particular nucleophilic side chain with one or more appropriately chosen electrophilic reagents can then be followed to probe its accessibility,¹⁰⁷ changes in accessibility under different circumstances,¹⁰⁸ or its intrinsic nucleophilicity.¹⁰⁹ The rate or yield of the modification at this particular side chain can be monitored by repetitively purifying a short peptide containing this amino acid from digests of the protein modified under different conditions or for various intervals of time.¹¹⁰

An effective way to perform the requisite purifications of the products of these reactions rapidly is with an **immunoabsorbent**. Immunoglobulins raised against a synthetic peptide¹¹¹ with the same amino- or carboxy-terminal sequence as the peptide containing the amino acid being modified are used to produce an affinity adsorbent able to capture out of a digest of the protein only the particular peptide containing the modified target.^{112–114} Because the immunoabsorbent recognizes sequences that do not contain the target of the modification, both modified and unmodified versions of the peptide are isolated simultaneously, and the fraction of the side chain chosen for investigation that has been modified in each sample is immediately apparent.¹¹⁰

During the covalent modification of a protein, even with as nonspecific a reagent as iodoacetamide,¹⁵ the various types of amino acids do not react as homogeneous populations. This is most readily discerned when the amount of incorporation into a particular type of amino acid is plotted as a function of the duration of the reaction.¹⁵ If the concentration of reagent remains constant, the natural logarithm of the amount of unmodified amino acid should decrease as a linear function of time because the reaction is pseudo-first-order (Equation 10–12). This is usually not observed, and the disappearance of a particular type of amino acid, such as histidine, lysine, or cysteine, as the modification proceeds usually displays **inhomogeneous kinetics** (Figure 10–7).¹⁵ This can be ascribed to the fact that each histidine, each lysine, or each cysteine in the sequence of the protein is in a different environment in the folded polypeptide and reacts at a unique rate with the reagent. For example, the three histidines of α -lactalbumin can be modified by iodoacetamide, but each reacts at a significantly different rate¹¹⁵ so that the disappearance of total histidine displays inhomogeneous kinetics.

It has already been noted that the environment surrounding a particular amino acid in a protein shifts its apparent acid dissociation constant from the value it would have in an unfolded polypeptide (Table 2–2). Such shifts of the acid dissociation constants from their intrinsic values move each of the inflections of the profiles of

Figure 10–7: Reaction of iodoacetamide with the lysines of glucose-6-phosphate isomerase.¹⁵ Glucose-6-phosphate isomerase (0.12 mM) was mixed with iodoacetamide (49 mM) at pH 8.5 and 40 °C. At the noted times a sample was removed from the solution, the reaction was quenched with 0.3 M 2-mercaptoethanol, and the sample was subjected to total amino acid analysis. The amount of unalkylated lysine (percentage of total) is plotted on a logarithmic scale as a function of time. Reprinted with permission from ref 15. Copyright 1970 *Journal of Biological Chemistry*.

log k'_i against pH (Figure 10–1) horizontally to coincide with the altered value of the respective pK_a and simultaneously move the plateau at high pH vertically in response to the Brønsted relationship (Equation 10–14). A unique shift occurs for each amino acid in the protein. An example of such an effect of environment on the nucleophilicity of acid–bases is provided by a pair of cysteine side chains, Cysteine 3 and Cysteine 32, in seminal ribonuclease.¹¹⁶ These two adjacent cysteines react more rapidly with 5,5′-dithiobis(2-nitrobenzoate) at pH 7 than do model compounds such as cysteine itself or cysteinyl-cysteine. The synthetic peptide MCCRKM, which incorporates the sequence of seminal ribonuclease around these two cysteines, however, has the same enhanced reactivity. It was shown that this enhanced reactivity is due to the fact that the cysteines are adjacent to an arginine and a lysine. These cationic amino acids lower the values of the acid dissociation constants for the two cysteines. Although the nucleophilicities of the thiolate anions also decrease accordingly, the Brønsted coefficient β is small (<0.2). Therefore, the increase in reactivity at pH 7 results from a significant increase in the concentration of the respective thiolate anions, which each have almost the same intrinsic nucleophilicity, k_{Cys} , as a cysteine the pK_a of which has not been lowered.

Although experiments involving covalent modification are usually designed to answer a specific question about a particular protein, there are several **common themes**. Covalent modification is often performed to identify particular amino acids within a binding site for a particular ligand such as a substrate for an enzyme, or the agonist or antagonist of a receptor, or for a segment of DNA. An amino acid involved in the function of a pro-

tein can be identified when its covalent modification inhibits that function. The acid dissociation constant for a particular amino acid in a protein can be determined from the rate of its modification as a function of the pH. The accessibility of particular amino acids to the solvent can be inferred from the rates of their covalent modification. The amino acids incorporated into a transient heterologous interface can be identified by changes in the rates of their modification upon formation of the complex between the two proteins. The close proximity of two amino acids in a protein can be revealed by their covalent cross-linking.

The most common use of covalent modification is to identify amino acids in a **site on a protein for binding a specific ligand**. One way this can be done is to measure the change in the accessibility of a particular amino acid upon the binding of the ligand to the protein. For example, the greater than 4-fold decrease in the rate constant for the reaction between acetic anhydride and Lysine 501 in ovine Na^+/K^+ -exchanging ATPase when MgATP is bound to the enzyme suggested that this lysine participates in the specific interactions between the protein and MgATP when it is bound.¹¹⁷ This suggestion was later verified by a crystallographic molecular model of the complex between ATP and a closely related enzyme.¹¹⁸ Lysines involved in the interface forming the complex between DNA topoisomerase of vaccinia virus and a double helix of DNA were identified by noting significant decreases in the yield of their modification by citraconic anhydride upon formation of the complex.¹¹⁹ In this latter experiment, advantage was taken of the reversibility of the acylation of lysines by citraconic anhydride. The products of the modification were unfolded and modified at the unacylated lysines with *N*-hydroxysuccinimide acetate (Figure 10-4), the citraconyl groups were removed, and the locations of the previously citraconylated lysines were identified by digesting the protein at the deprotected lysines with lysyl endopeptidase and examining the pattern of fragments produced.

Another way that an amino acid in a binding site on a protein is identified is to incorporate a reactive functional group into the ligand itself. For example, it was demonstrated that the amino-terminal threonine produced upon the normal posttranslational cleavage of γ -glutamyltransferase from *E. coli* between Glutamine 390 and Threonine 391 is in the active site of the enzyme because the threonine was covalently modified by 2-amino-4-(fluorophosphono)butanoic acid, an electrophilic mimic of the γ -glutamyl group in glutathione, a substrate of the enzyme.¹²⁰

Covalent modification often leads to the inactivation of a protein and identifies candidates for **functionally important amino acids**. The modification of Lysine 85, Histidine 88, and Histidine 161 in bovine cytochrome *b*₅₆₁ by diethyl pyrocarbonate leads to the inactivation of the fast electron transfer performed by

this protein,¹²¹ a fact suggesting that these two histidines and the lysine participate in this function.

The **pK_a for a particular amino acid** is often estimated from the rate of its reaction with an electrophile as a function of pH. The reaction of acetic anhydride with particular lysines in a protein has been used to monitor their individual acid dissociation constants and nucleophilicities.¹⁰ Because acetic anhydride is rapidly hydrolyzed, the yield of its incorporation at a set pH into a particular lysine in the protein, relative to the yield of its incorporation into an added standard amine, after the reaction has reached completion provides a direct measurement of the relative bimolecular rate constant for its reaction with that particular lysine at that pH. The situation is formally equivalent to Equation 10-21 with k_2 being the rate constant for reaction of the acetic anhydride with the standard amine. If the absolute rate constant for the reaction between acetic anhydride and the standard amine is known, the absolute bimolecular rate constant for the reaction between the lysine of interest and acetic anhydride at that pH can be calculated from the relative rate constant, $k_1(k_2)^{-1}$ in Equation 10-23. The behavior of this absolute rate constant as a function of pH (Figure 10-1) provides an estimate of the pK_a of the lysine.

It is also possible to measure a pK_a directly. For example, the pK_a of Cysteine 25 in papain¹²² was determined to be 8.5 at 25 °C and an ionic strength of 0.5 M¹²³ by following the rate of its reaction with chloroacetamide as a function of pH, the pK_a of Cysteine 115 in UDP-*N*-acetylglucosamine 1-carboxyvinyltransferase from *Enterobacter cloacae* was determined to be 8.3 by following the rate of its reaction with iodoacetamide as a function of pH,¹¹ and the pK_a of Lysine 166 in ribulose-bisphosphate carboxylase from *Rhodospirillum rubrum* was determined to be 7.9 by following the rate of its reaction with 2,4,6-trinitrobenzenesulfonate.³⁵

The reactivity of particular amino acids in the sequence of a protein can provide an indication of their **accessibility** to the aqueous phase. For example, a comparison between the observed rate constant for the reaction of a particular lysine in a protein with acetic anhydride and the rate constant calculated from its observed pK_a provides an estimate of the accessibility of that lysine to the solvent. Knowledge of the Brønsted coefficient β (0.48) and the absolute bimolecular rate constant for the free base of an unhindered lysine ($2700 \text{ M}^{-1} \text{ s}^{-1}$) of normal pK_a (10.8) with acetic anhydride at 10 °C¹⁰ permits the bimolecular rate constant expected for the modification of the free base of a fully accessible lysine with a particular pK_a to be calculated. For example, the pK_a of Lysine 501 in ovine Na^+/K^+ -exchanging ATPase was found to be 10.4, so the rate constant of the reaction of its free base with acetic anhydride at 10 °C should have been $1700 \text{ M}^{-1} \text{ s}^{-1}$.¹⁰⁹ The fact that the rate constant was only $400 \text{ M}^{-1} \text{ s}^{-1}$ indicated that Lysine 501 was not fully exposed on the surface of the protein. In most instances, the apparent accessibility of a particular amino acid is

determined by **steric effects**, engendered by neighboring amino acids in the folded polypeptide or a decrease or increase in its nucleophilicity brought about by its participation in intramolecular **hydrogen bonds**.

Tetranitromethane, which is large and quite polar (**10-3**), reacts with the un-ionized, neutral form of tyrosine. At neutral pH, all of the tyrosines in a protein should be un-ionized, and their modification by tetranitromethane should reflect only their accessibility.¹² There are eight tyrosines in human carbonate dehydratase B, and only three of them, Tyrosine 20, Tyrosine 88, and Tyrosine 114, react with tetranitromethane.¹² Subsequent to this assessment, the protein was studied crystallographically, and in the map of electron density only Tyrosine 20, Tyrosine 88, Tyrosine 114, and Tyrosine 129 were found to be "located on the surface of the molecule."¹²⁴ Aspartate 194 in bovine chymotrypsinogen A could not be modified in the native protein with ethyl glycinate and *N*-ethyl-*N'*-[3-(dimethylamino)propyl]carbodiimide even under conditions where 13 of its 15 carboxylates were modified completely.¹²⁵ Subsequently it was observed that Aspartate 194 is "buried" in the interior of the crystallographic molecular model of chymotrypsinogen.¹²⁶ When fructose-bisphosphate aldolase was modified with methyl acetimidate at high concentrations, only 20 of its 30 lysines were modified.¹²⁷ The 10 unmodified lysines reacted readily when the protein was unfolded, and it could be shown that these were 10 unique lysines in the sequence of the protein, presumably made unreactive by their surroundings in the folded polypeptide.

Site-directed mutation can also be used to monitor the accessibility of particular locations in the amino acid sequence of the protein. An α helix passes across the surface of the crystallographic molecular model of λ repressor.¹²⁸ In this α helix Isoleucine 84 and Methionine 87 are on the face of the α helix directed toward the interior of the protein while Tyrosine 85, Glutamate 86, Tyrosine 88, and Glutamate 89 are on the surface of the α helix that is accessible to the solution. After this observation had been made crystallographically, it was shown that only isoleucine at position 84 and either methionine or isoleucine at position 87, of all of the 20 amino acids, produces a functional protein, but 10-14 of the 20 amino acids can be substituted at the other four positions and still produce a functional protein.¹²⁹

Another covalent modification that has been used to assess the accessibility of particular amino acids in a folded polypeptide is **endopeptidolytic cleavage**. For an endopeptidase to cleave a peptide bond, the polypeptide at that location must be able to enter its active site. This has usually been assumed to require that the susceptible peptide bond be located on a somewhat flexible loop, on the outside surface of the protein, well exposed to the solvent. In the case of chymotrypsinogen A, the endopeptidolytic cleavages of the folded polypeptide that remove the amino acids between Leucine 13 and

Isoleucine 16 and between Tyrosine 146 and Alanine 149 to produce α chymotrypsin occur within two such loops.¹²⁶ In the case of deoxyribonuclease I, however, a less easily explained endopeptidolytic cleavage of the folded polypeptide has been observed. Under the proper set of conditions, chymotrypsin cleaves deoxyribonuclease I completely and exclusively at the peptide bond on the carboxy-terminal side of Tryptophan 178.¹³⁰ In the refined crystallographic molecular model of deoxyribonuclease I,¹³¹ Tryptophan 178 is found in the middle of an α helix that is a rigid feature of the structure. This α helix traverses the outer surface of the protein, but Tryptophan 178 is on the side of the α helix pointed toward the interior and itself is inaccessible. There are, however, no more accessible sites in the protein at which chymotrypsin could cleave, and it may be the case that in solution the α helix containing Tryptophan 178 is in equilibrium with a disordered loop.

Changes in the accessibility of amino acids on the surface of a protein brought about by its participation in an **association with another protein** can be monitored as changes in the yields of their covalent modification. For example, the yields of the reductive methylations of Lysines 50, 61, 68, 113, 284, and 291 with [¹⁴C]formaldehyde and NaCNBH₃ decreased 2-4-fold upon conversion of monomeric actin to helical filaments of actin.¹³² Covalent modification can also introduce bulky groups that sterically inhibit an association between two proteins. For example, when Histidine 40 of actin is modified with diethyl pyrocarbonate¹³³ or when Lysine 61 of actin is modified with fluorescein isothiocyanate,¹³⁴ the modified actin is no longer able to form helical polymers. All of these observations were used as evidence in favor of the molecular model of the helical polymer of actin (Figure 9-1B),¹³⁵ in which all of these amino acids ended up in the interfaces between the monomers. If the model is correct, the formation of the interfaces in the homopolymer should sterically hinder the reductive methylation of the lysines, and the addition of bulky functional groups to these histidines or these lysines on the actin monomers (Equations 10-24 and 10-26) should sterically hinder their polymerization.¹³⁵

The Fe³⁺ chelate **10-17**

10-17

was covalently attached at random to lysines on the surface of sigma factor rpoD isolated from DNA-directed

RNA polymerase of *E. coli*. When the normally occurring complex was formed between this modified protein and DNA-directed RNA polymerase, the tethered Fe^{3+} was able to catalyze cleavage at specific peptide bonds in the DNA-directed RNA polymerase when ascorbate and H_2O_2 were added.¹³⁶ These sites of cleavage identified locations on the surface of the RNA polymerase within or adjacent to the interface between it and sigma factor rpoD. This interface has also been probed by footprinting.

Footprinting is the identification of those peptide bonds on the surface of a protein that are protected from random nonspecific cleavage when that protein forms a complex with another protein. The peptide bonds protected are assumed to be within the footprint of the other protein upon the surface of the protein being examined. That footprint is the portion of the surface of the protein being examined that falls within the heterologous interface. DNA-Directed RNA polymerase from *E. coli* stripped of its sigma factor rpoD is cleaved at 83 different peptide bonds on its surface when it is exposed to the Fe^{3+} chelate of *N,N,N',N'*-tetracarboxymethyl-1,2-diaminoethane in the presence of ascorbate and H_2O_2 . When sigma factor rpoD is reassociated with the DNA-directed RNA polymerase, the cleavage at seven of these sites is prevented.¹³⁷ It was assumed that these seven peptide bonds are within the footprint of sigma factor rpoD upon DNA-directed RNA polymerase.

Covalent cross-linking uses covalent modification to assess the proximity of particular amino acids. The

functional groups at the two ends of a bifunctional cross-linking reagent are usually electrophiles commonly used in monofunctional reagents for the modification of proteins. They can be identical to each other (**8-1** and **8-2**), or they can be two electrophiles with different specificities (**8-3**). They can be connected by a chain of atoms stably bonded or a chain of atoms containing a bond that can be cleaved as desired (**8-3**) to permit later separation and identification of the cross-linked species.

Intramolecular cross-linking can be used to determine juxtapositions in a single folded polypeptide. The simplest example of such cross-links are naturally occurring cystines, which automatically provide evidence for the juxtaposition of two segments of polypeptide,¹³⁸ but there are unnatural, chemical methods for forming cross-links. The bifunctional reagent 2-(*p*-nitrophenyl)-3-(3-carboxy-4-nitrophenyl)thio-1-propene (**10-18**) can undergo a series of reversible addition-eliminations to form bridges between two nucleophilic amino acids (Figure 10-8), either lysines or cysteines.¹³⁹ The reaction is reversible as long as the nitrophenyl group is present to stabilize the carbanion but can be made irreversible by reducing the nitro group with dithionite. Therefore, the reagent can be permitted to step around the protein until the most stable cross-link is formed, and this cross-link can then be locked in by reduction. In this way, two pairs of intramolecular cross-links on bovine pancreatic ribonuclease, one between Lysine 7 and Lysine 37 and the other between Lysine 31 and Lysine 41, could be

Figure 10-8: Mechanism by which 2-(*p*-nitrophenyl)-3-(3-carboxy-4-nitrophenyl)thio-1-propene (**10-18**) cross-links adjacent lysines. The olefin on the *p*-nitrostyrene is activated by the electron-withdrawing capacity of the nitro group and participates in a sequence of reversible, nucleophilic addition-eliminations. Because the adduct is symmetric, two nucleophiles are cross-linked reversibly. In the first step of the reaction, the nitrothiobenzoate (Structure **10-2**) is the preferred leaving group from the asymmetric carbanion, but when the carbanion is then formed between two lysines, either can be the leaving group and the reagent can be passed from lysine to lysine over the surface of the protein. The nitrobenzyl carbanion is not that basic, so its protonation is reversible and this allows the cycles of addition and elimination to proceed. When the reaction is quenched with acid and the nitro group is reduced to the amine, the aminobenzyl proton is no longer acidic and the reagent is fixed in place.

formed in high yield when only 2 molar equivalents of the reagent was added initially to the protein. The β carbons of these two pairs of lysines are 1.3 and 1.1 nm apart, respectively, and each partner in a pair is on the same side of the crystallographic molecular model.

The reagent bromopyruvate is bifunctional by virtue of its alkyl bromide, which is an alkylating agent, and its carbonyl, which can form an imine with a lysine reversibly that can be reduced to the permanent secondary amine with NaCNBH_3 . Bromopyruvate is able to form an imine with Lysine 144 of 2-dehydro-3-deoxy-6-phosphogluconate aldolase and then alkylate Glutamate 56.^{140,141} This observation established the proximity of these two amino acids in the folded polypeptide before the crystallographic molecular model became available.¹⁴²

The participants in **heterologous interfaces** have also been probed by cross-linking. During the contraction of muscle, a complex must form between a subunit of myosin in its helical polymer and actin in its helical polymer (Figure 9-1B). This complex between actin and myosin from rabbit muscle was cross-linked with 1-ethyl-3-[3-(dimethylamino)propyl]carbodiimide, a reagent that couples carboxylates to lysines on the surfaces of proteins (Figure 10-5). The amino-terminal peptide produced by cleavage of actin by hydroxylamine between Asparagine 12 and Glycine 13 and the carboxy-terminal peptide produced by cleavage of actin by cyanogen bromide at Methionine 354 were both found to be cross-linked to myosin in the covalently cross-linked complex.¹⁴³ It was also found that amino acids within the segment of actin between Histidine 40 and Lysine 113 were covalently attached to myosin when the complex between it and actin was cross-linked by *N*-(ethoxycarbonyl)-2-ethoxy-1,2-dihydroquinoline, a reagent that also can couple carboxylates to lysines (Figure 10-6). On the basis of these results, amino acids within these three segments of actin are thought to be within the heterologous interface it forms with myosin.¹⁴⁴

Thiols, either in the form of cysteines in the sequence of the protein or introduced as covalent modifications, can be sites for cross-linking. It is possible to insert cysteines at specific positions in the amino acid sequence of a protein by site-directed mutation and then attempt to form cystines between them.¹⁴⁵ The actual formation of a cystine demonstrates that the two cysteines participating in it were adjacent to each other in the tertiary or quaternary structure of the protein. Proteins can also be modified by 2-iminothiolane to convert lysines to thiols:¹⁴⁶

These thiols are then oxidized to mixed disulfides to cross-link various lysines on the proteins. The 21 folded polypeptides within the 30S subunit of the ribosome have been cross-linked to each other in this way. The various products of the intramolecular cross-linking were identified by two-dimensional gel electrophoresis. During the electrophoresis, the disulfides linking pairs of these polypeptides were reduced by disulfide interchange to unlink them from each other between the first and the second dimension.

With 2-iminothiolane, as well as with dimethyl suberimide,^{147,148} dimethyl adipimide,¹⁴⁹ *N,N'*-1,4-phenylenedimaleimide,^{150,151} tetranitromethane,¹⁵² tartryldi (ϵ -aminocaproyl azide),¹⁵³ and dimethyl 3,3'-dithiobis(propionimide),¹⁵⁴ 26 pairs of covalently cross-linked polypeptides could be unambiguously identified among the products from the reactions of the 30S subunit of the ribosome from *E. coli*.¹⁵⁵ After these results were reported, a crystallographic molecular model of the 30S subunit became available.^{156,157} Five of the cross-linked pairs involved polypeptides S1 and S21, which were not identified in the maps of electron density of the 30S subunit.¹⁵⁷ Of the remaining 21 pairs, nine have significant portions of their folded structure touching each other so intimately that their cross-linking would be expected and four may be near enough to each other in the crystallographic molecular model to be intramolecularly cross-linked by a long linker (Equation 10-46), but three have only a few positions in their sequences close enough to be cross-linked and five are not even near each other in the crystallographic molecular model. These last five cross-linked products must have been the result of intermolecular cross-linking, and some of the others may be as well.

It is also possible to covalently cross-link thiols that have been introduced into a protein with 2-iminothiolane. For example, such inserted thiols can be cross-linked with 4,6-di(bromomethyl)-3,7-dimethyl-1,5-diazabicyclo[3.3.0]octadiene-2,7-dione (dibromobimane):

This reagent makes the final cross-link strongly fluorescent so that peptides containing the cross-linked lysines, still joined together, can be purified to identify their positions in the sequence of the protein.¹⁵⁸

In most experiments involving covalent modification of a protein with an electrophilic reagent, the effect of the modification on the normal function of that protein is first monitored. When a reagent that has an inter-

esting or desirable effect is discovered, the position or positions in the amino acid sequence of the protein at which the modification has occurred must be identified in order to correlate this functional effect with the structure of the protein. This identification is usually made by digesting the modified protein either chemically or enzymatically, isolating the peptides that have been modified, and analyzing them by direct sequencing or by mass spectrometry. The precise **position of the modification in the amino acid sequence** is defined by the appearance of the modified amino acid itself in one of the cycles of sequencing, by the disappearance of the amino acid normally found at that cycle, or from the masses of the fragments produced by bombardment of the vaporized peptide with helium in a tandem **mass spectrometer** (Figure 3–8).

Two inactivated products from the alkylation of bovine pancreatic ribonuclease with iodoacetate could be separated from each other in their native state before they were digested. Each had incorporated one carboxymethyl group. From one of the products, a tryptic peptide (Histidine 105 to Valine 124) containing 1-carboxymethylhistidine at position 119 was isolated; from the other product, a tryptic peptide (Glutamine 11 to Lysine 31) containing 3-carboxymethylhistidine at position 12 was isolated.¹⁵⁹

In the chromatogram of the tryptic digest of ferredoxin–NADP⁺ reductase inactivated with *N*-ethyl[2,3-¹⁴C₂] maleimide (Equation 10–30), there was one major radioactive peak that had the amino acid sequence SVSLCVXR, comprising positions 110–117 in the sequence of the protein. In the sequence of the unmodified protein, the amino acid at position X is a lysine. Because lysine was not observed in that cycle of Edman degradation, because trypsin failed to cleave between the lysine and the arginine as it usually does, and because amino acid analysis of the peptide following its hydrolysis in acid produced a peak at the position of *N*-succinyllysine on the chromatogram (Figure 1–3), the modification could be assigned to Lysine 116.⁴

When γ -glutamyltransferase from *E. coli* that had been covalently modified with 2-amino-4-(fluorophosphono)butanoic acid was digested with lysyl endopeptidase (Figure 3–2) and the resulting peptides were separated by reverse-phase adsorption chromatography, only one previously unobserved peak of absorbance appeared on the chromatogram. A mass spectrum of the peptide responsible for that peak identified it as the peptide TTHYSVDDK (positions 391–399 in the sequence of the protein) into which 1 mole of the phosphorylating agent had been incorporated. A mass spectroscopic determination of the sequence of that peptide (Figure 3–8) identified Threonine 391 as the site of phosphorylation.¹²⁰

When bovine cytochrome *b*₅₆₁ that had been modified with diethyl pyrocarbonate was submitted to matrix-assisted-laser-desorption ionization in a time-of-flight

mass spectrometer, it was observed that the modification had increased the mass of the protein by the equivalent of three ethylpyrocarbonyl groups ($3 \times 72 \text{ Da} \approx 28,253 \text{ Da} - 28,033 \text{ Da}$). When a tryptic digest of the protein was submitted to mass spectrometry, 33 new peptides appeared in the spectrum,* the masses of all but two of which could be explained as the result of modification only at Lysine 85, Histidine 88, and Histidine 161.¹²¹

The advantage of identifying a site of modification chemically is that several different methods of analysis can be applied to the isolated product; the advantages of mass spectrometry are its rapidity and its sensitivity.

Problem 10–1: Mercaptoethanol undergoes the following dissociation:

Suppose the total amount of mercaptoethanol in solution is equal to $[\text{SH}]_{\text{TOT}}$, a quantity you know since you added that much. Suppose, also, that there is a chemical reaction that occurs between only the anion, $\text{HOCH}_2\text{CH}_2\text{S}^-$, and an electrophile, X, and the rate of this reaction is

$$\text{rate} = k[\text{HOCH}_2\text{CH}_2\text{S}^-][\text{X}]$$

As the pH changes, $[\text{HOCH}_2\text{CH}_2\text{S}^-]$ changes although $[\text{SH}]_{\text{TOT}}$ is always the same.

- (A) Show that $\text{rate} = k\{f([\text{H}^+])\}[\text{SH}]_{\text{TOT}}[\text{X}]$
- (B) Give an explicit equation for $f([\text{H}^+])$.

* Of the 31 tryptic peptides, 24 were derivatives of the tryptic peptide from Threonine 83 to Arginine 111 containing Lysine 85 and Histidine 88, and seven were derivatives of the tryptic peptide from Tyrosine 157 to Lysine 191 containing Histidine 161. The various derivatives resulted from incomplete yields of modification, low yields of modification at other histidines in the peptides, and incomplete tryptic digestion.

- (C) Plot $\log [k_{\text{obs}}(k)^{-1}]$ against pH, where $k_{\text{obs}} \equiv k\{f([H^+])\}$. Indicate on the plot where $\text{pH} = \text{p}K_a$.
- (D) At what pH does the rate of the reaction become zero?
- (E) By what factor does the rate decrease for each decrease in pH of 1.00 when $\text{pH} < \text{p}K_a$?

Problem 10-2: Give all of the products and a mechanism for each of the following reactions.

Problem 10-3: Diisopropyl fluorophosphate inhibits serine endopeptidases by specific phosphorylation of the serine in the active site. Papain is an endopeptidase that does not have a serine in its active site. Nevertheless, it reacts with diisopropyl fluorophosphate with the result that 1 mol of phosphate is bound for every mole of enzyme but without loss of enzymatic activity.¹⁶⁰ The reaction between papain and the reagent was carried out with radioactive diisopropyl [³²P]fluorophosphate, the modified protein was digested with chymotrypsin, and the segment of enzyme containing the radioactive label

was isolated. It corresponded to amino acids 112–123 in the sequence of papain: –QVQPYNQGALLY–. What is the most likely site of alkylphosphorylation of papain?

Problem 10-4:

- (A) Draw the structure of the peptide RDVLMKE in the ionization state in which it would exist at pH 1.4. Indicate all lone pairs.

The peptide was modified with iodoacetamide at pH 1.4, 40 °C, for 20 h. Digestion with carboxypeptidase yielded the full complement of glutamic acid from the resulting peptide. Edman degradation yielded the full complement of arginine. It is possible to estimate the number of charges a peptide bears at a certain pH from its behavior on electrophoresis. This was done for the initial peptide and the product from its reaction with iodoacetamide.

pH	charge	
	original peptide	alkylated product
6.5	0	+1
2.1	+3	+4

- (B) Write a stoichiometric mechanism for the reaction that occurred between iodoacetamide and one of the side chains on this peptide.
- (C) How would the product of the reaction with iodoacetamide move on chromatography by cation exchange relative to the unreacted peptide?

Problem 10-5: Write the complete reaction that occurs between a cysteine in a protein and 5,5'-dithiobis (2-nitrobenzoate). Write out the resonance forms of the nitrothiobenzoate dianion. What properties of this dianion do the resonance forms explain?

Problem 10-6: A peptide has the sequence SVEKCYEKP.

- (A) How many charges does the peptide bear at pH 1.9? At pH 5.6?

The peptide was reacted with trimethyloxonium tetrafluoroborate

in aqueous solution at pH 6.0. Three methyl groups were covalently attached to the peptide. When the methylated and unmethylated peptides were examined by electrophoresis, the following result was observed.

- (B) What nucleophiles on the peptide have reacted with the trimethyloxonium cation? Write a mechanism for this reaction. Why is the trimethyloxonium cation so reactive?

Chapter 11

Immunochemical Probes of Structure

Immunoglobulins are proteins found, among other locations, in the blood serum of birds and mammals. Immunoglobulins are also called **antibodies**. In an animal, the function of an immunoglobulin is to recognize a foreign macromolecule, the antigen, by binding to it tightly. An **antigen** is any foreign macromolecule that elicits, upon its introduction into an animal, the production of immunoglobulins capable of binding to it with high affinity. Within the animal, when an antigen has been recognized by being bound to the immunoglobulin, it is usually destroyed. An important point which should be kept in mind is that the primary biological purpose for a particular immunoglobulin is to distinguish one particular foreign, undesirable macromolecule from the myriad of necessary macromolecules indigenous to the animal. Whenever an immunoglobulin makes a mistake by recognizing and binding not only to its antigen but also to one or more of the macromolecules normally present in the animal, these indigenous macromolecules are also destroyed in autoimmune processes detrimental to the animal. Therefore, the immune system has evolved to produce immunoglobulins that are highly specific in their recognition of molecular structure. Almost any macromolecule can serve as an antigen, but proteins are the most common antigens.

Because no predictions can be made as to what foreign antigens will have to be recognized and destroyed during the life of the animal, the immune system must be prepared to make immunoglobulins capable of **binding with high specificity** to any foreign molecule when it is presented to the animal in an antigenic form. An extreme example of the ability of the immune system to produce immunoglobulins able to bind any foreign molecule is the production of immunoglobulins that bind C_{60} fullerene,¹ a form of elemental carbon that is not encountered in any natural setting and that does not resemble any natural antigen.

The **serum** from any mammal or bird contains a wide variety of immunoglobulins, each with its own distinct amino acid sequence and each present in its own distinct concentration. They are the immunoglobulins that have been produced in response to all of the foreign antigens encountered by that particular individual during its peculiar lifetime. This mixture of immunoglobulins is present in the serum at a total concentration of 10–20 mg mL⁻¹.

The immune system of an animal can be stimulated

to produce new immunoglobulins recognizing a particular protein of interest by injecting that protein into the animal. Because the repertoire of immunoglobulins that an animal is capable of producing contains none that would recognize any of its own proteins, or they would be destroyed, the protein injected has to be from another species and different enough from any related indigenous protein to be recognized as foreign. Because the oligosaccharides found on the proteins of animals are so similar and because most species contain every possible sequence of these common oligosaccharides as a result of microheterogeneity, an immunoglobulin specific for an oligosaccharide on the protein from an animal will rarely be produced. There are no such problems, however, in producing immunoglobulins in animals that recognize bacterial oligosaccharides.² Because the immune system has evolved to recognize and destroy foreign organisms such as viruses and bacteria, the surfaces of which are large aggregates of many subunits or many different proteins, small proteins sometimes have to be covalently cross-linked to make them antigenic.³ If the **immunization** is successful, immunoglobulins that bind tightly to the protein that was injected appear at high concentration in the serum of the animal within two months.

The paradigm of the various types of immunoglobulins found in serum is **immunoglobulin G** (Figures 7–13 and 11–1).^{4–6} An immunoglobulin G is composed of two identical heavy α polypeptides ($n_{aa} = 440\text{--}450$) and two identical light β polypeptides ($n_{aa} = 210\text{--}220$).⁵ Each heavy α polypeptide is folded into four **internally repeating, superposable domains** designated V_H , C_{H1} , C_{H2} , and C_{H3} in the order in which they occur in the sequence of the protein. Each light β polypeptide is folded into two internally repeating, superposable domains, V_L and C_L . Each of these six different domains, each approximately 110 amino acids in length and each present in two copies in the intact immunoglobulin G, is superposable in its folded form on each of the other five (Figure 7–13). The V_H and V_L domains associate with each other, the C_L and C_{H1} domains associate with each other, and these associations produce an $\alpha\beta$ heterodimer of one heavy α subunit and one light β subunit. Two of these $\alpha\beta$ heterodimers are associated through their C_{H2} and C_{H3} domains to form the entire immunoglobulin.

An immunoglobulin G can be cut into three pieces. When the intact native protein is treated with papain,^{7,8}

cleavage occurs to the amino-terminal side of the cystines connecting the two heavy α polypeptides within the open, structureless segments (Figure 11-1), and two identical Fab fragments and one **Fc fragment** are produced. The designation Fab arises from the fact that this fragment contains the site that binds the antigen. The designation Fc originally referred to the fact that this fragment could be crystallized. It is now more informative and consistent to consider this the constant fragment. It is because it is constant that it can crystallize. Each of these fragments is a well-behaved, independent, soluble, globular protein. Each contains four of the original 12 internally repeating, superposable domains.

The advantage of using **Fab fragments** in experiments is that they are **univalent**. Each Fab fragment contains only one binding site for the antigen. An intact molecule of immunoglobulin G is necessarily bivalent because, as an $(\alpha\beta)_2$ homodimer, it must have two identical binding sites for antigen (Figure 11-1). The fact that two antigens can be bound by intact immunoglobulin G

complicates some experiments. A **bivalent analogue** of the Fab fragment can be produced by digesting intact immunoglobulin G with pepsin.^{9,10} The pepsin cleaves to the carboxy-terminal side of the cystines between the two heavy α subunits and produces a fragment, $(\text{Fab}')_2$, containing two Fab fragments joined by two or more cystines. The advantage of an $(\text{Fab}')_2$ fragment is that when it is reduced with dithiothreitol or 2-mercaptoethanol, it dissociates into two monovalent Fab' fragments the $\text{C}_{\text{H}}1$ domains of which are slightly longer than those of an Fab fragment. A permanently bivalent fragment that is the same size as an Fab fragment can be made by fusing the cDNAs encoding the V_{L} and V_{H} domains of a particular immunoglobulin. If the two cDNAs are connected to each other by a segment of DNA encoding a segment of flexible polypeptide too short to permit the intramolecular association of the domains in the expressed protein, they associate intermolecularly to form an antiparallel $(\text{V}_{\text{L}}-\text{V}_{\text{H}})_2$ homodimer with two identical sites for binding antigen.¹¹

Figure 11-1: Structure of a molecule of immunoglobulin G. (A) Skeletal drawing of the polypeptide backbone of the crystallographic molecular model of immunoglobulin G⁶ that is presented in stereo in Figure 7-13. This drawing was produced with MolScript.¹⁰³ (B) Diagrammatic representation of the molecule based on the internally repeating domains observed in its amino acid sequences.⁵ (Adapted with permission from ref 5. Copyright 1969 National Academy of Sciences.) The complete molecule is composed of 12 superposable domains, all homologous in amino acid sequence, each about 110 amino acids in length. In the center of each domain is a cystine (S—S) formed between two structurally adjacent cysteines, 60 amino acids apart in the amino acid sequence. A light β polypeptide and a heavy α polypeptide are linked by a cystine at the carboxy terminus of the light β polypeptide, and heavy α polypeptides are linked together by two or more cystines between the hinges that join the three arms. The 12 domains are referred to as variable domain, heavy α polypeptide (V_{H}); constant domain 1, heavy α polypeptide ($\text{C}_{\text{H}}1$); constant domain 2, heavy α polypeptide ($\text{C}_{\text{H}}2$); constant domain 3, heavy α polypeptide ($\text{C}_{\text{H}}3$); variable domain, light β polypeptide (V_{L}); and constant domain, light β polypeptide (C_{L}). Oligosaccharides (CHO) are attached to the two $\text{C}_{\text{H}}2$ domains. The three arms are the two antigen-binding fragments (Fab) and the constant fragment (Fc). The binding sites for the antigens are at the tips of the Fab arms and are formed by the variable domains from heavy and light subunits, respectively. The light dotted lines indicate where papain cleaves the molecule to produce the two Fab fragments and the Fc fragment; the heavy dashed lines indicate where pepsin cleaves the molecule to produce the $(\text{Fab}')_2$ fragment. The Fab fragments are missing the cystines holding the fragments of the heavy α subunits together; the $(\text{Fab}')_2$ fragments include these cystines. The hinges at which the cleavages by endopeptidases occur are indicated by the arrows in panel A.

The flexible, unsupported segments of polypeptide that connect the Fab portions to the Fc portion of an intact immunoglobulin G (Figure 11-1) are usually about 20 aa long but can be as long as 70 aa.¹² These are its **hinges**. It is the open structure of these hinges that permits the papain or the pepsin to cleave the immunoglobulin G into its fragments. Because these hinges are so long, the two Fab portions in an intact immunoglobulin G are constantly moving relative to each other and relative to the Fc portion. When these segments are shortened sufficiently by site-directed mutation, the immunoglobulin becomes rigid.¹³

The **major immunoglobulins** in the serum of a mammal are immunoglobulins G (10–20 mg mL⁻¹), immunoglobulins M (1 mg mL⁻¹), and immunoglobulins A (1 mg mL⁻¹). Each of these immunoglobulins contains light β subunits that are indistinguishable from one type to the next. It is the heavy α subunits, always present in equimolar ratio to the light β subunits, that distinguish one type of immunoglobulin¹⁴ from the other. The heavy α subunits of all of these immunoglobulins are homologous to each other over the first three domains. It is in the peripheral portions of their Fc segments that they differ.

Immunoglobulin M has a longer heavy α polypeptide ($n_{aa} = 570$ –580) than the one in immunoglobulin G by one extra domain, $C_{\mu}4$, which would be the analogue of $C_{H}4$, if $C_{H}4$ existed. Immunoglobulin M is a pentameric complex of five $(\alpha\beta)_2$ heterotetramers held together by cystines among themselves. The cystines cross-link pairs of $C_{\mu}3$ domains to form a pentameric ring of the heterotetramers.

Immunoglobulin A has a heavy α polypeptide only about 30 amino acids ($n_{aa} = 470$ –480)¹⁵ longer than that of immunoglobulin G. Immunoglobulin A is a mixture of monomeric $(\alpha\beta)_2$ heterotetramers similar to those of immunoglobulin G and higher oligomers of $(\alpha\beta)_2$ heterotetramers held together by cystines between their $C_{\alpha}3$ domains.¹⁶

Both immunoglobulins M and A have a short polypeptide J associated with them that may promote their initial oligomerization even before the intertetrameric cystines are formed.¹⁶ Immunoglobulins M and A have their binding sites for antigens in a similar location to those on immunoglobulins G and distant from the regions ($C_{\mu}3$, $C_{\mu}4$, and $C_{\alpha}3$) that account for their distinct oligomeric structures. The only significant differences between these types of immunoglobulins and immunoglobulins G is their size and, hence, their valence. Monovalent Fab fragments can be produced from each.^{14,15,17} Although the injection of an antigen usually stimulates the production of immunoglobulins G, it is not unusual for it to stimulate production of the other types, either instead of or along with immunoglobulins G.

An immunoglobulin of a particular sequence is produced by a **colony of lymphocytes**, all derived from one single cell that was initially stimulated to divide and

manufacture. All members of the colony secrete immunoglobulins with identical α polypeptides and identical β polypeptides. The colony assumes its identity from its pedigree and not from its situation. All of the lymphocytes in the colony are descendants of the same cell, but each member of the colony, like all other lymphocytes, is dispersed by the bloodstream and lymphatic system and wanders independently and at random through the animal as it continuously manufactures its particular immunoglobulin. The sole product of the members of a particular colony is this one immunoglobulin continuously released into the serum and extracellular fluid. Each time a lymphocyte is **stimulated to divide and manufacture** its particular immunoglobulin against a particular antigen, a new colony is established. The particular amino acid sequences of the two subunits of the immunoglobulin produced by a particular colony confer the ability to bind a particular antigen.

Because many (10–100) different lymphocytes are stimulated to divide and manufacture by molecules of the same antigen, many different colonies continuously produce immunoglobulins after exposure of an animal to a particular antigen. Each of these immunoglobulins has a different amino acid sequence, but all are specific for that one antigen. They differ, however, in the location on the surface of the antigen that they recognize and to which they bind and in the strength with which they bind to that location, as reflected in their individual dissociation constants for the binding of antigen. Such a set of immunoglobulins, each capable of recognizing the same antigen but each different from the others, is referred to as a **polyclonal** set. The product of the reaction of an intact animal to an antigen is always a polyclonal set of immunoglobulins, which are present as a complex mixture in the serum of the animal.

In a normal animal, the various colonies are stable contributors to the mixture of immunoglobulins in the serum necessary to deal with antigens in the environment. Occasionally, the controls maintaining the stable population of the colony fail, and one lymphocyte begins to multiply malignantly. This uncontrolled cancerous growth causes an enormous increase in the number of lymphocytes producing an immunoglobulin of just one unique sequence and structure. Such a cancer is referred to as a myeloma. The serum of such individuals contains high concentrations of only one type of immunoglobulin. Such **myeloma proteins** are present in sufficient quantities to be purified, sequenced,⁵ and crystallized.⁴ Myeloma proteins appear by chance as the products of the random malignant transformation of normal lymphocytes, and the antigens to which most myelomas are directed are unknown.

The disadvantage of a myeloma protein is that the investigator cannot choose the antigen against which it is directed. Its advantage is that it can be purified to homogeneity, and the purified protein is necessarily composed of identical copies of the same molecule, each with an

identical ability to recognize the antigen. The advantage of the ability to select the antigen and the advantage of the homogeneity of the product have been combined in the production of **monoclonal immunoglobulins**.¹⁸ In this procedure, lymphocytes from the spleen of a mouse that has been immunized with the antigen of interest are fused with cultured murine myeloma cells that normally secrete a particular myeloma protein or, even better, myeloma cells that have lost their incitement to secrete an immunoglobulin. These cultured myeloma cells are immortal cell lines that were originally derived from a myeloma in a mouse and that continuously grow and divide either in flasks in an incubator or as solid tumors in mice. Hybrids, each produced by the fusion of one lymphocyte and one myeloma cell, are selected on the basis of their ability to grow on a particular medium. The hybrids are then reproduced in dishes as single colonies of cells.

Because each colony in the dish arose from one single cell, the cells in a particular colony produce only the immunoglobulin originally secreted by the parental lymphocyte that fused to the myeloma cell and the myeloma protein originally secreted by that myeloma cell. Therefore, each colony is the offspring of only one lymphocyte in the mouse from which the spleen was taken. If that lymphocyte happened to be producing one of the immunoglobulins directed against the antigen originally injected into the mouse, its offspring can be cultivated for the production of a homogeneous monoclonal immunoglobulin recognizing that antigen. To identify the colonies secreting monoclonal immunoglobulins against the antigen of interest, each colony is individually screened. When a colony producing a monoclonal immunoglobulin that has the desired specificity has been identified by the screen, it is expanded either in culture or in an animal so that significant amounts of that monoclonal immunoglobulin can be produced and purified.

Although a few intact myeloma proteins⁴ and intact monoclonal immunoglobulins (Figure 11-1)¹⁹ have been crystallized and submitted to crystallographic analysis, most of the crystallographic molecular models containing complexes with antigens are those of Fab fragments.^{20,21} The sites on the surface of an intact immunoglobulin that bind tightly to the two respective copies of the antigen are at the far ends of the Fab arms (Figure 11-1), at the tip of the portion of the intact molecule formed from the association of a V_H domain and a V_L domain. The Fab fragment retains this site in its entirety, and it is on the opposite end of the fragment from the carboxy-terminal point of cleavage that produced the Fab fragment. An example of a complex between an Fab fragment and its antigen is that between lysozyme from *Gallus gallus* and the Fab fragment of a murine monoclonal immunoglobulin (Figure 11-2).^{20,22}

In the **complex between an immunoglobulin and its antigen**, the single site on the Fab fragment for binding the antigen is formed from six loops of random

meander, three from each polypeptide, heavy and light. These loops are the **complementarity-determining regions** of the structure. Each of these six loops is one of the connections between two of the strands of the antiparallel β structure that form the superstructure of the core of the respective domains (Figure 11-2).

The amino acid sequences in the loops of these six complementarity-determining regions show remarkable variation among the different immunoglobulins, and they are referred to as the **hypervariable regions** of the sequences.²³ It is this variety of amino acid sequence that gives the immunoglobulins as a class their ability to provide individual proteins each tailored to bind a particular antigen. The specific sequences in these loops define the specificity of the particular immunoglobulin. Both the specific amino acid sequence and the lengths of these loops differ among the various immunoglobulins. The variations in sequence, as well as the variations in length, cause both the structure of the polypeptide forming these loops and the distribution of functional groups over the surface formed by these loops to differ dramatically from one immunoglobulin to the next.²⁴ As an illustration of the opportunism of biological processes, it is also possible for a sequence that dictates the glycosylation of an asparagine to be found in a complementarity-determining region and for the oligosaccharide attached to that asparagine to contribute favorably to the binding of the antigen.²⁵ It is these variations in structure and chemical character that produce the array of potential specificities at the site formed by the six loops. In contrast to this wild variation, the structures of the cores of the V_H domain and the V_L domain remain constant because the amino acid sequences forming these cores are well conserved.²⁶

Each immunoglobulin that appears in response to an antigen possesses a binding site that is formed by the complementarity-determining regions and that binds an epitope on the antigen. An **epitope** is the region on the antigenic protein that interacts directly with the binding site on the immunoglobulin. An antigen can have one or many epitopes, and each epitope elicits many different colonies each producing a different immunoglobulin recognizing that epitope and binding to it with its own particular dissociation constant. Each epitope is one of the regions on the antigen that induced the reproduction of the members of the colony of lymphocytes and their production of that particular immunoglobulin. Usually, an epitope is one or two short sequences of amino acids plus two or three other side chains in the antigen that are all adjacent to each other on its surface and that associate specifically with the surface formed by the six complementarity-determining regions. The epitope and the binding site on the immunoglobulin combine noncovalently as if they were two faces forming a heterologous interface in a heterooligomeric protein.

In the crystallographic molecular model of the complex between lysozyme and the Fab fragment

Because of their almost limitless variety and because they are adventitious, **interfaces** between immunoglobulins and their antigens are paradigms for all heterologous interfaces, and the details of the interactions within these interfaces²⁹ are typical of those found

Figure 11-2: Crystallographic molecular model of lysozyme from *G. gallus* bound to the Fab fragment of a murine monoclonal immunoglobulin G.^{20,22} A complex was formed between lysozyme and the Fab fragment of murine monoclonal immunoglobulin D1.3, and the complex was crystallized from 20% poly(ethylene glycol). A crystallographic molecular model was prepared from the map of electron density. (A) Skeletal drawing of the polypeptide backbones of the complete crystallographic molecular model. The Fab fragment (lower two-thirds of the drawing) is drawn so that the heavy α subunit (thick bonds) and light β subunit (thin bonds) include both domains from each subunit (V_H and C_H1 and V_L and C_L , respectively). The lysozyme (bonds of intermediate thickness) is at the top of the structure. The two epitopic loops of random meander in lysozyme that are in contact with the complementarity-determining loops of the immunoglobulin are Aspartate 18 to Asparagine 27 and Lysine 116 to Leucine 129. (B) Detailed view of the interface between these two loops from the lysozyme (thick bonds at the top) and the six loops of the complementarity-determining regions, three from each subunit of the Fab fragment (thinner bonds). Each complementarity-determining region and the segments from each of its ends that anchor it in the two β sheets of the respective domain of the immunoglobulin are included in the drawing. The two ends of each of the eight segments of polypeptide represented in the figure, two from the lysozyme (Lys), three from the heavy α subunit (H), and three from the light β subunit (L), are labeled by their position in the respective amino acid sequence. Side chains (thinnest bonds) within or adjacent to the interface are included in the drawing. Hydrogen bonds are dashed lines. Glutamine 121 at the center of the interface between the lysozyme and the Fab fragment is identified. These drawings were produced with MolScript.¹⁰³

Table 11-1 Amino Acids within the Interface between a Murine Monoclonal Immunoglobulin G and Its Antigen, Micrococcal Nuclease^a

micrococcal nuclease		immunoglobulin		contacts

^aThe crystallographic molecular model was that for the complex between the Fab fragment of murine monoclonal immunoglobulin N10 and micrococcal nuclease from *S. aureus*.²⁷ ^bComplementarity-determining region. Those from the heavy α polypeptide of the immunoglobulin are designated H and those from the light β polypeptide are designated L. Numbering is from the amino terminus. ^cAmino acids from the indicated loops of the complementarity-determining regions that contact the particular amino acid on the surface of micrococcal nuclease. ^dvan der Waals contacts. ^eHydrogen bond between two neutral atoms or between one charged atom and one neutral atom. ^fHydrogen bond between oppositely charged atoms. ^gDonor or acceptor where charge is ambiguous.

in other examples of heterologous associations.³⁰ Usually 5–10 nm² of **accessible surface area** from both antigen and immunoglobulin is buried and 5–20 hydrogen bonds form across the interface (Table 11-1), with donors and acceptors from both side chains and backbone. Normally, there are few ionized **hydrogen bonds** (Table 11-1),²⁹ but in the interface between cytochrome *c* and murine monoclonal immunoglobulin E8 there are five.³¹

Waters are also incorporated as structural elements into these interfaces. For example, in the interface within the crystallographic molecular model of equine cytochrome *c* and the Fab fragment of murine monoclonal immunoglobulin E8,³¹ there are 38 positions occupied by molecules of water,³² 16 of which are present at the same locations in crystallographic molecular models of either the uncomplexed antigen or uncomplexed Fab fragment or in both, and these locations are simply incorporated into the interface within their respective faces. Eight of these waters bridge the two proteins. In the interface between lysozyme from *G. gallus* and the murine Fab fragment HyHEL-63,³³ there are also 38 positions occupied by molecules of water,³² 14 of which are present at the same locations in uncomplexed antigen and uncomplexed Fab fragment, and eight of these

bridge the two proteins; and in the interface between human tissue factor and the murine Fab fragment D3h44 there are 46 positions occupied by molecules of water,³² 23 of which are incorporated as structural elements of the uncomplexed antigen and uncomplexed Fab fragment, and 19 of these bridge the two structures.

The central and most critical amino acid in the epitope on lysozyme recognized by murine monoclonal immunoglobulin D1.3 (Figure 11-2B) is Glutamine 121, the side chain of which occupies a distinct hole among the six loops of the complementarity-determining regions on the surface of the Fab fragment (Figure 11-2B). Each of the three amino acids lining the hole for Glutamine 121 is from a different complementarity-determining loop, one from the heavy α subunit and two from the light β subunit, and this places the hole in the very center of the binding site on the Fab fragment. If Glutamine 121 is replaced by either a histidine or an asparagine by site-directed mutation, the antigen is no longer bound by the immunoglobulin. In the normal structure of lysozyme, Glutamine 121 is fully exposed to the solvent.

It is often the case that an epitope seems to be **focused on a particular amino acid** on the surface of a

protein. For example, about 30–40% of the polyclonal immunoglobulins raised to human cytochrome *c* fail to bind to the cytochrome *c* from *Macaca mulatta*, which differs from the human protein only by the replacement of Isoleucine 58 by a threonine.³⁴ These immunoglobulins that fail to recognize cytochrome *c* from *M. mulatta* do, however, recognize cytochrome *c* from *Macropus canguru* that differs from the human at several other locations but does contain Isoleucine 58. No immunoglobulins raised to the cytochrome *c* from *M. mulatta* failed to recognize the cytochrome *c* from the human, and this result suggests that when a cytochrome *c* contains a threonine at position 58, as does the protein from *M. mulatta*, this region on the external surface³⁵ is not antigenic.³⁴ The impression left by these observations is that Isoleucine 58 is the key amino acid in this epitope, as is Glutamine 121 in the epitope of lysozyme.

In the crystallographic molecular model of the complex between lysozyme and murine monoclonal immunoglobulin D1.3, the structure of the lysozyme is identical, within the error of the models, with its structure in the absence of the immunoglobulin,²⁰ and the structures of both the V_L and the V_H domains of the Fab fragment are also identical, within the errors of the models with their structures in the uncomplexed Fab fragment,³⁶ even though the two domains have shifted slightly relative to each other by 0.1 nm. In this instance, formation of the complex between antigen and immunoglobulin is simply the docking of two **complementary faces**. In the crystallographic molecular model of the complex between human tissue factor and the Fab fragment of murine monoclonal immunoglobulin D3h44, “conformational changes upon formation of the complex are very small and almost exclusively limited to the reorientation of side-chains”.³²

Usually, however, the **conformations of both antigen and immunoglobulin change** noticeably as the complex is formed.³¹ The relative orientations of the V_H domain and V_L domain can shift by 5–10°. ²¹ One or more of the loops of the complementarity-determining regions can be reconfigured³⁷ or can pivot so that their tips move as much as 1.0 nm.³⁸ Side chains on both antigen and immunoglobulin often reorient by rotating around their carbon–carbon bonds.^{27,31} Flexible strands of polypeptide on the surface of the antigen readily rearrange upon formation of the complex.²¹ Most of these changes, however, are small ones, and the surface formed by the six complementarity-determining regions in the uncomplexed immunoglobulin has a shape that is already roughly complementary to the surface of the uncomplexed epitope,³¹ so that only a few readjustments are required upon formation of the complex.

The binding site on an immunoglobulin is usually a flat surface or a depression on the surface of a globular protein formed from the V_H and V_L domains (Figure 11–2). **Viruses** appear to take advantage of this feature of the site. The surface of picornaviruses such as rhinoviruses and

polioviruses are highly irregular. They are furnished with bosses at the 5-fold rotational axes of symmetry of the icosahedral shell. These bosses are separated from each other by deep depressions on the surface of the virus. The epitopes on polioviruses are located mainly on the bosses themselves and a few small protruding segments of polypeptide.³⁹ It is believed that the crucial regions of the surface of rhinoviruses that allow them to produce an upper respiratory infection are located in the depressions between the bosses.⁴⁰ These locations would be inaccessible to immunoglobulins. Each time the epitopes on the bosses or the smaller protrusions of rhinoviruses sustain a sufficient number of mutations to escape recognition, an antigenically novel but still infectious rhinovirus arises. The actual machinery of infection, lying as it does within the depressions, would be protected from being recognized by any immunoglobulin.

This strategy depends on the fact that most antigen binding sites are themselves flat or concave. On the murine monoclonal immunoglobulin HyHEL-5, however, Tyrosine 33 and Tyrosine 53 from complementarity-determining regions 1 and 2, respectively, of the V_H domain form a protrusion that juts out of the almost flat surface that constitutes the binding site for lysozyme, its antigen. In the complex between this immunoglobulin and its antigen, this protrusion fits into a deep groove on the surface of the protein that forms the active site of the enzyme.⁴¹ Consequently, immunoglobulins do not do so often but they can recognize their antigens by protruding into their structure instead of surrounding a protrusion on their surface.

The interface between antigen and immunoglobulin seen in the crystallographic molecular model²¹ of the neuraminidase from influenza virus and the Fab fragment from murine monoclonal immunoglobulin NC41 is formed from at least four juxtaposed strands of polypeptide from distant segments of the amino acid sequence of the neuraminidase. When amino acids in any one of three of these four strands are mutated, the neuraminidase can no longer bind to the immunoglobulin. When amino acids in the fourth strand are mutated, the affinity of the binding is noticeably diminished. All of these results indicate that the epitope on this protein for this immunoglobulin is a large region on the surface comprising all four of these strands. It seems an inescapable conclusion that this epitope would cease to exist if the protein were to unfold in this region. Such an epitope is a **conformationally specific epitope**.

Many immunoglobulins, however, will recognize their antigens even when the antigenic protein is no longer in its native structure. These are **sequence-specific immunoglobulins**. The paradigm of this class would be an immunoglobulin that, when covalently coupled to a stationary phase, can be used to isolate by affinity adsorption a peptide comprising its epitope from a digest of its antigen;⁴² such an immunoglobulin can recognize its epitope even when it is a formless peptide.

The ability of an immunoglobulin to recognize short peptides from an endopeptolytic digest of its antigen⁴³ or short synthetic peptides with sequences of amino acids from its antigen^{44,45} is used routinely, in the absence of a crystallographic molecular model of the complex between intact antigen and immunoglobulin, to **identify the epitope** on the antigen recognized by the immunoglobulin. In fact, when crystals of a complex between Fab fragment and intact antigen cannot be made, a crystallographic molecular model of a peptide from the antigen bound within the binding site on the immunoglobulin is assumed to depict accurately at least a portion if not all of the structure of the interface in the complex with the intact antigen.⁴⁶

Usually the class of sequence-specific immunoglobulins is distinguished from the class of conformationally specific immunoglobulins. Although the monoclonal immunoglobulin NC41 specific for viral neuraminidase that was used in the crystallographic studies seems to be an obvious member of the latter class, the evidence for such conformationally specific immunoglobulins is often anecdotal. A protein is irreversibly unfolded and loses its antigenic properties. To unfold a polypeptide irreversibly, however, it is usually either covalently modified⁴⁷ or noncovalently and intermolecularly polymerized by aggregation. Either the epitope could be covalently modified or it could be sterically sequestered within an aggregate of the protein during such uncontrolled reactions. If either of these events occurs, it appears as if the immunoglobulin were conformationally specific and recognized only the native structure of the protein when actually it was sequence-specific and recognized a single linear sequence of amino acids that was simply covalently modified or inaccessible. The technical difficulty is to unfold the polypeptide of the antigen to a monodisperse random polymer without doing the same thing to the immunoglobulin, which is also a folded polypeptide. Digestion of the antigen accomplishes this goal by producing structureless peptides, but if the immunoglobulin fails to recognize any of these peptides it could simply be the case that cleavage has occurred within the epitope.

It is probably the case that the distinction between sequence-specific and conformationally specific immunoglobulins is one of degree. For example, a polyclonal set of immunoglobulins was raised against native micrococcal nuclease from *S. aureus* ($n_{aa} = 149$) and purified on the basis of its ability to recognize a fragment of the intact polypeptide comprising amino acids 99–149. These immunoglobulins could bind the intact, folded polypeptide of micrococcal nuclease 2×10^4 times more tightly, as judged from the dissociation constants, than they could the fragment.⁴⁸ The fragment is a monodisperse random polymer, and it may be that the binding site on the immunoglobulin recognizes only the small portion of the random polymer that by chance has assumed the proper conformation. This would explain

the much greater dissociation constant of the fragment relative to the native protein. It is also possible, however, that the immunoglobulins still recognize the epitope or portions of the epitope after it is unfolded, but with much smaller free energy of dissociation. A difference in dissociation constant of even the magnitude observed for the complexes between the immunoglobulins and the nuclease, if the concentrations of immunoglobulin and antigen and the individual dissociation constants are in the appropriate ranges, would be observed as a complete elimination of the ability of antigen to bind to immunoglobulin when it is in fact only a finite attenuation of the ability of antigen to bind to immunoglobulin.

Because the immune system was developed to recognize and destroy foreign organisms such as viruses and bacteria and because other systems are used by animals to eliminate small toxic molecules, antigens are always large macromolecules, usually proteins, and never small molecules. This fastidiousness of the immune system can be circumvented by covalently attaching a small molecule to a carrier protein as a **hapten**. The attachment is accomplished with chemical couplings analogous to those used for covalent modification or cross-linking of proteins. In fact, many substances that are able to covalently modify proteins produce undesirable immune reactions by attaching to proteins in an animal or the incautious investigator and turning those immunologically benign proteins into malignant antigens.

A hapten, when covalently attached to the carrier protein, protrudes from its surface even more dramatically than Glutamine 121 does from the surface of lysozyme. Because of its peculiar chemical structure, the hapten is usually the focus of the immune system; and because it protrudes from the surface, the entire hapten usually ends up occupying a deep hole or deep crevice among the loops of two or three complementarity-determining regions.^{17,49,50} These facts explain why the unattached hapten can usually be bound efficiently by the immunoglobulin. For example, polyclonal immunoglobulins raised against a protein the lysines of which had been modified by 2,4,6-trinitrobenzenesulfonate (Reaction 10–28) bind N^{ϵ} -(2,4,6-trinitrophenyl)lysine with dissociation constants of 10^{-7} to 10^{-9} M.⁵¹ It is this ability of an immunoglobulin raised against a hapten to **bind tightly the small molecule** from which the hapten was derived that permits immunoglobulins to be used in highly specific assays for small molecules.⁵²

Although immunoglobulins for use in protein chemistry are usually raised by injecting an intact protein into an animal, it is also possible to raise immunoglobulins directed against **synthetic peptides** with the same amino acid sequence as a segment from a particular protein.⁵³ The synthetic peptides are attached as haptens to another protein. For example, the amino-terminal amino acid sequence of the large tumor antigen from simian virus is AcMDKVLNR-, where Ac is a post-

translationally added acetyl group. Immunoglobulins raised against a synthetic peptide with this sequence that had been covalently attached to bovine serum albumin as a hapten were able to recognize and bind exclusively to the large tumor antigen protein in crude homogenates from animal cells infected with the simian virus.⁵³ Immunoglobulins directed against a particular peptide can be purified by using a stationary phase to which the peptide is attached as an affinity adsorbent.^{54,55}

The difficulty inherent in the use of immunoglobulins raised against a particular amino acid sequence in a protein to study that protein in its native conformation is that the investigator, a fallible judge, rather than the immune system, which is less fallible, has chosen the epitope. A native protein does not expose many sequences sufficiently for immunoglobulins to recognize them. If the investigator has chosen the epitope, there is only a small chance that it will be **accessible** on the surface of the antigen and recognized by an immunoglobulin in the native protein, unless the choice is the safe one of the amino terminus or the carboxy terminus, which are usually well exposed in a native protein. The segment of sequence against which the immunoglobulin was raised, however, will usually be accessible in the unfolded polypeptide.

Any solution of a protein, even pristine cytoplasm, freshly drawn plasma, or a solution of redissolved crystals, contains some of the irreversibly **unfolded polypeptide** of any particular protein. Immunoglobulins raised against synthetic peptides necessarily bind preferentially, and often exclusively, to any unfolded protein exposing the sequence of amino acids against which they were raised because the original antigen itself was a structureless peptide of that sequence. Yet most experiments are designed with the requirement that the immunoglobulins recognize and bind to the native protein for the conclusion to be valid.

Crystallographic molecular models of complexes between immunoglobulins raised against synthetic peptides and the peptides themselves heighten these concerns.⁵⁶ In the binding site on the immunoglobulin, the peptide usually binds rigidly in a conformation that differs dramatically from the conformation that the same sequence of amino acids assumes in the native protein. Furthermore, it is, as might be expected, usually buried in a crevice among the loops of the complementarity-determining regions. Consequently, it is difficult to understand how such an immunoglobulin can ever recognize that sequence in the native protein.

The solution to this problem is analytical. When either monoclonal immunoglobulins or polyclonal immunoglobulins raised against synthetic peptides are used, one can assume that each folded polypeptide possesses only one epitope, either exposed or buried. It is also possible to purify by affinity adsorption a subset of polyclonal immunoglobulins recognizing only one epitope from a set of polyclonal immunoglobulins raised

against an intact protein.^{34,55} If every molecule of protein in a solution can bind one immunoglobulin at a particular epitope, then the immunoglobulin is recognizing the native protein. If only a small percentage of the molecules of protein in a solution can bind an immunoglobulin at that epitope, it is only the unfolded polypeptides that are presenting that epitope. Consequently, if every protomer of an antigen binds one molecule of an immunoglobulin, when only immunoglobulins directed against one epitope are present, then the immunoglobulins must be recognizing the epitope when it is in the native protein. In any experiment relying on the assumption that the immunoglobulins recognize the native protein, it must be demonstrated both that the immunoglobulins bind to only one unique epitope and that every protomer of the antigen is capable of binding one molecule of immunoglobulin. In the absence of such a demonstration, the conclusions reached can be disregarded.

In contrast to these difficulties encountered when they are used to examine a native protein, immunoglobulins raised against a synthetic peptide can be used to **purify a peptide** containing a particular amino acid in the sequence of a protein from an endopeptolytic digest of that protein.⁵⁵ The amino acid sequence surrounding Lysine 380 of the α subunit of acetylcholine receptor is -SAIEGVKYIAEHM-. The synthetic peptide KYIAE was coupled covalently as a hapten to bovine serum albumin, and polyclonal immunoglobulins were raised against this antigen in rabbits. Because the peptide had been coupled to the serum albumin through the amino groups of its lysine and of its amino terminus, the carboxy-terminal sequences -YIAE protruded as haptens from the surface of the serum albumin. The antiserum was passed over a stationary phase to which the peptide KYIAE had been covalently attached, and immunoglobulins specific for the carboxy-terminal sequence -YIAE were adsorbed by the affinity adsorbent. After all of the other proteins in the serum had been washed away, the adsorbed immunoglobulins were eluted. These purified immunoglobulins in turn were covalently attached to a stationary phase to produce an immunoabsorbent specific for the carboxy-terminal sequence -YIAE. When acetylcholine receptor was digested with glutamyl endopeptidase (Figure 3-2) and the digest was passed over the immunoabsorbent, the peptide GVKYIAE was adsorbed and eluted in high yield and high purity.⁵⁷ The covalent modification of Lysine 380 in intact, native acetylcholine receptor could be readily monitored by using this immunoabsorbent to purify rapidly the peptide containing it.

Such an immunoabsorbent can purify a peptide from the digest of a large protein, which contains so many peptides that a direct purification by chromatography would be difficult if not impossible. If a chemical modification of an amino acid in the protein within the sequence included in the peptide occurs in low yield so

that the modified peptide is only a minor component of the digest, the immunoadsorbent will still purify it.⁵⁷ In fact, the targeted amino acid can be destroyed by the modification and the protein cleaved at the point of destruction, and the immunoadsorbent will still purify the peptide containing the remaining fragment of that amino acid.⁵⁸ By use of such an immunoadsorbent, for example, the modification of a particular amino acid in a protein can be followed kinetically⁵⁹ or its accessibility to a particular electrophile under different circumstances can be monitored.⁶⁰

Immunoglobulins directed against an antigenic protein can effect immunoprecipitation. An **immuno-precipitate** is a visible, white precipitate that forms when an antigen and its immunoglobulin are present in solution at the proper concentrations. Each immunoglobulin has at least two binding sites for antigen (Figure 11-1). Each antigen, if it is a protein, is usually polyvalent. A **polyvalent antigen** is one that has more than one epitope. If the polyclonal mixture of immunoglobulins in the serum contains several monoclonal immunoglobulins directed against different epitopes on the antigen and if this mixture of immunoglobulins is mixed in the proper ratio with that antigen, an immunoprecipitate forms containing antigen and immunoglobulin cross-linked among themselves. The ratio of concentrations at which maximum precipitation occurs is known as the **equivalence point**. If there is only one epitope on the antigen that has elicited the immune response, no precipitate will form. An Fab fragment, because it is univalent, cannot produce a precipitate. If a large excess of antigen is present, each immunoglobulin has its binding sites filled with antigens that are not bound to other immunoglobulins and no precipitate forms. If a large excess of immunoglobulin is present, each antigen is surrounded by immunoglobulins, each with its other binding site vacant, and no precipitate forms. Such soluble complexes of excess antigen and excess immunoglobulin are present under all circumstances, and it is never possible to precipitate directly all of the antigen or all of the immunoglobulins even at equivalence. Finally, the molar ratio between antigenic protein and immunoglobulin in a precipitate gathered at equivalence is a complicated function of the number of epitopes, their relative affinities, and the distribution of the different monoclonal immunoglobulins in the polyclonal mixture.

After a protein of interest has been injected as a potential antigen into an animal, the appearance of the desired immunoglobulins in the serum is often detected by the ability of those immunoglobulins to form an immunoprecipitate. The simplest way to produce the proper ratio of concentrations in order to observe a precipitate is to layer a solution of the antigen onto a sample of the serum in a narrow tube. As antigen diffuses into the serum and immunoglobulin diffuses into the solution of antigen, there will be a point along the two gradients at which the concentrations are those necessary for

precipitation to occur and a visible **disc of precipitate** will form at this location.

Immunodiffusion is a more sophisticated procedure for permitting antigen and immunoglobulin to diffuse into each other.⁶¹ Antigen and serum are placed in separate wells cut in a block of agar, and as they diffuse outward into the agar and towards each other, there will be a line between the two wells along which the ratio of concentrations is appropriate for precipitation. Along this line a white immunoprecipitate will form. When the original antigen and the same protein from a different species or a mutant variety of the antigen are placed in two adjacent wells both the same distance from the well containing immunoglobulin, the pattern of the lines of immunoprecipitate demonstrates whether or not the related protein shares all of the epitopes present on the original antigen.⁶²

Complement fixation is a procedure for detecting the relative concentrations of immunoprecipitates in a series of samples.⁶³ It is sensitive to concentrations of immunoprecipitate much smaller than can be observed visually. The procedure can be performed on a series of mixtures of antigen and immunoglobulin at different ratios of concentration to obtain a direct measurement of the equivalence point, which is the ratio at which complement fixation reaches its maximum level.

An immunoprecipitate is held together by a complex collection of interfaces formed between the binding sites on the tips of the Fab arms of the various immunoglobulins present in antiserum and their respective epitopes on the molecules of antigen. Each of the individual reactions between an epitope and the binding site on the Fab arm of an intact immunoglobulin is a simple dissociation:

where Fab is the binding site, Ep is the epitope, and Ep·Fab is the immune complex (Figure 11-2). The immune complexes between epitopes on antigens and immunoglobulins are quite strong, a fact that permits an immunoprecipitate to form even when antigen and immunoglobulins are present at the low concentrations used for procedures such as complement fixation. More useful than the strength of the association, however, is the fact that because k_{-1} is almost always a small rate constant, dissociation of the complex is slow. Most of the procedures that use immunoglobulins depend on this **slow dissociation** of the complexes between them and their antigens. The slow dissociation permits the complex between antigen and its immunoglobulin to be separated either from an excess of the specific immunoglobulin and other immunoglobulins and proteins in an antiserum or from all of the other proteins with which the antigen is mixed. For example, an

immunoprecipitate can be extensively washed without dissociating. Immunoblotting, immunostaining, and immunoadsorption also rely on this advantage of the slow dissociation.

One of the most important uses of immunochemistry is to identify the particular protein to which the antibody is directed. For example, a specific immunoglobulin can be used to stain only its antigen among all of the proteins in a heterogeneous mixture separated by electrophoresis.⁶⁴⁻⁶⁷ First the proteins that have been separated by electrophoresis on a slab of poly-

acrylamide are transferred laterally by electrophoresis onto a membrane of nitrocellulose or poly(vinylidene difluoride) placed against the slab of polyacrylamide. This **electrotransfer** produces a **blot** on which the bands of protein in the polyacrylamide have become bands of protein arrayed in the same pattern but now plastered onto the membrane of polymer (Figure 11-3A).⁶⁸ Then the blot is soaked in a solution of the specific immunoglobulin, and excess immunoglobulins are rinsed away. The immunoglobulins that were bound by the antigen are **immunostained** with a second

Figure 11-3: Immunostaining of immunoblots of NADH dehydrogenase (ubiquinone) from bovine heart mitochondria. (A) NADH Dehydrogenase (ubiquinone) was dissolved in a solution of dodecyl sulfate and submitted to electrophoresis on a slab of polyacrylamide. Following the electrophoresis, the separated polypeptides on the gel were electrotransferred laterally onto a membrane of poly(vinylidene difluoride) placed against the slab by applying an electric field perpendicular to the plane of the slab. The protein in each band remained at the same position on the field and adhered tightly to the poly(vinylidene difluoride). The membrane was then stained with Coomassie brilliant blue.⁶⁸ The 25 bands that appeared represent only a fraction of the more than 40 polypeptides in NADH dehydrogenase (ubiquinone). Reprinted with permission from ref 68. Copyright 1992 Elsevier B.V. (B-G) The complexes between dodecyl sulfate and the polypeptides of NADH dehydrogenase (ubiquinone) of 704, 444, 430, 228, 217, and 75 aa were each purified from subcomplexes of the enzyme.^{73,74} Following purification, each of them was injected into rabbits, and polyclonal immunoglobulins specific for each of the polypeptides were purified from the respective antiserum^{71,72} by binding them to the respective polypeptide immobilized on a membrane of nitrocellulose, washing away the other proteins, and eluting the immunoglobulins.⁷⁵ Membranes of poly(vinylidene difluoride) to which electrophoretically separated polypeptides of intact NADH dehydrogenase (ubiquinone) had been electrotransferred as in part A were then immunostained⁷⁶ with purified rabbit polyclonal immunoglobulins against the polypeptides of (B) 444 aa, (C) 217 aa, (D) 75 aa, (E) 704 aa, (F) 430 aa, and (G) 228 aa, respectively, followed by goat polyclonal immunoglobulins that were raised against rabbit immunoglobulin G and to which peroxidase had been covalently coupled. The electrophoretic separation in lane A and those in lanes B-G were performed in different laboratories on different polyacrylamide gels that produced different mobilities. (H-K) Intact NADH dehydrogenase (ubiquinone) with its more than 40 subunits was cross-linked with ethylene glycol bis(succinimidyl succinate). The product of the reaction was dissolved in a solution of dodecyl sulfate. Four identical samples of this solution were submitted to electrophoresis in separate lanes, the separated polypeptides electrotransferred to a sheet of poly(vinylidene difluoride), and the respective lanes were immunostained as in part B-H with immunoglobulins specific for the polypeptides of (H) 75 aa, (I) 217 aa, (J) 444 aa, and (K) 704 aa, respectively.⁷⁶ The respective un-cross-linked polypeptide is the lowest band in each lane, and covalent complexes in which the polypeptide participates are represented by the higher bands. immunoglobulin directed against the first immunoglobulin, for example, ovine anti-murine immunoglobulin, to which either peroxidase⁶⁹ or alkaline phosphatase⁶⁶ has been attached. The peroxidase or alkaline phosphatase produces a colored precipitate at the location of the antigen (Figure 11-3, panels B-H). In this way, one protein can be picked out of a complex mixture because it is the only protein that is stained. For example, a murine monoclonal immunoglobulin that had been selected for its ability to inhibit the mitochondrial dicarboxylate transporter from *Pisum sativum* immunostained only one polypeptide on an immunoblot of a polyacrylamide gel on which the hundreds of polypeptides from intact mitochondria dissolved in a solution of dodecyl sulfate had been separated electrophoretically.⁷⁰ That polypeptide was assumed to be the transporter.

Immunostaining of immunoblots is also used to identify which polypeptides are components of a particular covalent complex produced by **cross-linking**. NADH Dehydrogenase (ubiquinone) is a large protein composed of more than 40 different polypeptides (Figure 11-3A).⁶⁸ Immunoglobulins that specifically recognize the polypeptides of 75, 217, 228, 430, 444, and 704 aa were produced in rabbits⁷¹⁻⁷⁴ and purified by binding them to their antigens and then eluting them.⁷⁵ On immunoblots of polyacrylamide gels on which the complete protein with its more than 40 polypeptides had been separated (Figure 11-3A), each of the immunoglobulins directed immunostaining only to the polypeptide against which it was raised (Figure 11-3, lanes B-G).⁷⁶

The complete protein was then cross-linked with ethylene glycol bis(succinimidyl succinate), and the polypeptides that were separated by electrophoresis were again immunoblotted and immunostained with the immunoglobulins specific for the polypeptides of 75, 217, 444, and 704 aa (Figure 11-3, lanes H-K). Covalent complexes between the polypeptides of 217 and 75 aa; 444 and 75 aa; 444 and 217 aa; 704 and 444 aa; 704, 444, and 75 aa; and 704, 444, and 217 aa could be positively identified on the basis of their mobility and, more importantly, the fact that they were immunostained by the appropriate immunoglobulins. The most interesting result was the fact that none of these four polypeptides had been cross-linked to any of the other polypeptides in the complex. Because there are many polypeptides that have mobilities similar to others in the protein, only the immunostaining could sort out the products of the cross-linking reaction.

One of the most effective ways to raise immunoglobulins that recognize a particular protein with high specificity is to use as a hapten a synthetic peptide with the sequence of the **amino terminus** or the **carboxy terminus** of that protein. Polyclonal immunoglobulins were raised against the synthetic peptide SEFIGA, the carboxy-terminal sequence of the human receptor for epidermal growth factor. The peptide had been attached as a hapten through its amino terminus to

bovine serum albumin so the immunoglobulins recognized the carboxy-terminal sequence -EFIGA. These polyclonal immunoglobulins were purified by passing the antiserum over an affinity adsorbent composed of a solid phase to which the peptide had been attached covalently. When a homogenate of cultured human cells was dissolved in a solution of dodecyl sulfate and submitted to electrophoresis and the separated polypeptides were immunoblotted, the immunoglobulin raised against the peptide SEFIGA directed immunostaining only to the polypeptide of the receptor for epidermal growth factor.⁷⁷ The solution submitted to electrophoresis contained all of the hundreds of polypeptides in the cells, and yet only the receptor for epidermal growth factor was recognized by the polyclonal immunoglobulins.

Immunoglobulins can also be used to isolate a particular protein by **immunoabsorption**. An **immunoabsorbent** is a stationary phase to which an immunoglobulin specific for a particular antigen has been covalently bound and with which that antigen can be purified by affinity adsorption.^{78,79} For example, although the protein had not been purified, the amino acid sequence of Shaker S4 K⁺ channel from *Drosophila melanogaster* had been determined genetically. The protein was expressed in Sf9 insect cells following their infection with baculovirus into the DNA of which complementary DNA encoding the protein had been inserted. The expressed protein could then be purified⁸⁰ on an immunoabsorbent to which had been covalently attached immunoglobulins raised against the synthetic peptide EEEDTLNLPKAPVSPQDKS, an amino acid sequence from a region of the protein (amino acids 333-351) thought to be an exposed loop connecting two α helices.

The gene encoding dystrophin, the protein that is missing in muscles of patients suffering from Duchenne/Becker muscular dystrophy, had been identified before dystrophin itself was known to exist.⁸¹ An immunoabsorbent, containing immunoglobulins raised against an expressed fusion protein containing a fragment of 556 aa from the amino acid sequence of dystrophin, was used to purify it.⁸²

The voltage-gated chloride channel from *Torpedo californica* had also been identified and sequenced genetically before it had been purified. It was then purified in one step of affinity adsorption by use of a stationary phase to which immunoglobulins recognizing the hydrophilic sequence EGQREGLEAVKVQTEDP from the protein had been coupled covalently.⁸³

Immunoabsorption can also be accomplished by adding an excess of specific immunoglobulins to a solution to saturate all of the antigen, passing the solution over agarose to which protein A from *S. aureus*, a protein with a high affinity for immunoglobulin G, has been covalently attached,⁸⁴ and eluting the adsorbed antigen from the agarose after the other proteins have been rinsed away.

A protein can be identified by **tagging it with an epitope**.⁸⁵ A short segment of DNA encoding the amino acid sequence of an epitope to which an immunoglobulin has already been raised is inserted in phase at one end of the reading frame for the protein of interest. The protein is then expressed from the complementary DNA into which the insertion has been made, and the expressed protein contains the amino acid sequence of the tag at one of its ends. The protein thus tagged can be identified by immunostaining and isolated by immunoadsorption with the immunoglobulins directed against the epitope. In this way, the protein encoded by an unidentified reading frame in a segment of genomic DNA or complementary DNA can be identified and purified. If a protein has been tagged by an epitope at one of its ends, an immunoblot of a digest of that protein separated by electrophoresis in a solution of dodecyl sulfate will provide a map of the positions in the amino acid sequence at which cleavage occurred during the digestion. The lengths of the successive **end-labeled fragments** will correspond to the positions of cleavage in the sequence of the protein.⁸⁶

Immunoglobulins are also used to **screen libraries** of cDNA.⁸⁷ If immunoglobulins specific for a protein of completely unknown sequence have been made, they can be used in such a screen to detect the complementary DNA for that protein. The complementary DNAs to be screened are inserted into plasmids that cause the proteins they encode to be expressed when they are transfected into bacteria. The transfected bacteria are spread onto a field and grown into individual colonies, each of which consequently contains protein expressed from the cDNA on its respective plasmid. The bacteria are lysed and their proteins are immobilized on a surface in such a way that the immobilized proteins remain in the same location on the field and produce a replica of the original pattern of the colonies. The replica is soaked with the immunoglobulins that recognized the protein of interest and then washed, and those colonies that contained antigen are identified by immunostaining or by binding radioactive protein A from *S. aureus* to the bound immunoglobulins. The bacteria in a colony identified in this way can then be replicated and the cDNA sequenced.

Immuno-electron microscopy is used to identify the region on the surface of a protein containing the epitope against which particular immunoglobulins are directed. Most proteins, including immunoglobulins, are large enough to be observed in the electron microscope when embedded in a glass of negative stain. When the embedded complex between a protein and an immunoglobulin or the Fab fragment of an immunoglobulin is observed on an electron micrograph, the immunoglobulin or Fab fragment appears as a protrusion on the surface of the protein that it recognizes. Often the Fab arms and the Fc trunk of an immunoglobulin can be distinguished; usually, however, an

immunoglobulin appears only as a vague elongated structure. If the protein has a characteristic shape, the location of the epitope recognized by the immunoglobulin on the surface of that shape can be identified. α_2 -Macroglobulin is a molecule that in an electron micrograph has the shape of a letter H; a murine monoclonal immunoglobulin specific for the domain of about 200 aa responsible for the binding of the α_2 -macroglobulin to its receptor binds to the ends of the arms on the H.⁸⁸ Fibrinogen is a molecule that, in an electron micrograph, has three globular domains arranged in a row; a murine monoclonal immunoglobulin specific for the carboxy-terminal 150 amino acids of its α polypeptide binds near the central domain of the structure.⁸⁹

The multicatalytic endopeptidase complex is a cylinder composed of 14 different subunits, each present in two copies. A murine monoclonal immunoglobulin specific for one of these subunits binds at both ends of the cylinder, consistent with the existence of a 2-fold rotational axis of symmetry at the center of the cylinder and locating the positions in the cylinder of the two copies of that subunit.⁹⁰ Murine monoclonal immunoglobulins against several of the subunits in the multicatalytic endopeptidase complex were always bound at two symmetrically displayed locations on the surface of the cylinder, and the respective angles between those positions when the cylinder was viewed along its axis could be used to position those subunits relative to the 2-fold rotational axis of symmetry that is normal to the cylindrical axis and at the middle of the cylinder.⁹¹

The most extensive application of immuno-electron microscopy has been an examination of the distribution of the constituent polypeptides over the surface of the two subunits of the ribosome from *Escherichia coli*. The application of these procedures to the 30S subunit serves as an example. Although it was unknown at the time these experiments were performed, the core of the **30S ribosomal subunit** is formed from ribosomal RNA, and luckily almost all of its constituent polypeptides are distributed over its external surface and are accessible to immunoglobulins.

The 21 unique polypeptides found in the 30S subunit of the ribosome can be separated and catalogued by two-dimensional gel electrophoresis (Figure 11-4).^{92,93} They have been separated and individually purified,⁹³ and their amino acid sequences have been determined.⁹⁴ Polyclonal sets of immunoglobulins have been raised against most of these polypeptides. When immunoglobulins specific for one of them were mixed with intact 30S ribosomal subunits and the immune complexes were then prepared for electron microscopy, individual immunoglobulins bound to individual 30S ribosomal subunits or cross-linking two 30S ribosomal subunits could be observed (Figure 11-5).⁹⁵⁻⁹⁸ The 30S ribosomal subunit has a characteristic, asymmetric shape and the epitopes recognized by these immunoglobulins could be assigned to certain regions on the surface of that shape.

Figure 11-4: Separation of the polypeptides composing the 30S subunit of ribosomes from *E. coli*.⁹³ Intact ribosomes were isolated from a homogenate of bacteria by centrifugation. They were dissociated into subunits by treatment with MgCl_2 , and the 30S subunit was separated from the 50S subunit by centrifugation through a gradient of sucrose. The protein was extracted from the 30S ribosomal subunit and dissolved in 6 M urea. The individual polypeptides were separated in the first dimension at pH 9.6 and in the second dimension at pH 4.6. Separation in each dimension was performed in 6 M urea. The proteins were stained with amido black. Although only 17 components are observed, three polypeptides coelectrophorese at one spot and two pairs of polypeptides coelectrophorese at two other spots. The total number of polypeptides is 21. Reprinted with permission from ref 93. Copyright 1973 *Journal of Biological Chemistry*.

Two different laboratories have determined the distributions of the various polypeptides over the surface of the 30S ribosomal subunit, based on the relative distributions of the antigenic sites.^{99,100} In each of these two sets of observations, the location at which each individual immunoglobulin was bound on the 30S ribosomal subunit was ascertained by deciding visually which projection and which orientation of a crude three-dimensional structure of the 30S ribosomal subunit each image in the micrograph represented. Both of these two crude structures, although significantly different from each other, incorporated a small globular domain, a large globular domain, and a significant protrusion on one side. These three features served to orient the particles, and the positions of the various polypeptides could be assigned relative to them. Luckily, these features did appear in the crystallographic molecular model of the 30S subunit (Figure 11-5).^{95,101}

Although there was initially significant disagreement about the distribution of these antigens over the surface of the 30S subunit,^{96,102} the differences were resolved, and in the final maps from the two laboratories,^{99,100} the agreement is quite close. Furthermore, these distributions determined by immunoelectron microscopy are in remarkable agreement with the distribution of the folded polypeptides over the crystallographic molecular model that was obtained 10 years later.^{95,101}

Problem 11-1: A polyclonal set of immunoglobulins was produced against the synthetic peptide -ETYY, the carboxy-terminal sequence of Na^+/K^+ -exchanging ATPase, a protein embedded in the membranes of animal cells. Immunoglobulins recognizing this peptide were purified by affinity adsorption on a solid phase to which the peptide had been attached. The immunoglobulins were made radioactive by reductive methylation (Figure 10-3) with formaldehyde and sodium [^3H]borohydride to a final specific radioactivity of $10,760 \text{ cpm nmol}^{-1}$. Equal amounts of this immunoglobulin were mixed with increasing amounts of homogeneous Na^+/K^+ -exchanging ATPase in its membrane-bound form so that bound and unbound immunoglobulin could be separated by centrifugation after equilibrium had been reached. The amount of bound immunoglobulin increased linearly with the amount of membrane-bound protein added. It was found that each milligram of protein of purified Na^+/K^+ -exchanging ATPase could bind 670 cpm of radioactive immunoglobulin regardless of the final concentration of immunoglobulin. The asymmetric unit of Na^+/K^+ -exchanging ATPase is composed of one α polypeptide ($n_{\text{aa}} = 1020$) and one β polypeptide ($n_{\text{aa}} = 300$). What fraction of the molecules of the ATPase displays epitopes?

A monoclonal immunoglobulin was also produced against Na^+/K^+ -exchanging ATPase. This monoclonal immunoglobulin could bind the synthetic peptide HLLVMKGAPER, which has a sequence identical to a segment of the sequence from the α polypeptide of the enzyme. The relative concentration of binding sites of this immunoglobulin in a solution could be determined by an indirect immunoassay. When samples of a solution of this monoclonal immunoglobulin, at a final concentration of 11 nM in binding sites for antigen, were mixed and brought to equilibrium with increasing concentrations of Na^+/K^+ -exchanging ATPase, the concentration of unoccupied binding sites for antigen decreased. A final concentration of Na^+/K^+ -exchanging ATPase of $300 \mu\text{g mL}^{-1}$ was required to decrease the concentration of active immunoglobulin by greater than 90% (from 11 nM to less than 1 nM). What fraction of the molecules of Na^+/K^+ -exchanging ATPase displays epitopes accessible to the immunoglobulin?

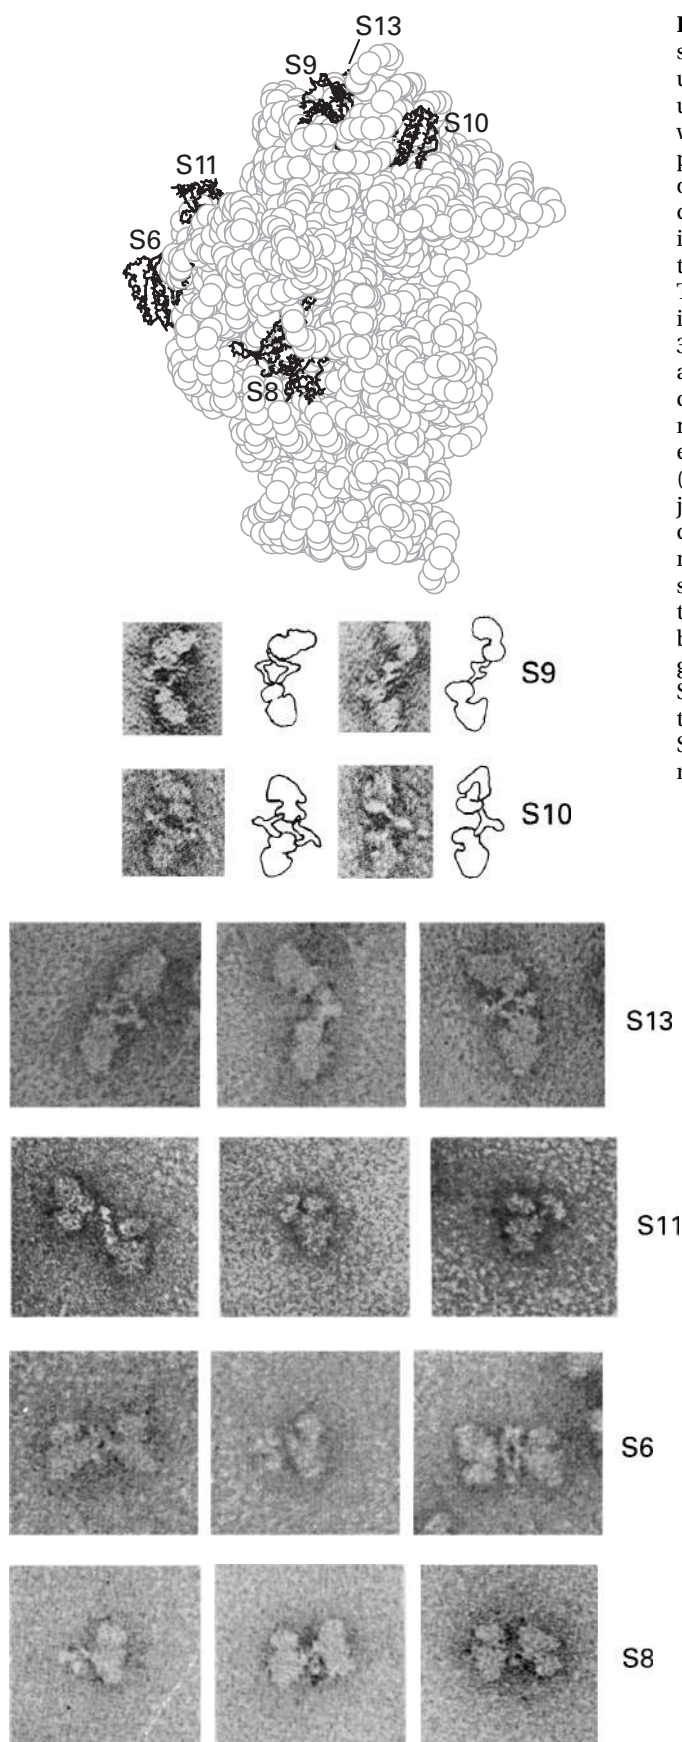

Figure 11-5: Immuno-electron microscopy of the 30S subunit of the ribosome. A drawing of the crystallographic molecular model of the 30S subunit from *Thermus thermophilus* is at the top.⁹⁵ The ribosomal RNA and unhighlighted polypeptides are drawn in a space-filling representation in which a sphere was placed at each α carbon of the proteins and at each phosphorus atom of the nucleic acid. The backbones of the polypeptides of those subunits that were used as antigens in the various experiments are drawn in skeletal representation and identified by the standard numbering. Subunit S13 is located on the surface of the 30S subunit just over the top of the view presented. This drawing was produced with MolScript.¹⁰³ The electron micrographs are of immune complexes between polyclonal immunoglobulins G and 30S ribosomal subunits from *E. coli*. Purified 30S subunits were mixed with the polyclonal immunoglobulins raised against the particular purified polypeptide: S9, S10, S13, S11, S6, or S8. The complexes that formed were adsorbed to a layer of carbon on a grid for microscopy, negatively stained with uranyl acetate, and observed in the electron microscope. The immunoglobulins G are Y-shaped proteins (Figure 11-1) that connect two globular 30S ribosomal subunits or bind to just one. The 30S subunits in the micrographs can be recognized by their characteristic shapes as illustrated by the crystallographic molecular model. At the top in the view of the crystallographic molecular model presented is a smaller globular domain, to the left a significant protrusion, at the bottom the larger globular domain, and to the right a deep cleft between the upper and lower domains. The top two panels of micrographs, for polypeptides S9 and S10, are results from the laboratory of Stöffler.⁹⁶ Reprinted with permission from ref 96. Copyright 1975 held by the authors. The lower rows of micrographs, for polypeptides S13,⁹⁷ S6,⁹⁸ S11,⁹⁷ and S8,⁹⁸ are results from the laboratory of Lake. Reprinted with permission from refs 97 and 98. Chapter 12

Physical Measurements of Structure

Physical properties used to assess the structure of a protein are its standard diffusion constant, its standard sedimentation coefficient, its intrinsic viscosity, and the angular dependence of its ability to scatter light, X-radiation, and neutrons, all of which respond to the shape of the macromolecule; its absorption of light, which responds to the environments around particular chromophores, in particular the peptide bonds; its fluorescence or the fluorescence of chromophores covalently attached to it, which can be used to measure molecular shape and intramolecular dimensions; and its nuclear magnetic resonance spectrum, which can be used to map spatial relationships among the amino acids in the native structure. These physical properties are derived from measurements made of solutions of the protein. When a crystallographic molecular model is not available, such physical measurements provide the only structural information about a particular protein. As more and more crystallographic molecular models become available, however, physical measurements have become valuable complements to crystallography. Because they are structural measurements of the protein in solution, they can be used to validate a crystallographic molecular model, or in some situations to adjust the crystallographic molecular model to correct for differences between the structure of a molecule of protein in a crystal and its structure in solution.

Shape

A molecule of protein dissolved in an aqueous solution of moderate ionic strength is a compact solid of peculiar shape coated with a **layer of water** that is more or less fixed upon its surface and that has the effect of smoothing its roughness. The available crystallographic molecular models of various proteins are similar enough to each other to provide an accurate mental picture of the boundary between the molecule of protein proper and the liquid water of the bulk phase. Crevices on the surface of a molecule of protein are filled with molecules of water. Although these molecules of water are rapidly exchanging with their neighbors more peripherally located, the locations where they sit are always occupied and can be considered to be permanent features of the molecule of protein. Their net effect is to fill the crevices on the surface of the folded protein. Between these

crevices, over the open surface of a molecule of protein, a large number of molecules of water are situated in locations that are also permanently occupied, even though constantly exchanging. The relative positions of these locations becomes less and less fixed the farther they are situated from the atoms of the molecule of protein until a region is reached where the water is no different from the water in an otherwise identical solution lacking the protein. This continuous transition between the molecules of water fixed to two or three donors and acceptors of hydrogen bonds on the surface of a molecule of protein and the molecules of water in the bulk solvent is characterized by a gradual, rather than an abrupt, decrease of attachment. Therefore, no distinct boundary exists between the macromolecule and the solvent. Nevertheless, the concept of the hydrodynamic particle¹ is necessary if specific dimensions are to be extracted from physical measurements of the shapes of molecules of protein dissolved in free solution.

The **hydrodynamic particle** is the covalent molecule of protein and any molecules of water and any solutes that behave during the measurement as if they were affixed to the molecule of protein. An **affixed molecule of water** would be a specific location upon the surface of the protein continuously occupied by one or another molecule of water over a period of time long enough that the measurement registers it as a permanent feature.

If it is assumed that a hydrodynamic particle exists, its **mass** m_h (in grams) will be

$$m_h = \frac{M_{\text{prot}}(1 + \delta_{\text{H}_2\text{O}})}{N_A} \quad (12-1)$$

where M_{prot} is the molar mass (grams mole⁻¹) of the protein, $\delta_{\text{H}_2\text{O}}$ denotes the grams of water bound for every gram of protein (Table 6-4), and N_A is Avogadro's number (6.022×10^{23} mol⁻¹). It should be recalled that M_{prot} , the molar mass of the covalent structure of the protein, is almost always calculated directly from the amino acid sequences and stoichiometries of its constituent polypeptides and the amount of any posttranslational modifications.

The **volume** of the hydrodynamic particle (centimeters³) should be

$$V_h = \frac{M_{\text{prot}}}{N_A} (\bar{v}_{\text{prot}} + \delta_{\text{H}_2\text{O}} \nu_{\text{H}_2\text{O}}^0) \quad (12-2)$$

where \bar{v}_{prot} is the partial specific volume of the protein in $\text{cm}^3 \text{ gram}^{-1}$ and $\nu_{\text{H}_2\text{O}}^0$ is the specific volume of pure water in $\text{cm}^3 \text{ gram}^{-1}$.

If **other solutes** j are attached to the hydrodynamic particle, Equation 12-1 is expanded by adding a set of terms δ_j , each of which is the grams of each solute j for every gram of protein, and Equation 12-2 is expanded by adding a set of terms $\delta_j \bar{v}_j$, where the \bar{v}_j are the partial specific volumes ($\text{cm}^3 \text{ gram}^{-1}$) of the solutes j . An example of bound solutes for which these additional terms are major features of these equations is a case in which the protein has bound detergents or bound lipids.²

The **standard diffusion coefficient** of a protein ($\text{cm}^2 \text{ second}^{-1}$) is designated as $D_{20,w}^0$, where the superscript indicates extrapolation to a zero concentration of protein and the subscripts indicate a correction to a temperature of 20 °C and to a solvent with the viscosity of pure water. The standard diffusion coefficient is a measure of f , the **frictional coefficient** (grams second^{-1}) of the hydrodynamic particle in water at 20 °C at infinite dilution:

$$f = \frac{k_B T}{D_{20,w}^0} \quad (12-3)$$

where k_B is Boltzmann's constant ($1.381 \times 10^{-16} \text{ erg K}^{-1}$) and T is the temperature (293.15 K). A standard diffusion coefficient and a frictional coefficient are particular and **intrinsic properties** of a given protein in a given solution.

The concept of the hydrodynamic particle qualifies the meaning of the diffusion coefficient presented in Chapter 1 and the frictional ratio presented in Chapter 6. By use of the equation for the frictional coefficient of a sphere, a **minimum frictional coefficient** for the hydrodynamic particle at infinite dilution can be defined as

$$f_{0,h} \equiv 6\pi\eta R_{0,h} \quad (12-4)$$

where the subscript zero refers to the minimization and η is the viscosity (pascal seconds). The viscosity of pure water at 20 °C is 1.002 mPa s. The **hydrodynamic radius**, $R_{0,h}$, is defined as the radius (centimeters) of a sphere with the same volume as the hydrodynamic particle:

$$R_{0,h} \equiv \left(\frac{3V_h}{4\pi} \right)^{1/3} \quad (12-5)$$

Consequently

$$f_{0,h} = 6\pi\eta \left[\frac{3M_{\text{prot}}}{4\pi N_A} (\bar{v}_{\text{prot}} + \delta_{\text{H}_2\text{O}} \nu_{\text{H}_2\text{O}}^0) \right]^{1/3} \quad (12-6)$$

The hydrodynamic radius, $R_{0,h}$, the radius of a sphere with the same volume as the hydrodynamic particle, must not be confused with the apparent radius, or Stokes radius, of the particle, a , the radius of a sphere with the same standard diffusion coefficient as the particle.

The definition of the minimum frictional coefficient for the molecule of protein, that expected of a hydrated sphere of the same volume as the hydrated molecule of protein, incorporates the water bound to the protein rather than treating the protein as if it were unhydrated as was done earlier (Equation 8-39). If $\delta_{\text{H}_2\text{O}}$ is 0.3 g (g of protein)⁻¹, consistent with the values in Table 6-4, the **hydrated effective sphere** should have a volume 1.4 times as large as the unhydrated effective sphere (if \bar{v}_{prot} is taken as 0.74 $\text{cm}^3 \text{ g}^{-1}$ and $\bar{v}_{\text{H}_2\text{O}}$ as 1.00 $\text{cm}^3 \text{ g}^{-1}$), and the frictional coefficient of the hydrated effective sphere of protein, $f_{0,h}$, should be 1.12 times larger than the frictional coefficient of the unhydrated effective sphere of protein, $f_{0,unh}$. This is consistent with the fact that the smallest frictional ratios, $f/f_{0,unh}$, observed for globular proteins are always greater than or equal to 1.1 when no correction is made for hydration.

The relationship between the frictional ratio (f/f_0) and the shape of a particle has been derived for **ellipsoids of revolution**, either prolate or oblate.³ The relationships can be presented graphically (Figure 12-1A).¹ After the frictional ratio ($f/f_{0,h}$) for the hydrodynamic particle has been calculated from the observed value of the frictional coefficient f (Equation 12-3) and the calculated value of $f_{0,h}$ (Equation 12-6), the apparent **axial ratio**, a/b , of the hydrodynamic particle can be read from the graph.

Molecules of protein are neither prolate nor oblate ellipsoids of revolution, but exact solutions to the hydrodynamic equations are available only for these shapes. Such an approximation, however, may provide some insight into the shape of a particular molecule of protein, especially when the frictional ratio differs greatly from 1. Such a result cannot be explained on the basis of an unexpectedly high degree of hydration and states that the protein of interest is peculiar in its shape. In the particular case where the molecule is thought to resemble a **cylindrical rod** of length L and diameter d , it has been concluded that the dimensions of that cylindrical rod can be calculated by using the frictional ratio to determine the axial ratio of an equivalent prolate ellipsoid, a/b , and then applying the formula

$$\frac{L}{d} = \left(\frac{3}{2} \right)^{1/2} \frac{a}{b} \quad (12-7)$$

The segment of rope formed by triple-helical collagen type I (Figure 9-33), usually referred to as a protofil-

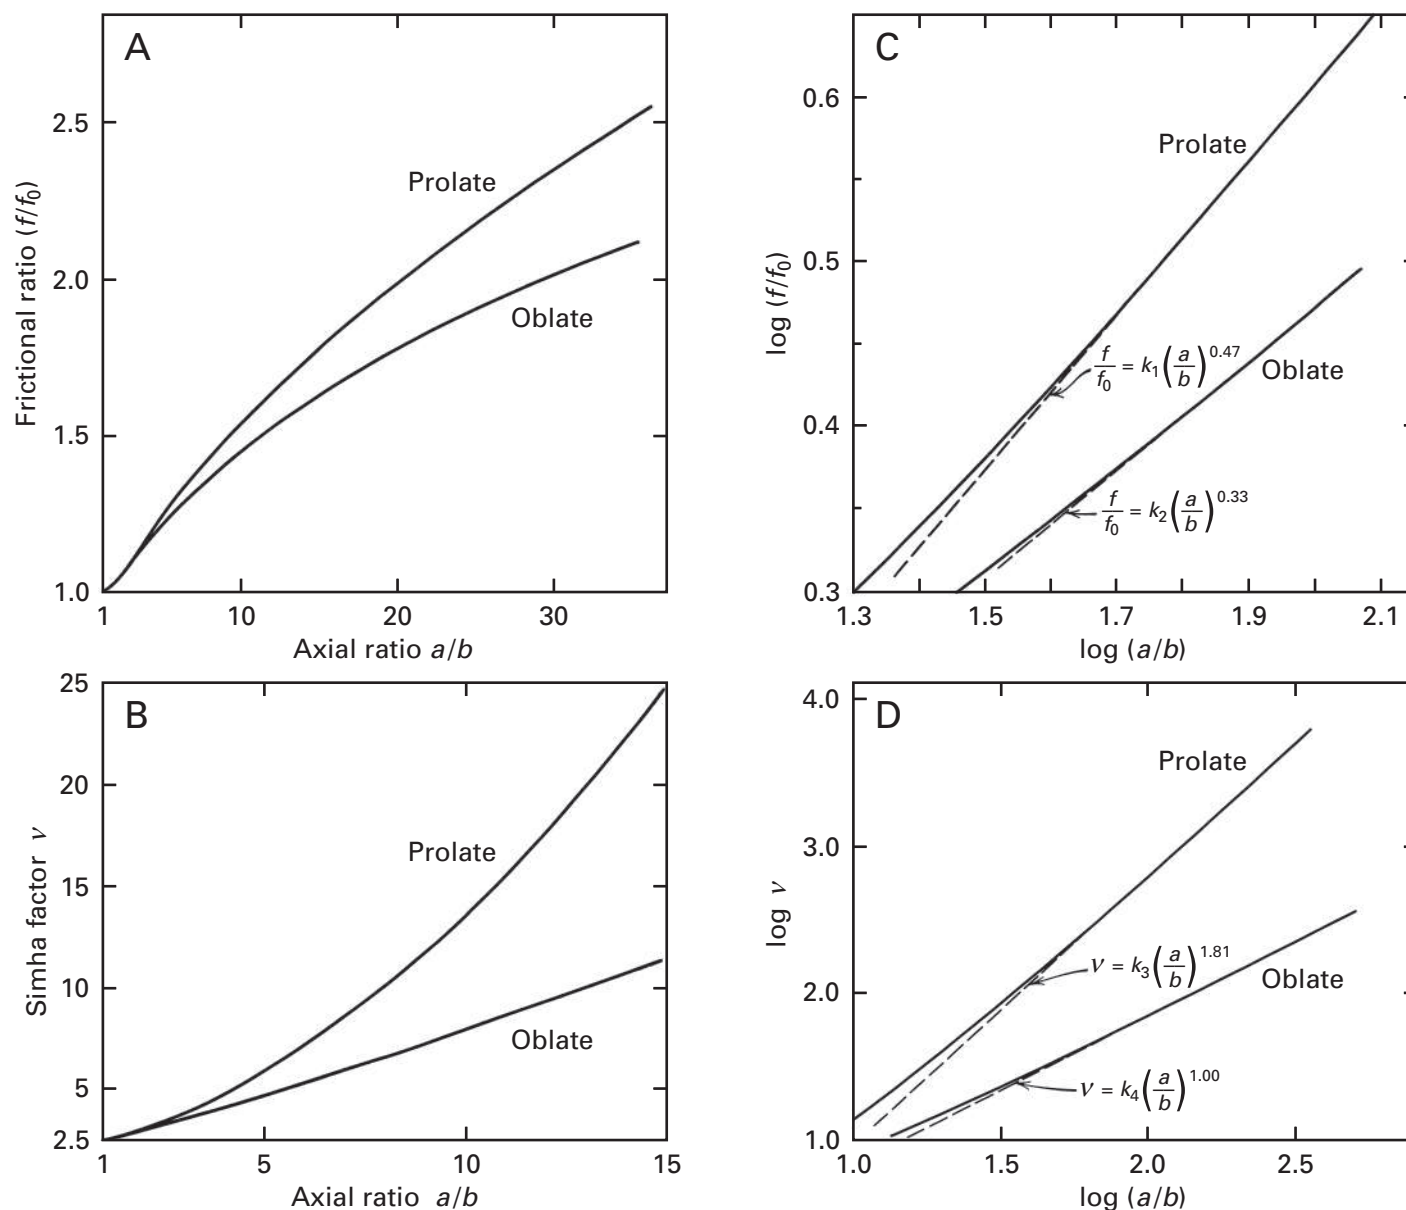

Figure 12-1: Graphic relationships¹ between the axial ratio (a/b) of an oblate ellipsoid of revolution or a prolate ellipsoid of revolution and either (A) the frictional ratio (f/f_0) or (B) the Simha factor (ν). A prolate ellipsoid of revolution is generated by rotation around the major axis of an ellipse; an oblate ellipsoid of revolution, by rotation around the minor axis. The relationships for smaller values of the axial ratio are given directly. For large values of the axial ratio (>10) the logarithm of the frictional ratio (C) or the logarithm of the Simha factor (D) is given as a function of the logarithm of the axial ratio. The frictional ratio or the Simha factor, determined experimentally, can be converted into an axial ratio with the appropriate graph. When the axial ratios are greater than 100, each of the four curves in panels C and D becomes a straight line to infinity. As a result, values of the frictional ratios or the Simha factors that are greater than those on the graphs can still be converted to values for axial ratios with the use of the slopes of these lines for extrapolation. The slope of the line in panel C for logarithms of the frictional ratios of prolate ellipsoids is 0.47; that for oblate ellipsoids, 0.33; the slope of the line in panel D for logarithms of the Simha factors for prolate ellipsoids is 1.81; and that for oblate ellipsoids, 1.00. Reprinted with permission from ref 1. Copyright 1961 John Wiley.

ament, is known to be a rod. The molar mass of a triple-helical rope of collagen type I is $281,000 \text{ g mol}^{-1}$, its partial specific volume¹ is $0.695 \text{ cm}^3 \text{ g}^{-1}$, and its standard diffusion coefficient¹ is $0.85 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$. If it is assumed that $\delta_{\text{H}_2\text{O}} = 0.3 \text{ g g}^{-1}$, then the frictional ratio for the hydrodynamic particle, $f/f_{0,h}$, would be 5.3, for which the ratio of L/d would be 210 (Figure 12-1C and Equation 12-7). The volume of the hydrodynamic particle containing a

segment of rope of collagen type I, based on the assumption that $\delta_{\text{H}_2\text{O}} = 0.3$, would be 460 nm^3 (Equation 12-2), which would fill a cylinder 285 nm long with a diameter of 1.35 nm. From the dimensions of the triple helix (Figure 9-33) and the length of the polypeptide, a molecule of unpolymerized collagen type I is thought to be 300 nm long.

It is also possible to calculate the frictional coeffi-

cient for a **string of spherical beads**⁴ in various geometric arrangements. Fibronectin in electron micrographs appears as a flexible segment of rope 130 nm in length. A string of spherical beads of that length and with a total volume equal to that of a molecule of fibronectin has a frictional coefficient equal to that calculated from its standard diffusion coefficient.⁵ Before the length of a molecule of caldesmon had been established by electron microscopy, it was calculated that a string of spherical beads 74 nm in length with a total volume equal to that of a molecule of the protein would have a frictional coefficient equal to that observed for a molecule of the protein.⁶ It was later shown that the length of the rope-like molecule of caldesmon seen in electron micrographs of the protein is about 70 nm.⁷ A string of 12 small spherical beads ($r = 0.8$ nm) attached to a single larger spherical bead ($r = 3$ nm) produced a structure that resembles electron micrographs of vinculin and has a frictional coefficient equal to that calculated from the standard diffusion coefficient observed for the protein.⁸

The frictional coefficient of a molecule of protein can also be determined by **sedimentation velocity**. Consider a hydrodynamic particle dissolved in aqueous solution that is submitted to a high centrifugal force in the rotor of an ultracentrifuge. The centrifugal force on the particle is equal to $m_h \omega^2 r$, where ω is the angular velocity (radians second⁻¹) of the rotor, m_h is the mass (grams) of the hydrodynamic particle, and r is the distance (centimeters) the particle is from the axis of the rotor. This centrifugal force is countered by the buoyant force, which is equal to $V_h \rho_{\text{sol}} \omega^2 r$, where ρ_{sol} is the density (grams centimeter⁻³) of the solution displaced by V_h , the volume (centimeters³) of the hydrodynamic particle. The net force on the particle is

$$F = \omega^2 r (m_h - V_h \rho_{\text{sol}}) \quad (12-8)$$

Because the measurements are extrapolated to a solution of protein at a concentration of zero in only water, it can be assumed that ρ_{sol} is insignificantly different from ρ_0 , the density of water at the appropriate temperature. Because ρ_0 is the reciprocal of $V_{\text{H}_2\text{O}}^0$, when expressions for m_h (Equation 12-1) and V_h (Equation 12-2) are substituted, the net force is

$$F = \frac{M_{\text{prot}}}{N_A} \omega^2 r (1 - \bar{v}_{\text{prot}} \rho_0) \quad (12-9)$$

The term $(M_{\text{prot}}/N_A)(1 - \bar{v}_{\text{prot}} \rho_0)$ is the **buoyant mass** of the hydrodynamic particle of the protein.

The net force (Equation 12-9) causes the hydrodynamic particle to accelerate. As it accelerates, the frictional force, which is equal to fu , where f is the frictional coefficient (grams second⁻¹) and u is the velocity (centimeters second⁻¹) of the hydrodynamic particle,

increases in direct proportion to the velocity of the particle until it just balances the net centrifugal force. At that point, a steady state is achieved, the forces on the hydrodynamic particle are equal and opposite, the particle travels in the direction of the centrifugal force at its **terminal velocity**, and

$$fu = \frac{M_{\text{prot}}}{N_A} \omega^2 r (1 - \bar{v}_{\text{prot}} \rho_0) \quad (12-10)$$

This equation can be rearranged to give

$$s \equiv \frac{u}{\omega^2 r} = \frac{M_{\text{prot}} (1 - \bar{v}_{\text{prot}} \rho_0)}{f N_A} \quad (12-11)$$

The term on the left, $u\omega^{-2}r^{-1}$, which is the observed velocity normalized for all of the parameters of the instrument, can be directly measured, and it is referred to as the **sedimentation coefficient**, s . The standard sedimentation coefficient (seconds) for the hydrodynamic particle is designated as $s_{20,w}^0$, where superscript and subscript have the same meaning as before. Because sedimentation coefficients of proteins are between 10^{-13} and 10^{-11} s, the unit 10^{-13} s is designated as S, the Svedberg.

Because it is only a function of universal constants and the properties of the molecule of protein itself, the standard sedimentation coefficient is also an intrinsic property of the protein. In particular it is, as is the standard diffusion coefficient, a direct measurement of the frictional coefficient

$$f = \frac{M_{\text{prot}} (1 - \bar{v}_{\text{prot}} \rho_0)}{s_{20,w}^0 N_A} \quad (12-12)$$

To use Equation 12-12, the molar mass of the protein must be a fixed and known quantity. If the protein is normally engaged in a reaction that changes its molar mass, such as the equilibrium between the dimers and the tetramer of hemoglobin, a molar mass cannot be assigned. If the protein is participating in such a reaction, abnormally large decreases in the sedimentation coefficient will occur as the concentration of the protein is decreased upon extrapolation to the zero concentration of protein.

Aspartate carbamoyltransferase from *Escherichia coli* (Figure 9-37) serves as an example of the application of analysis by sedimentation to the study of a hydrodynamic particle of known shape. It is a protein of molar mass 308,100 g mol⁻¹, and its standard sedimentation coefficient $s_{20,w}^0$ is 11.6 S,^{9,10} from which a frictional coefficient f of 11.6×10^{-8} g s⁻¹ can be calculated. The minimum frictional coefficient, $f_{0,\text{unh}}$, for the unhydrated protein ($\delta_{\text{H}_2\text{O}} = 0$), folded as a sphere, would be 8.5×10^{-8} g s⁻¹ (Equation 12-6). If hydration of

0.3 g g^{-1} is assumed, this would give a frictional ratio $f/f_{0,h}$ of 1.22. Although the protein (Figure 9–37) does not have the axial ratio suggested by the frictional ratio (a/b would be 5 were the protein an oblate ellipsoid), the value of 1.22 probably results from both the irregular shape of the molecule and an abnormally large amount of bound water within the central cavity between the two C subunits.

It has been demonstrated crystallographically¹¹ that when aspartate carbamoyltransferase binds the enzymatic inhibitor *N*-(phosphonacetyl)-L-aspartate, the protein undergoes a conformational change that alters the disposition of its subunits significantly. A **conformational change** in a protein is any change in its structure brought about by a change in the solution, for example, the addition of an inhibitor. The net effect of this particular conformational change in aspartate carbamoyltransferase is to move the two trimers of catalytic α subunits (Figure 9–37) 1.2 nm farther apart. In the process, the water-filled space between the two C subunits widens by the same amount. This change in structure caused by the binding of the inhibitor can be detected as a change in the sedimentation coefficient of aspartate carbamoyltransferase.^{9,10} This change is accurately quantified by difference sedimentation analysis in which the two samples, with and without the inhibitor, are simultaneously monitored in separate cells in the same rotor.¹² The sedimentation coefficient^{9,10} decreases by 3.4% upon the change in structure. The diameter of the space between two trimers of catalytic α subunits of aspartate carbamoyltransferase is about 8 nm,¹¹ so the increase in the amount of water between them resulting from a movement apart of 1.2 nm should be about $40,000 \text{ g mol}^{-1}$. This change alone should increase the frictional coefficient (Equation 12–6) by 3–4%, which would account completely for the observed change of 3.4%.

Both the high frictional ratio for unexpanded aspartate carbamoyltransferase and the increase in hydration experienced upon its expansion illustrate the fact that **oligomeric proteins**, because of the spaces among the subunits, display greater hydration than monomeric proteins. From results of measurements of the scattering of X-radiation at small angles by solutions of proteins, it has been calculated that while monomeric proteins have values of $\delta_{\text{H}_2\text{O}}$ of 0.25–0.35 g g^{-1} , oligomeric proteins have significantly higher values for $\delta_{\text{H}_2\text{O}}$ of 0.35–0.7 g g^{-1} .^{13,14} If the hydration of aspartate carbamoyltransferase in its unexpanded state were 0.6 g g^{-1} , its frictional ratio would be only 1.13, a value that is easily accounted for by its irregular shape.

Desmin is one of the proteins that forms intermediate filaments (Figures 9–35 and 9–36). The monomeric unit of the polymer is an α_2 dimer of two identical polypeptides; those from chicken are 463 aa long. The core of the dimer is a coiled coil of two α helices, one from each polypeptide. This coiled coil is contained within a fragment of the dimer containing the polypep-

tides from Glycine 70 to Phenylalanine 415 that can be produced by digestion with chymotrypsin. The standard sedimentation coefficient of this dimeric fragment is 2.85 S, while the standard sedimentation coefficient of an $(\alpha_2)_2$ dimer of this dimer is 3.85 S.¹⁵ If it is assumed that both of these oligomers, the dimer and the dimer of dimers, can be represented as cylindrical rods, L/d for the α_2 dimer is 28 and that for the $(\alpha_2)_2$ dimer of dimers is 44. Consequently, the $(\alpha_2)_2$ dimer of dimers is 1.7 times longer than one α_2 dimer. If this approximation is realistic, the coiled coils of the two dimers must be staggered by about 0.7 of their length in the dimer of dimers.

The standard diffusion coefficient and the standard sedimentation coefficient provide **independent determinations** of the frictional coefficient of a molecule of protein. The force producing net flux of protein when diffusion is measured is chemical potential, which is unrelated to, as well as being somewhat less concrete of a concept than, centrifugal force. Furthermore, the theoretical derivations of the relationship between the diffusion coefficient and the frictional coefficient and that between the sedimentation coefficient and the frictional coefficient are entirely different. It is of interest to compare (Table 12–1) the two frictional coefficients, that calculated from diffusion (f_{diff}) and that calculated from sedimentation (f_{sed}). Depending upon one's prejudice, the agreement between the numbers is either as one expected or quite gratifying. The lack of any systematic deviation verifies the assumption, first made by Einstein, that the same frictional coefficient applies to both diffusion and sedimentation.

The frictional ratios ($f_{\text{av}}/f_{0,h}$), where f_{av} is the average of the two measurements, are close to 1 (1.1–1.2) for most globular proteins (Table 12–1), but even in these instances the frictional ratios of the hydrated particles predict (Figure 12–1A) an axial ratio of greater than 3, which is unrealistic. These values of 1.1–1.2 do not indicate elongation but reflect the fact that molecules of protein, even when they are almost spherical, are not smooth spheres but globular macromolecules with **irregular, rough surfaces**. Proteins such as fibrinogen, apolipoprotein(a), and plasminogen, however, which are known from other observations to be highly asymmetric, have much higher frictional ratios.

The specific examples of **elongated or excessively hydrated proteins** described in detail so far, collagen, fibronectin, caldesmon, vinculin, aspartate carbamoyltransferase, and desmin, are macromolecules about which enough is known that the hydrodynamic measurements can be evaluated comprehensively. When no other structural information is available about a protein, a frictional ratio around 1.1 is strong evidence that it is globular, but frictional ratios greater than 1.1 are difficult to interpret. For example, the fact that human bifunctional polynucleotide 3'-phosphatase/5'-kinase has a frictional ratio ($f/f_{0,h}$; $\delta_{\text{H}_2\text{O}} = 0.3$) of 1.30¹⁹ could result from an unusually irregular shape, an elongated shape,

or an abnormally large amount of bound water or, most likely, some combination of all of these factors.

Measurement of the **viscosity** of a solution of a protein also provides an evaluation of the shape of the hydrodynamic particle. When a fluid flows through a cylindrical capillary under the appropriate circumstances, laminar flow occurs. The fluid immediately adjacent to the walls of the capillary is stationary, and the fluid at the center of the capillary has the highest rate of flow. Each cylindrical lamina between the center and the wall moves with an intermediate velocity that, as the distance from the center increases, monotonically decreases to a value of zero at the wall. **Laminar flow** requires that each cylindrical lamina move more slowly than its neighbor toward the center. As such, shear occurs between adjacent lamina throughout the capillary. The surfaces at which shear occurs are all parallel to the axis of the capillary. The more viscous the fluid, the more difficult it will be for these surfaces of shear to move across one another, and the more slowly the fluid will flow through the capillary. The time required for a given volume of a fluid to move through a given capillary at a given hydrostatic pressure is directly proportional to η , the viscosity (pascal seconds) of the fluid.

The addition of macromolecules such as proteins to the fluid in the capillary interrupts the shear that otherwise would occur in the solution in their vicinity and increases the viscosity of the solution. This increase can be expressed in terms of the **specific viscosity**, η_{sp} , which is defined by

$$\eta_{sp} \equiv \frac{\eta' - \eta}{\eta} = \frac{\eta'}{\eta} - 1 \quad (12-13)$$

where η' is the viscosity of the solution containing a particular concentration of the protein and η is the viscosity of an otherwise identical solution lacking the protein. The specific viscosity is a positive number because η' is always greater than η . The specific viscosity is the normalized incremental increase in the viscosity caused by the protein.

If the flow through the capillary is driven only by the weight of the fluid, the specific viscosity is readily measured because

$$\frac{\eta'}{\eta} = \frac{t'\rho'}{t\rho} \quad (12-14)$$

where t is the time for a given volume of a solution to flow through the capillary, ρ is the density of the solution, and the primed and unprimed terms refer to the solution of protein and an identical solution lacking the protein, respectively.

The specific viscosity, η_{sp} , is the fractional increase in the viscosity of the solution due to addition of the protein, and it increases monotonically as the concentration of protein is increased. To render this increase an intrinsic property of the protein, regardless of its concentration, the **intrinsic viscosity**, $[\eta]$ (centimeters³ gram⁻¹), is defined as

$$[\eta] \equiv \lim_{\gamma_{prot} \rightarrow 0} \frac{\eta_{sp}}{\gamma_{prot}} \quad (12-15)$$

where γ_{prot} is the concentration of protein in grams centimeter⁻³. At low concentrations of protein, η_{sp} should be directly proportional to γ_{prot} , and $[\eta]$ is simply the slope of

the line of η_{sp} plotted against γ_{prot} . Neither the specific viscosity nor the intrinsic viscosity is itself a viscosity. The intrinsic viscosity is sometimes called the **limiting viscosity number** to avoid this confusion.

For macromolecules such as proteins, it can be shown¹ that

$$[\eta] = v \frac{V_h N_A}{M_{prot}} \quad (12-16)$$

$$[\eta] = v \left(\bar{v}_{prot} + \delta_{H_2O} v_{H_2O}^0 \right) \quad (12-17)$$

where v is a dimensionless coefficient of proportionality referred to as the **Simha factor**. On the basis of Einstein's calculations, the value of v for a spherical hydrodynamic particle is 2.5. As with the frictional ratio, $f/f_{0,h}$, the relationship between the Simha factor v and shape has been derived for ellipsoids of revolution.²⁰ The relationships can be presented graphically (Figure 12-1B). If a value for δ_{H_2O} is assumed, v can be calculated from

$$v = \frac{[\eta]}{\bar{v}_{prot} + \delta_{H_2O} v_{H_2O}^0} \quad (12-18)$$

and the apparent value of the axial ratio can be read from the graph.

From Equation 12-17, if $\delta_{H_2O} = 0.3 \text{ g g}^{-1}$, $\bar{v}_{prot} = 0.74 \text{ cm}^3 \text{ g}^{-1}$, and $v_{H_2O}^0 = 1 \text{ cm}^3 \text{ g}^{-1}$, $[\eta]$ would be $2.6 \text{ cm}^3 \text{ g}^{-1}$ if the hydrodynamic particle were a sphere regardless of its molar mass. What this means is that as long as δ_{H_2O} and \bar{v}_{prot} do not vary significantly, the viscosities observed for a set of solutions, each of a different spherical molecule of protein and each at the same concentration in grams centimeter⁻³, will be the same regardless of whether the mass is distributed among only a few large spheres because the protein has a large molar mass or is distributed among many small spheres because the protein has a small molar mass. Most globular proteins do have intrinsic viscosities between 3.0 and $4.0 \text{ cm}^3 \text{ g}^{-1}$ regardless of their molar masses. An observation of an intrinsic viscosity in this range demonstrates that a protein is globular.

Intrinsic viscosity is dramatically **more sensitive to the asymmetry of a molecule** of protein than is the frictional coefficient. The frictional coefficient of a molecule of collagen type I is only 5 times larger than the frictional coefficient it would have if it were a hydrated sphere, but the intrinsic viscosity of a solution of collagen type I is 460 times larger than the intrinsic viscosity it would have if it were a hydrated sphere. The intrinsic viscosity of collagen type I¹ is $1150 \text{ cm}^3 \text{ g}^{-1}$. If it is assumed that $\delta_{H_2O} = 0.3 \text{ g g}^{-1}$, the Simha factor is 1160 (Equation 12-18), and if it is assumed that the molecule is cylindrical, the axial ratio (a/b) of the hydrodynamic

particle would be 140 (Figure 12-1D) and the ratio of cylindrical length to diameter (L/d) would be 170 (Equation 12-7). This ratio is that of a cylinder of length 260 nm with a diameter of 1.5 nm and a volume of 460 nm^3 . As noted before, collagen type I is 300 nm in length.

Another procedure that can provide information about the shape of a molecule of protein is the **scattering** of electromagnetic radiation or neutrons. In the earlier discussion of light scattering, it was mentioned that the intensity of the scattered light from a solution of protein can depend on the angle at which the measurement is made. This is due to the fact that if the molecule of protein has at least one dimension that is an appreciable fraction of the wavelength of the light, photons scattered from different points in the same molecule of protein will be out of phase, and **intramolecular interference** due to these mismatched phases will diminish the overall intensity of the scattered light. This interference increases as the angle at which the scattered light is measured, the scattering angle θ (Figure 8-4), is increased. At a scattering angle of 0, the angle of the **forward scattering** i_0 , there is no interference. It is the forward scattering that contains information about the molar concentration of particles in the solution, and hence the molar mass of those particles.

It can be shown that, when the contribution of the virial coefficients to the scattering is eliminated by extrapolating the measurements to zero concentration of protein

$$\lim_{\gamma_{prot} \rightarrow 0} \frac{K \gamma_{prot}}{R_\theta} \left(\frac{\partial \bar{n}}{\partial \gamma_{prot}} \right)_{T,P,\mu}^2 = \left(\frac{1}{M_{prot}} \right) \left[\frac{1}{P(\theta)} \right] \quad (12-19)$$

where K is the optical constant (moles centimeter⁻⁴) defined by Equation 8-28, R_θ is the Rayleigh ratio (centimeters⁻¹) calculated from the measurements by Equations 8-30 or 8-31, γ_{prot} is the concentration of protein in the units of grams centimeter⁻³, $(\partial \bar{n} / \partial \gamma_{prot})_{T,P,\mu}$ is the change (centimeters³ gram⁻¹) in the refractive index of the solution as a function of the concentration of the protein, and M_{prot} is the molar mass (grams mole⁻¹) of the protein. As noted previously, the incremental scattering i_θ is the scattering that results only from the molecules of protein and is measured as the difference in scattering between the solution containing protein and an identical solution not containing protein.

The function $P(\theta)$ is the factor by which the intensity of the light scattered only by the protein, the incremental scattered light (i_θ), is decreased as a result of the interference:²¹

$$P(\theta) = 1 - \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2 \frac{\theta}{2} + \dots \quad (12-20)$$

where R_G is the radius of gyration (centimeters) of the molecule of protein and θ is the angle relative to the incident radiation at which the scattered radiation is measured. The value for the wavelength of the light, λ , is its wavelength in the solution

$$\lambda = \frac{\lambda_0}{\tilde{n}} \quad (12-21)$$

where λ_0 is its wavelength in a vacuum. Equation 12-20 is an infinite series, but at small values of θ the higher terms become negligible and the approximation

$$\lim_{\theta \rightarrow 0} \frac{1}{P(\theta)} = \frac{1}{1 - \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2 \frac{\theta}{2}} = 1 + \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2 \frac{\theta}{2} \quad (12-22)$$

can be used. In practice

$$\lim_{\substack{\theta \rightarrow 0 \\ \gamma_{\text{prot}} \rightarrow 0}} \frac{\gamma_{\text{prot}}}{R_\theta} = \frac{\gamma_{\text{prot}}}{R_0} \left(1 + \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2 \frac{\theta}{2} \right) \quad (12-23)$$

A plot of the left-hand quotient, extrapolated to zero concentration of protein at each value of θ , against $\sin^2(\theta/2)$, for small values of θ , will be a straight line from the slope and intercept of which a value of R_G , the radius of gyration, can be calculated. Equation 12-19 emphasizes that the interference arising from the shape of the molecule of protein is independent from the colligative property of light scattering from which its molar mass can be estimated.

The radius of gyration of the molecule of protein is the molecular parameter that is obtained from the angular dependence of the intensity of the scattered radiation and that provides information about the shape of the molecule of protein. The **radius of gyration** of a solid of uniform scattering density, as is usually assumed to be the case for proteins, is defined by the relationship

$$R_G^2 = \frac{\int_{\text{vol}} r^2 dV}{\int_{\text{vol}} dV} \quad (12-24)$$

where r is the distance of a volume element dV from the center of mass. The integration is performed over the whole volume of the solid. The advantage of the radius of gyration is that it can be calculated by numerical integration for any structure, for example, a crystallographic molecular model, and compared to the value obtained

from the measurement. For example, in an elongated protein such as fibronectin, which is known to be constructed from internally repeating domains, radii of gyration can be calculated for various rigid structures built from a string of spheres each representing one of the individual domains of the molecule, and these calculated values can be compared to the observed value for the radius of gyration estimated by light scattering.²²

The radius of gyration for a single sphere of uniform density is

$$R_G = \left(\frac{3}{5} \right)^{1/2} R_{\text{sph}} \quad (12-25)$$

where R_{sph} is the radius of the sphere. The radius of gyration for a cylindrical rod is

$$R_G = \frac{L_r}{12^{1/2}} \quad (12-26)$$

where L_r is the length of the rod. The radius of gyration for a prolate ellipsoid²³ is

$$R_G = \left(\frac{2a^2 + b^2}{5} \right)^{1/2} \quad (12-27)$$

where a and b are the semi-major and semi-minor axes, respectively.

The effect of the finite size of the molecule of protein on the scattered light is that its intensity, as reflected in R_θ (Equation 8-30 or 8-31), decreases as θ increases, owing to intramolecular interference, but its intensity will decrease significantly only if the term $[16\pi^2 R_G^2 \sin^2(\theta/2)]/3\lambda^2$ in Equation 12-23 is large enough to cause a measurable effect. In practice,¹ this means that at least one dimension of the protein must be greater than $\lambda/20$. The sizes of most molecules of protein are too small for this to be the case when visible light ($\lambda = 300\text{--}500$ nm in water) is used as the radiation. For example, the decrease in light scattering from a solution of fibronectin measured at a wavelength of 436 nm (in vacuo) was only about 10% at the maximum possible $\sin^2(\theta/2)$ of 0,²⁴ even though fibronectin has a molar mass of $519,000 \text{ g mol}^{-1}$, is a string of domains with a total length of 180 nm, and has a radius of gyration of 8.6 nm.²²

For most proteins, significant decreases in angular light scattering are observed only when **X-radiation** is used ($\lambda = 0.1\text{--}0.2$ nm). Unfortunately, this is radiation of such **short wavelength** that complete intramolecular interference occurs at quite small values of θ (Equation 12-20), and the scattered radiation from a solution of protein becomes equal to that from the solution lacking protein when θ is only $1\text{--}2^\circ$. Fortunately, accurate measurements of scattered X-radiation can be made at the necessary small angles. The values for R_G obtained from

small-angle X-ray scattering, for example, 1.75 nm for myoglobin,²⁵ 2.3 nm for cyclic AMP-dependent protein kinase,²⁶ and 1.36 nm for reduced cytochrome *c*,²⁷ demonstrate the ability of this technique to provide information about small globular proteins.

When the observations of **X-ray scattering** are presented, a different convention is used to approximate $P(\theta)$. Because

$$\exp(-x) = 1 - x + \frac{x^2}{2!} - \frac{x^3}{3!} + \dots \quad (12-28)$$

the first two terms in Equation 12-20 are identical to the first two terms in the expansion of $\exp[(16\pi^2 R_G^2 \sin^2(\theta/2)/3\lambda^2)]$, and at small angles^{21,28}

$$\lim_{\theta \rightarrow 0} \ln P(\theta) = - \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2 \frac{\theta}{2} \quad (12-29)$$

Because at such small angles none of the terms in Equation 12-19 except i_θ (see Equations 8-30 and 8-31) and $P(\theta)$ change as θ is varied, a plot of $\ln i_\theta$ as a function of $\sin^2(\theta/2)$ at the smallest angles will give a straight line with a slope of $-16\pi^2 R_G^2/(3\lambda^2)$.^{*} From this slope R_G is readily determined.

In reports of studies of X-ray scattering, there are several ways in which the observations are analyzed. First, the data can be presented directly (Figure 12-2A)²⁶ as the natural logarithm of the observed incremental scattering intensity ($\ln i_\theta$) as a function of q , where

$$q \equiv \frac{4\pi \sin(\theta/2)}{\lambda} \quad (12-30)$$

The advantage of this presentation is that the scattering calculated from a particular model of the molecule of protein as a function of q can be compared to the complete set of scattering data. Second, the data can be presented in a **Guinier plot** as $\ln i_\theta$ as a function of q^2 (Figure

12-2B). The advantage of this presentation is that a radius of gyration can be estimated from the limiting slope at the smallest values of scattering angle θ , typically those less than 1° (Figure 12-2A). Third, the **distance distribution function** $p(r)$, which is the Fourier transform of the scattering function

$$p(r) = \frac{1}{2\pi} \int i_\theta q r \sin(qr) dq \quad (12-31)$$

can be calculated. The distance distribution function $p(r)$ is the frequency with which vectors of a length r connect two volume elements within the molecule of protein (Figure 12-2C). In practice, the inverse Fourier transform of Equation 12-31

$$i_\theta = 4\pi \int_0^{d_{\max}} p(r) \frac{\sin(qr)}{qr} dr \quad (12-32)$$

where d_{\max} is the maximum dimension of the particle, is used to compute $p(r)$ in reverse.²⁹

In a plot of the distance distribution function $p(r)$ against r , the **longest dimension of the molecule** of protein is the intercept of the function with the abscissa. For example, the longest dimension of a molecule of cyclic AMP-dependent protein kinase is 7.2 nm (Figure 12-2C). From scattering curves of myoglobin in its native state (Figure 4-18), after the removal of its heme, and then in solution at pH 2, the gradual expansion of the protein as its structure was disrupted could be followed by monitoring the gradual increase in the value of this intercept.²⁵

The shape of the distance distribution function provides information about the shape of the molecule of protein.²⁹ If the molecule of protein is globular, the distance distribution function $p(r)$ has a fairly symmetric shape with a single maximum (Figure 12-2C). If the molecule of protein has an elongated structure, the distance distribution function will be skewed. If it is elongated in only one dimension so that it is prolate in shape, the maximum will be shifted to short distances because there are more short vectors in a prolate solid than there are long vectors.²⁹ There is a slight indication of such an elongation in Figure 12-2C. If the molecule of protein contains two well-separated globular domains, there will be two maxima in the distance distribution function, the one at shorter distances for vectors confined within each domain and the one at longer distances for vectors between domains.

A distinction can be made between small-angle scattering and solution scattering. Measurements of **small-angle scattering** are confined to the region of the scattering function for angles that are only large enough to define accurately the distance distribution function $p(r)$. This range of small angles also includes scattering at the smallest angles, which provides an estimate of the

* Unfortunately, investigators who study the scattering of X-radiation and neutrons use a different convention for the scattering angle (Figure 8-4) from those who study the scattering of light. The same scattering angle routinely designated as θ during measurements of light scattering is routinely designated as 2θ during measurements of X-ray scattering and neutron scattering. Consequently, the angles θ from measurements of X-ray scattering and neutron scattering must be multiplied by a factor of 2 before they are used as angles θ in the equations presented in this text. The term $\sin^2(\theta/2)$ used when results of light scattering are presented thus becomes $\sin^2 \theta$ when results of small-angle X-ray scattering and neutron scattering are presented, and values of $\sin^2 \theta$ from X-ray scattering and neutron scattering are equivalent to values of $\sin^2(\theta/2)$ in the equations used in this text. In measurements of X-ray scattering and neutron scattering, the slope of the line when $\ln i_\theta$ is plotted as a function of the $\sin^2 \theta$ used by these investigators has the value $-16\pi^2 R_G^2/3\lambda^2$.

Figure 12-2: Scattering of X-radiation of wavelength 0.154 nm by a solution of cyclic AMP-dependent protein kinase at a concentration of 66 μM .²⁶ (A) Solution scattering curve. The natural logarithm of the incremental scattering intensity ($\ln i_\theta$) of the entire set of data, which includes intensities to 1% of the maximum scattering, is plotted as a function of q (Equations 8–30, 8–31, 12–19, 12–29 and 12–30). The set of data includes scattering angles θ to 3.5° , the largest angle at which incremental scattering intensity could be measured. (B) Small-angle X-ray scattering curve. In a Guinier plot, the natural logarithm of the incremental scattering intensity is plotted as a function of q^2 at scattering angles less than 1° ($q < 0.7$) for all of the data from the same set as in panel A. The limiting slope (the line drawn in the figure) provides the radius of gyration (2.31 nm) of the unliganded cyclic AMP-dependent protein kinase. (C) Distance distribution function. The Fourier transform (Equation 12–31) of the scattering profile in panel A is the distance distribution function $p(r)$, the frequency with which two volume elements within the actual structure of cyclic AMP-dependent protein kinase in solution are a distance r from each other. It provides an estimate of the longest dimension (7.2 nm) of the molecule of protein. The crystallographic molecular model of cyclic AMP-dependent protein kinase has a peptide bound in the active site. A molecular model of the empty protein was constructed in which the two structural domains enclosing the peptide were opened by 39° relative to their orientation in the crystallographic molecular model. Each carbon, oxygen, and nitrogen in this hypothetical model was converted into an equivalent sphere of scattering density. The interference expected from this arrangement of spheres as a function of scattering angle is the curve drawn through the complete set of data in panel A, and the distance distribution function $p(r)$ calculated from that theoretical scattering curve in panel A is the curve drawn through the data in panel C. radius of gyration (Figure 12-2B; Equations 12–19 and 12–29) and an estimate of the forward scattering i_0 and hence the molar mass of the protein (Equation 12–19). **Solution scattering** includes the data at larger scattering angles, where more features are observed (Figure 12-2A), such as subsidiary peaks in the scattering function. In the region of small-angle scattering, the connection between measurements of scattering and hydrodynamic measurements is most apparent. In the region of solution scattering, information about the internal structure of the protein is revealed.

The **complete solution scattering curves** for different proteins are distinct (Figure 12-3),³⁰ and these distinctions indicate that each solution scattering curve contains information about the structure of the molecule of protein beyond just its radius of gyration and distance distribution function. There are several methods for extracting this information.³¹ Small uniform spheres can be arranged to produce a hypothetical structure thought to represent the structure of the molecule of protein, and a theoretical solution scattering curve for this arrangement can be calculated and compared to the observed solution scattering curve.³² The spheres can be the individual atoms in a crystallographic molecular model,^{33,34} and it is possible to calculate the **theoretical solution scattering curve** that a particular crystallographic molecular model should produce.²⁹ In order to duplicate the observed solution scattering curve with the theoretic-

Figure 12-3: Solution scattering curves for, in descending order, myoglobin (my), troponin C in the presence of Ca^{2+} (tc- Ca^{2+}), troponin C in the absence of Ca^{2+} (tc), a tandem pair of fibronectin type 3 domains from $\beta 4$ integrin (fn_2), spermadhesin PSP-I/PSP-II (sad), chymotrypsinogen A (ch), the domain C-lytA from pneumococcal autolysin (ly), superoxide dismutase (sd), ovalbumin (ov), tubulin (tb), nitrite reductase (NO-forming) (nr), and catalase (cat).³⁰ The observed curves of scattering density were normalized by dividing each along its length by the intensity of the forward scattering i_0 , and the logarithms of these normalized profiles are presented, displaced by one logarithmic unit from each other. For example, $\log i_0$ for the scattering curve of myoglobin was arbitrarily designated as 15; that for ovalbumin, 7; and that for catalase, 4. The data are the irregular curves. The smooth curves drawn through the data are theoretical scattering curves of interference as a function of q calculated from respective arrangements of sets of spheres of 0.3 nm radius, each arrangement with the same total volume as the respective molecule of protein. The spheres were systematically rearranged until their arrangement reproduced the experimental curve as closely as possible. The final arrangement of spheres in each case ended up resembling in its shape the crystallographic molecular model of the respective protein. Reprinted with permission from ref 30. Copyright 2000 Elsevier B.V.

cal scattering curve, however, it is necessary to include a layer of hydration around the molecule of protein that is about 0.3 nm thick.³⁵ The density of the water in this layer has a density 1.05–1.20 times that of the bulk water.²⁹ It is also possible to represent the domains of a molecule of protein as ellipsoids of the appropriate

dimensions in a particular arrangement and calculate the scattering curve of this representation (Figure 12-2A, solid line).²⁶

A rough estimate of the shape of a molecule of protein of unknown structure can be derived from the complete scattering curve alone with no preconceptions. An envelope can be generated by spherical harmonics. By systematically adjusting the parameters of the spherical harmonics, the scattering curve calculated from the envelope can be made to fit to the experimental scattering curve of the protein.³⁶ The resulting envelope will have two to four ellipsoidal protrusions of size, shape, and orientation determined by the fit to the data. It is also possible to rearrange systematically a set of uniform spherical beads until the structure they form produces a scattering curve matching the one observed (solid lines in Figure 12-3).³⁰

The ideal wavelength for studying the shape of most proteins by scattering would be somewhere between 1 and 10 nm. Unfortunately, light of these wavelengths cannot be readily generated. Neutrons produced in nuclear reactors, however, have velocities high enough that a beam with a wavelength of around 1 nm can be produced.^{37,38} This wavelength permits measurements of neutron scattering of solutions of proteins to be made to an angle θ of 20–40° before interference becomes too large. Measurements of **neutron scattering** from a solution of protein as a function of scattering angle are traditionally treated just as are those from X-ray scattering (Figures 12-2A and 12-3) even though observations can be made to much greater angles. In the range of small angles, Guinier plots provide radii of gyration and distance distribution functions, and complete solution scattering curves are fit with molecular models of the protein.^{37,39,40}

Neutrons are scattered by atomic nuclei and each isotope of each element scatters neutrons with a characteristic efficiency, quantified in its **scattering length**. The most dramatic difference in scattering length is that between the nucleus of hydrogen, a proton, and the nucleus of deuterium, a deuteron. Their neutron scattering lengths are –3.74 fm and 6.67 fm, respectively. The negative sign for that of a proton indicates that it scatters neutrons 180° out of phase to those scattered by a deuteron, so that the contrast produced by interference between a neutron scattered from a proton and that scattered from a deuteron is dramatic.

This large **difference in scattering length** between proton and deuteron has been used to map the distances between the proteins in the 30S ribosomal subunit from *E. coli* (Figure 11-5) by neutron scattering.⁴¹ The 21 deuterated proteins found in a 30S subunit were produced by growing bacteria on $[\text{D}_2]\text{H}_2\text{O}$. Pairs of deuterated proteins were reassembled into the same 30S subunit with the RNA and the other proteins all undeuterated. The incremental scattering of neutrons due to just the interference between each pair of deuter-

ated proteins was measured by subtracting the scattering from a mixture of the two respective types of 30S subunits that each contained only one of the two deuterated proteins.⁴² The Fourier transform (Figure 12-2C) of this incremental neutron scattering function provides the frequency with which vectors of length r connect a volume element in one deuterated protein with a volume element in the other. The maximum in such a curve is an estimate of the distance between the centers of mass of the two proteins in the 30S subunit. Enough of these distances (92 out of a possible 210) were measured to establish the relative positions of all 21 of the proteins in the 30S subunit.⁴¹ The majority of these relative positions agreed with their relative positions in the crystallographic molecular model of the 30S subunit.⁴³

Because the molecules of protein in solution are randomly oriented, solution scattering curves for X-radiation or neutrons are rotationally averaged and by themselves can provide only **spherically symmetric structural information**. Because molecules of protein are not spherically symmetric, some information about the structure of the protein must be available to constrain the model. For example, scattering of X-radiation or neutrons can be used together with crystallographic information. Crystallographic molecular models of the domains of a protein may be available but not a crystallographic molecular model of the complete protein, and scattering curves can provide models for the dispositions of the domains in the intact protein.⁴⁴ Intact immunoglobulin M is a pentameric ring of five subunits each composed of two Fab portions and one Fc portion formed from folded polypeptides related to those forming immunoglobulin G (Figure 11-1). Ten copies of a crystallographic molecular model of an Fab fragment of immunoglobulin G and five copies of a crystallographic molecular model of an Fc fragment of immunoglobulin G could be arranged to produce a structure with a calculated solution scattering curve in agreement with that observed for immunoglobulin M, and the appropriate combinations of Fab and Fc fragments could be arranged to produce structures with calculated solution scattering curves in agreement with those observed for the respective fragments.³²

Measurements of X-ray or neutron scattering from a solution of a protein for which a complete crystallographic molecular model is available have also proven to be valuable complements to the crystallographic observation. The usual result is that the theoretical solution scattering curve calculated from the crystallographic molecular model agrees closely with the one that is observed.^{29,45} Such coincidences are further evidence that the crystallographic molecular model represents the structure of the protein when it is in solution.

There are, however, a number of instances in which measurements of scattering have been used to **adjust crystallographic molecular models**. Two independently

shifting domains in a crystallographic molecular model of a protein are often confined to a particular orientation either by the packing forces of the crystal or by the binding of a ligand. A measurement of the radius of gyration from small-angle X-ray scattering of the protein in solution unconfined by the packing forces or in the absence of that ligand can be matched with a value calculated from a molecular model of the protein in which the domains have a different orientation from those observed crystallographically.⁴⁶ From a crystallographic molecular model of the protein²⁷ or a systematically altered conformation of that molecular model, the frequency with which vectors of length r actually do connect volume elements within the model can be calculated and compared with the observed distance distribution function. In Figure 12-2C, the line through the points was calculated from an altered conformation of the crystallographic molecular model of cyclic AMP-dependent protein kinase. This altered conformation was proposed to represent the structure that the molecule assumes in solution in the absence of the peptide that was bound to the protein when it was crystallized.

The disagreement between an observed solution scattering curve and that calculated from a crystallographic molecular model is also an indication that the protein assumes a conformation different from that of the crystallographic molecular model when it is dissolved in a solution of a particular composition,³⁴ for example, in which ligands for the protein may be dissolved.³³ Theoretical solution scattering curves calculated from likely alternative conformations often indicate how the structure of the protein has changed. In the case of aspartate carbamoyltransferase, it had been possible to crystallize the protein in the conformation it assumes when its regulatory β subunits bind MgATP. Even so, the crystallographic molecular model of this conformation⁴⁷ had to be adjusted before it would produce a theoretical X-ray solution scattering curve that agreed with the one observed for it in solution.⁴⁸ Only when the distance between the two catalytic α_3 trimers in the crystallographic molecular model (Figure 9-37) was increased 0.3 nm by reasonable rotations of the regulatory β_2 dimers did the theoretical curve agree with the observed curve.

The examples of measurements of small-angle X-ray scattering for cyclic-AMP dependent protein kinase (Figure 12-2C) and of X-ray solution scattering for aspartate carbamoyltransferase illustrate the use of scattering in comparisons of the **structure of a protein in solution** to its structure in a crystallographic molecular model. In both of these instances, the measurements of scattering were used to adjust appropriately and realistically the structure of the crystallographic molecular model, and there are other instances in which such adjustments have also been required.^{29,31} The fact that reasonable adjustments in the orientations of domains or the disposition of subunits are all that is necessary to

bring errant crystallographic molecular models into coincidence is further evidence that the crystallographic molecular model represents the structure of the protein. The solution scattering curves of helical polymeric proteins can also provide information about the parameters of the helix into which the monomers are assembled.³⁸

The difficulty with measurements of hydrodynamic properties or of small-angle scattering for assessing the shape of a molecule of protein is that they often provide only one unambiguous numerical result, either a frictional coefficient, a Simha factor, or a radius of gyration. If the frictional ratio $f/f_{0,h}$ is less than 1.15, the Simha factor ν is less than 4.0, or the radius of gyration R_G is near a value of $(3/5)^{1/2} R_{0,h}$, it can be concluded that the protein is globular. If the value of one or more of these parameters for a given protein is significantly greater than the values expected for a sphere, it is usually necessary to conclude that the protein has a highly irregular surface, has an extended structure, has a high degree of hydration, or has some combination of these features. It is clear from the foregoing discussion of some of the results that larger values of these parameters are consistent with a large set of particular arrangements of the available mass and values for hydration. The only reason so much is heard about prolate and oblate ellipsoids of revolution is not that molecules of proteins are such geometric solids but that frictional coefficients and radii of gyration can be calculated explicitly for such solids. In using any of these measured parameters in an informative way, other details about the structure of the protein are essential.

One way to observe the shape of a molecule of protein directly is by **electron microscopy**. The three symmetrically protruding regulatory subunits on aspartate carbamoyltransferase and the hollow, water-filled cavity between its two rotationally symmetric, trimeric α_3 subunits (Figure 9–37), which together probably account for its abnormally large frictional coefficient, were first observed in electron micrographs of the protein (Figure 12–4A)^{49,50} before there was a crystallographic molecular model. Another protein with an abnormally large frictional coefficient is fibrinogen. Electron micrographs of fibrinogen (Figure 12–4B),⁵¹ which turned out to be remarkably accurate representations of its structure, were published 20 years before a crystallographic molecular model of the protein (Figure 13–22) became available.⁵²

To prepare it for direct observation in the electron microscope, a protein molecule can either be **negatively stained** by being embedded in a glass of the salt of a heavy metal ion such as uranyl cation or phosphotungstate anion (Figure 12–4C, upper four images)^{53,54} or be positively stained by being **rotary shadowed**⁵⁵ with a layer of platinum that produces a metallic replica of the molecule (Figure 12–4C, lower four images). In the former method, the molecule of protein, because it is less electron dense than the glass, appears as a light image against a dark background; in the latter method, the mol-

ecule of protein coated with the metal appears dark against a light background. Whenever results from such electron microscopic studies are presented, a representative field of molecules (Figure 12–4D)⁵⁶ should be shown so that the reader can judge what fraction of the molecules of protein on the film of carbon or in the metallic replica give images that resemble the images chosen for a gallery of “representative” views (Figures 12–4A–C).

Collagen XII from *Gallus gallus* is a trimer of three polypeptides. All three polypeptides in the trimer are encoded by the same gene, but there are two forms of the polypeptide, one 3100 aa long and the other about 2700 aa long, produced by translation of alternatively spliced versions of the same messenger RNA;⁵³ the shorter translation is missing the amino-terminal 400 aa of the sequence. The carboxy-terminal 380 aa of each polypeptide contains two segments (152 and 103 aa) of collagen repeat, and in this region the three polypeptides of the trimer should form an interrupted triple-helical rope of collagen (Figure 9–33) with two segments 45 and 30 nm in length. This triple-helical rope is the structure holding the three polypeptides together in the oligomer. The amino-terminal 1870 aa of the short splice variant contains 10 fibronectin type III modular domains, strung together in a necklace that should be 32 nm in length,²² and one amino-terminal von Willebrand factor type A modular domain, a globular structure about 4 nm in diameter. The longer splice variant has an additional eight fibronectin type III modular domains (26 nm) and two additional von Willebrand factor type A domains. The electron micrographs of collagen type XII display a structure that is the fulfillment of these expectations (Figure 12–4C).^{53,54} The single, thin collagen tail of 75 nm is kinked about 30 nm from its end.⁵⁴ There is a central globular region from which three significantly thicker arms extend, each either a short or a long variant; the short variant is about 40 nm long with a globular ball at its end,⁵³ and the long variant is about 90 nm long with a globular ball in its middle and two globular balls at its end.⁵⁴ The three polypeptides enter the center wrapped around each other in the collagen tail and leave the center separately as three fibronectin necklaces.

Electron micrographs of activated bovine coagulation Factor Va were instrumental in explaining its unusual behavior upon sedimentation analysis. The protein has a molar mass⁵⁷ of 170,000 g mol⁻¹ and a standard sedimentation coefficient,⁵⁸ $s_{20,w}^0$, of 8.2 S, from which a frictional ratio $f/f_{0,h}$ of 1.6 (based on the assumption that $\delta_{H_2O} = 0.3$) can be calculated. When activated coagulation Factor Va was observed by electron microscopy, it was found to be two globular domains of protein, very similar in diameter, attached together through a narrow neck.⁵⁹ This shape seen in the electron micrographs is responsible for the unusually large frictional ratio of this protein. Although an axial ratio for a prolate ellipsoid was calculated from the earlier results of the sedimentation

analysis,⁵⁸ it was moot when the electron micrographs became available.⁵⁹

Rotary shadowing is usually used for **estimating the dimensions of extended molecules** such as collagen XII (Figure 12-4C), nidogen,⁶⁰ inversion-specific glycoprotein,⁶¹ fibulin,⁶² and myosin.⁵⁵ The molecule of protein is spread upon a flat sheet of mica before being coated with metal. Consequently, a long, thin, flexible molecule should lie almost flat upon the surface, and the contour length of its replica in the two-dimensional micrograph should be almost as long as its actual contour length in three dimensions. For this reason, rotary shadowing is thought to be the most reliable method to obtain estimates of the length of an extended molecule of protein. For example, the frictional ratio $f/f_{0,h}$ for a fragment of caldesmon (amino acids 166–450 from a polypeptide of 756 aa)⁶³ is 2.2, consistent with a cylinder of the appropriate volume that is 40 nm long. Electron micrographs of this fragment of caldesmon that had been rotary-shadowed with platinum and tungsten displayed elongated molecules of uniform thickness with contour lengths that averaged 35 nm. In rotary-shadowed images, globular domains such as the two heads of myosin or the three globular domains of nidogen appear as dark, unfeathered lumps. Although globular proteins constructed from clusters of globular domains or from globular subunits can appear as clusters of dark lumps upon rotary shadowing,⁶⁴ they usually appear as single undifferentiated and structureless lumps of platinum. Negative staining (Figure 12-4A,D) or embedding in amorphous vitreous ice is required to obtain images displaying details of the structure of a globular protein.

Phosphorylase kinase is a globular protein with a dramatically peculiar shape. Because of its unusual shape, a collection of digitized micrographic images of individual molecules (Figure 12-4D) could be superposed by a computer and stacked one upon the other.⁵⁶

The average of this stack of images could be calculated, and this average represents an enhanced image of the actual molecule (inset, Figure 12-4D). The chalice seen in the **enhanced image** can be imperfectly discerned in each of the individual selected images (Figure 12-4D), and this correspondence fulfills the usual requirement placed upon any reconstruction. A similar procedure has been applied to α_2 -macroglobulin⁶⁵ to obtain enhanced images. This protein has a shape almost as peculiar as that of phosphorylase kinase.

It is also possible to obtain a **three-dimensional reconstruction of the structure** of a macromolecule observed in an electron micrograph. An electron micrograph of a macromolecule is the two-dimensional projection either of the structure of that macromolecule if it is embedded in amorphous vitreous ice or of the mold of that macromolecule if it is embedded in negative stain. It has already been noted that the two-dimensional Fourier transform of the projection of a three-dimensional object is a central section of the three-dimensional Fourier transform of the unprojected object (Equations 9-4 through 9-6). From the complete three-dimensional Fourier transform of the object, the distribution of scattering density within the object, and hence details of its three-dimensional structure, can be calculated by Fourier transformation. To gather the complete three-dimensional Fourier transform of the object, Fourier transforms of projections of the object in a large number of different orientations must be assembled. This is accomplished in a helical polymeric protein by the fact that the helical array positions the monomer in specific, defined orientations, each of which provides a different projection. When molecules are not arranged in such an array but scattered upon the field, as are the molecules of phosphorylase kinase in Figure 12-4D, it is necessary to define the precise orientation of each of them relative to the plane of the micrograph before their individual

Figure 12-4: Asymmetric molecules of protein viewed by electron microscopy. Solutions of the protein of interest ($10 \mu\text{g mL}^{-1}$ to 1.0 mg mL^{-1}) were applied to electron microscopic grids coated with a thin film of carbon⁴⁹ supported by a net of either collodion or formvar. The layer of carbon ($\sim 5 \text{ nm}$) was ionized so that it was hydrophilic enough to accept the aqueous solution. The molecules of protein were adsorbed to this surface and were then negatively stained with either 2% phosphotungstate (panel A) or 1–2% uranyl formate (panels B and D). The water evaporates to leave a glass of the heavy metal salt in which are embedded the molecules of protein. (A) Gallery of selected images⁵⁰ of aspartate carbamoyltransferase from *E. coli* (Figure 9-37) viewed either along one of its 2-fold rotational axes of symmetry (left three images) or along its 3-fold rotational axis of symmetry (right three images) at $480000\times$. Reprinted with permission from ref 50. Copyright 1972 American Chemical Society. (B) Gallery of selected images of bovine fibrinogen⁵¹ at $480000\times$. The elongated molecule has globular domains at each end. Reprinted with permission from ref 51. Copyright 1981 Academic Press. (C) Selected images of collagen type XII from *Gallus gallus*^{53,54} at $240000\times$. The upper four images were negatively stained with uranyl formate. Reprinted with permission from ref 54. Copyright 1992 Blackwell Publishing. The lower four images are molecules of protein that were rotary shadowed.⁵⁵ A solution of the protein was sprayed into an aerosol mist and droplets of the mist were adsorbed to a sheet of mica. A beam of platinum atoms was directed at an angle of 6° onto the surface of the mica as it was rotated at $120 \text{ revolutions min}^{-1}$. The resulting thin film of platinum containing replicas of the molecules of protein was transferred to a copper grid. In the four rotary-shadowed images, selected representatives of a homotrimer of long splice variants (l_3), of a homotrimer of short splice variants (s_3), and of the two heterotrimers (l_2s , ls_2) are presented at $240000\times$. Reprinted with permission from ref 53. Copyright 1995 The Rockefeller University Press. (D) A field of negatively stained molecules of phosphorylase kinase⁵⁶ at $480000\times$. This is an accurate representation of the usual situation. Most of the molecules of protein negatively stained on the grid are featureless asymmetric structures. The minority that present a repeating, definable image (indicated by arrowheads) are selected by the microscopist as representative images of the protein and presented in galleries as in panels A and B. In this instance, the shape of the individual images of phosphorylase kinase was so peculiar that digitized optical densities of a large number of the selected images of individual molecules (62) could be sequentially superposed by a computer to obtain an enhanced image (inset). Reprinted with permission from ref 56. Copyright 1985 Academic Press.

Fourier transforms can be summed together to obtain the complete three-dimensional Fourier transform of the average molecule.

When the objects scattered over the field of the electron micrograph are viruses, the icosahedral symmetry of each of the viral coat proteins permits the exact orientation of each individual virion to be estimated.^{66–70}

The **assignment of an orientation** to each virion permits the Fourier transforms of their projections to be added together to obtain a complete three-dimensional Fourier transform of the average viral particle. In this way, a three-dimensional reconstruction of the structure of the viral coat⁷¹ and other appendages of the virus that are distributed with icosahedral symmetry^{72,73} can be calculated. For such reconstructions, the viral particles are usually suspended in a layer of amorphous vitreous ice.

If it is possible to define somehow the orientation of each member of a population of asymmetric molecules spread upon a grid at random, the same type of summation can be performed. If the molecule has a tendency to lie upon the carbon surface in a preferred orientation, for example, the molecules of phosphorylase kinase that settle on the grid to present a projection in the shape of a chalice (Figure 12–4D), this tendency orients them in one dimension but fortunately only in one dimension. The direction in which each individual oriented molecule faces upon the surface is random, and the direction in which each faces can be defined by direct observation. When the grid is then tilted 50°, a large collection of molecules, each in a completely different three-dimensional orientation but each in a known three-dimensional orientation relative to the others, is created.⁷⁴ From a summation of their individual Fourier transforms in the **tilted image**, a three-dimensional Fourier transform of the structure of the average molecule can be gathered. From this Fourier transform, a molecular model can be calculated. Such reconstructions have been performed for human α_2 -macroglobulin⁷⁵ and the 50S subunit of the ribosome.^{76,77} The resulting molecular model of the 50S subunit of the ribosome, albeit at low resolution, resembled quite closely the crystallographic molecular model that became available 12 years later.⁷⁸

Problem 12–1: Calculate the values of f_{sed} , f_{diff} , and $f_{0,\text{unh}}$ from \bar{v} , $s_{20,w}^0$, $D_{20,w}^0$, and M_{prot} for each protein in Table 12–1. From tabulated values of $f_{\text{av}}/f_{0,h}$ determine a/b for

each protein on the assumption that they are prolate ellipsoids of revolution.

Problem 12–2: Human immunoglobulin G is a protein with a molar mass of 167,000 g mol^{−1} and a partial specific volume of 0.739 cm³ g^{−1}.

- Assume hydration to be 0.3 g of H₂O (g of protein)^{−1} and calculate the minimum frictional coefficient, $f_{0,h}$, for the hydrated hydrodynamic particle at 20 °C in water.
- The standard sedimentation coefficient $s_{20,w}^0$ for immunoglobulin G is 7.0×10^{-13} s, and the standard diffusion coefficient $D_{20,w}^0$ is 4.0×10^{-7} s^{−1}. Calculate the frictional coefficient, first from the standard sedimentation coefficient and then from the standard diffusion coefficient.
- From the average of these two estimates of the frictional coefficient and from the estimate of the minimum frictional coefficient of the hydrated hydrodynamic particle, estimate the axial ratio a/b upon the assumption that the molecule is a prolate ellipsoid of revolution.
- The shape of an immunoglobulin G is displayed in Figure 7–13. How does this structure compare with your estimate of its shape?

Problem 12–3: Thiosulfate sulfurtransferase is a monomeric enzyme. The polypeptide from bovine liver is 296 amino acids in length and has a molar mass of 33,160 g mol^{−1}. In water at 20 °C the standard sedimentation coefficient of the native protein is 3.00×10^{-13} s, and its standard diffusion coefficient is 7.50×10^{-7} cm² s^{−1}. The partial specific volume of the protein is 0.742 cm³ g^{−1}.

- Calculate the frictional coefficient of the protein.
- Calculate the frictional ratio for the hydrodynamic particle $f/f_{0,h}$, with the assumption that the hydration of the protein is 0.3 g of H₂O (g of protein)^{−1}.
- What would be the axial ratio of an ellipsoid of revolution with this frictional ratio?
- How does this estimation compare to the crystallographic molecular model of the protein (Figure 9–18)?

Problem 12–4: The standard sedimentation coefficient of human fibrinogen is 7.63×10^{-13} s, its molar mass is 344,000 g mol^{−1}, and its partial specific volume is 0.725 cm³ g^{−1}.

- Assume $\delta_{\text{H}_2\text{O}} = 0.3$ and determine the volume of the hydrodynamic particle, the frictional coefficient of fibrinogen, its frictional ratio, and its axial ratio and dimensions on the basis of the assump-

- tion that it is a prolate ellipsoid of revolution or a cylindrical rod.
- (B) The length of the fibrinogen molecule has been determined to be 45 nm by electron microscopy (Figure 12–4B) and 45 nm by direct measurement of its crystallographic molecular model (Figure 13–22A). Calculate the dimensions of a prolate ellipsoid or a cylindrical rod with the same volume as the hydrodynamic particle and a major axis of length 22.4 nm.
- (C) The intrinsic viscosity of fibrinogen⁷⁹ is 27 cm³ g^{−1}. Calculate its Simha factor ν and estimate its axial ratio and molecular dimensions on the basis of the assumption that it is a prolate ellipsoid of revolution or a cylindrical rod.

Problem 12–5: The heads of myosin (Figure 13–30A) can be detached from the intact protein by mild treatment with the endopeptidase papain. The detachable domain that was one of the heads and that is produced by the digestion with papain is referred to as the S1 fragment. It is a complex of three folded polypeptides. The S1 fragment from chicken muscle contains the amino-terminal 845 aa of the α polypeptide, or heavy chain, of myosin and two shorter polypeptides, or light chains, of lengths 149 and 163 aa.

- (A) Estimate the molar mass of the S1 fragment from the lengths of its three constituent polypeptides.

The following table lists physical properties of the S1 fragment.⁸⁰

property	value
$s_{20,w}^0$	5.8×10^{-13} s
$D_{20,w}^0$	4.6×10^{-7} cm ² s ^{−1}
\bar{v}	0.73 cm ³ g ^{−1}
$[\eta]$	6.4 cm ³ g ^{−1}

- (B) Calculate the frictional coefficient of the S1 fragment.
- (C) Assume a hydration of 0.3 g g^{−1}, and calculate the frictional ratio for the S1 fragment.
- (D) Assume a hydration of 0.3 g g^{−1}, and calculate the Simha factor for the S1 fragment.
- (E) Estimate the axial ratio that the S1 fragment would have if it were a prolate ellipsoid of revolution.
- (F) The following are two orthogonal views of a space-filling representation of the crystallographic molecular model of the S1 fragment of myosin.⁸¹ Estimate its axial ratio from the figures.

- (G) What value would δ_{H_2O} have to have for both the intrinsic viscosity and the frictional ratio to give the axial ratio you measured from the crystallographic molecular model?

Problem 12–6: Tropomyosin is a protein formed from identical folded polypeptides each 284 amino acids in length ($M_{\text{prot}} = 32,680$ g mol^{−1}). It has a partial specific volume of 0.72 cm³ g^{−1}. The molar mass of tropomyosin was determined by osmotic pressure. Each measurement was extrapolated to $\gamma_{\text{prot}} = 0$. The osmotic pressure at 0 °C as a function of ionic strength is presented in the following table.⁸²

ionic strength (M)	$\lim_{\gamma_{\text{prot}} \rightarrow 0} \frac{\Pi}{\gamma_{\text{prot}}}$ (mmHg cm ³ g ^{−1})
0.10	126
0.20	154
0.27	193
0.30	236
0.60	254
1.10	264

- (A) What are the values for the apparent molar masses of tropomyosin at the several ionic strengths? Show in detail the calculation of molar mass at ionic strength of 0.10 M.
- (B) How many polypeptides compose the major form of tropomyosin present in solution at high ionic strength? What is the exact molar mass of just this major form? Why does the number-average molar mass increase as the ionic strength is lowered?

- (C) The following data⁸² were gathered from solutions of tropomyosin at an ionic strength of 1.1 M:

γ_{prot} [g (100 mL) ⁻¹]	η'/η
1.210	0.33
1.299	0.44
1.466	0.64
1.588	0.76
1.793	0.96
2.223	1.29
2.972	1.72
4.603	2.14

where η' is the viscosity of the solution of protein, η is the viscosity of the solvent, and γ_{prot} is the concentration of protein. Determine the intrinsic viscosity $[\eta]$ at this ionic strength.

- (D) Assume that $\delta_{\text{H}_2\text{O}} = 0.3 \text{ g of H}_2\text{O (g of protein)}^{-1}$ and calculate the Simha factor ν . From ν determine the axial ratio for tropomyosin if it were a prolate ellipsoid of revolution by using Figure 12-1B,D.
- (E) From spectroscopic measurements it is known that, at all ionic strengths, tropomyosin is >90% α -helical. It is a coiled coil in which the two α helices wrap around each other as the strands in a two-stranded rope. The length of an α helix for each of its amino acids is 0.15 nm. Calculate the length of a molecule of tropomyosin at high ionic strength and, assuming it to be a cylindrical rod, calculate its diameter from its hydrated molecular volume. What is its actual axial ratio? Compare this to the axial ratio obtained from ν .
- (F) The intrinsic viscosities of solutions of tropomyosin also vary with ionic strength:⁸²

$[\eta]$	ionic strength (M)
1.00	1.1
1.03	0.6
1.23	0.3
1.75	0.2
2.45	0.1

Plot molar mass against specific viscosity and explain the correlation in terms of structures that could form as the ionic strength is lowered.

Problem 12-7: The following are a set of data for the light scattering of a series of solutions (0.2–0.8 g L⁻¹) of myosin.⁸³ The wavelength of light used for the observations was 436 nm (in a vacuum). The solutions were examined at a temperature of 20 °C, and the refractive

index of the solvent in which the myosin was dissolved was 1.34. The refractive index increment $(\partial\tilde{n}/\partial\gamma_{\text{prot}})_{P,\mu}$ for myosin is 0.208 cm³ g⁻¹, and the molar mass of myosin is 527,000 g mol⁻¹.

θ (deg)	$\lim_{\gamma_{\text{prot}} \rightarrow 0} \frac{\gamma_{\text{prot}}}{R_\theta}$ (g cm ⁻²)
30	0.74
35	0.74
40	0.78
45	0.80
50	0.83
55	0.86
60	0.89
70	0.95
90	1.07
110	1.17
140	1.24

- (A) What was the wavelength of the light in the solutions?
- (B) What is the radius of gyration of the myosin under these circumstances?
- (C) What would be the length of a rod with this radius of gyration?
- (D) What is the length of the molecules of myosin in Figure 13-30A? The magnification stated in the legend for Figure 13-30A is for the figure in the text.

Problem 12-8: Triskelion is a protein that assembles into spherical structures known as clathrin coats. These clathrin coats are the structures that surround the coated vesicles formed from the invagination of the plasma membrane of an animal cell at sites known as coated pits. Bovine triskelion is formed from three identical heavy polypeptides ($n_{\text{aa}} = 1675$ polypeptide⁻¹, $M_{\text{prot}} = 191,590 \text{ g mol}^{-1}$) and three identical light polypeptides ($n_{\text{aa}} = 228$ polypeptide⁻¹, $M_{\text{prot}} = 25,080 \text{ g mol}^{-1}$). Its partial specific volume, calculated from its amino acid composition, is 0.744 cm³ g⁻¹.

- (A) Calculate the unhydrated volume of triskelion.
- (B) What would be the unhydrated radius ($R_{0,\text{unh}}$) and the unhydrated radius of gyration ($R_{\text{G,sph}}$) of triskelion if it were a sphere?

The light scattering of triskelion dissolved in a buffered solution was monitored either as a function of the concentration of protein (γ_{prot}) or as a function of the scattering angle θ .⁸⁴ Reprinted with permission from ref 84. Copyright 1991 American Chemical Society.

Open and closed circles show the plots of $[K\gamma_{\text{prot}}/R_\theta]_{\theta \rightarrow 0}$ against the concentration of clathrin and $[K\gamma_{\text{prot}}/R_\theta]_{\gamma_{\text{prot}} \rightarrow 0}$ against $\sin^2(\theta/2)$, respectively. The units on the vertical axis are moles gram^{-1} . The authors of this study have used an optical constant K that incorporates the increment of the refractive index so that its value is $2\pi^2\bar{n}_0^2(\partial\bar{n}/\partial\gamma_{\text{prot}})^2/N_A\lambda_0^4$. The refractive indices (\bar{n}) of the two solutions were both 1.34. The laser used in the experiment emitted polarized light of wavelength 632.8 nm in the vacuum.

- (C) How well does the molar mass of the protein observed in the light scattering experiment agree with that calculated from the sequences of the constituent polypeptides of triskelion?
- (D) From the slope of the appropriate line in the figure, calculate the radius of gyration for triskelion.

(One way to approach this problem is to multiply both sides of Equation 12-23 by the optical constant K .)

- (E) Is triskelion a globular protein?

Problem 12-9: The definition of Rayleigh's ratio for the scattering of unpolarized light is

$$R_\theta \equiv \frac{r^2 i_\theta}{I_0 (1 + \cos^2 \theta)}$$

where i_θ is the intensity of the scattered light due only to the protein at an angle θ to the incident beam. At very low angles ($\theta \leq 5 \times 10^{-2}$ rad), $\cos^2 \theta \approx 1.00$. In this situation, by Equation 12-19

$$P(\theta) = \lim_{\gamma_{\text{prot}} \rightarrow 0} \frac{i_\theta}{\gamma_{\text{prot}}} \left[\frac{r^2}{2I_0 K M_{\text{prot}}} \left(\frac{\partial \bar{n}}{\partial \gamma_{\text{prot}}} \right)_{T, P, \mu}^{-2} \right]$$

and

$$\ln P(\theta) = \lim_{\gamma_{\text{prot}} \rightarrow 0} \left(\ln \frac{i_\theta}{\gamma_{\text{prot}}} - A \right)$$

where A is a constant determined by the values of all of the fixed parameters in the brackets. At very low angles, the approximation of Equation 12-29 is also valid, and it follows that

$$\lim_{\gamma_{\text{prot}} \rightarrow 0} \ln \frac{i_\theta}{\gamma_{\text{prot}}} = A - \frac{16\pi^2 R_G^2}{3\lambda^2} \sin^2 \frac{\theta}{2}$$

If ω is expressed in radians

$$\sin \omega = \omega - \frac{\omega^3}{3!} + \frac{\omega^5}{5!} - \dots$$

- (A) Show that

$$\lim_{\substack{\theta \rightarrow 0 \\ \gamma_{\text{prot}} \rightarrow 0}} \ln \frac{i_\theta}{\gamma_{\text{prot}}} = A - \frac{16\pi^2 R_G^2}{3\lambda^2} \left(\frac{\theta}{2} \right)^2$$

It is more convenient to take a series of measurements at varying scattering angles, θ (in radians), of a single solution of protein than to measure the scattering at a fixed angle for several solutions of protein. Therefore, what is usually done is to determine the slope of $\ln(i_\theta/\gamma_{\text{prot}})$ as a function of θ^2 at various fixed values of γ_{prot} and then extrapolate to $\gamma_{\text{prot}} = 0$. If, however, γ_{prot} is held constant, as is done in such an experiment, then

$$\lim_{\theta \rightarrow 0} \ln \frac{i_\theta}{\gamma_{\text{prot}}} = \lim_{\theta \rightarrow 0} \ln i_\theta + \ln \gamma_{\text{prot}}$$

and at constant γ_{prot}

$$\lim_{\theta \rightarrow 0} \ln i_\theta = A' - \frac{16\pi^2 R_G^2}{3\lambda^2} \left(\frac{\theta}{2} \right)^2$$

where A' is a constant equal to $A - \ln \gamma_{\text{prot}}$.

- (B) What should be the slope of the line for a plot of $\ln i_\theta$ against θ^2 at low concentrations of protein and low scattering angle?

Immunity protein is a protein produced by strains of the bacterium *E. coli* producing colicin E₃. The intensities of the scattered X-rays ($\lambda_0 = 0.154$ nm; $\bar{n} = 1.33$; $\lambda = 0.116$ nm) as a function of the square of the scattering angle were measured for a series of solutions of immu-

nity protein.²³ Reprinted with permission from ref 23. Copyright 1983 *Journal of Biological Chemistry*.

The natural logarithm of the intensity of the scattered X-rays, $\ln i_\theta$, is presented as a function of the square of the scattering angle θ in $\text{radians}^2 \times 10^4$. (A value of 6.0 on the abscissa is equal to $6.0 \times 10^{-4} \text{ rad}^2$.) The values for the concentration of protein (γ_{prot} in milligrams milliliter⁻¹) are indicated to the right. The slopes of the lines in the plot are

γ_{prot} (mg mL ⁻¹)	slope (rad ⁻²)
2.9	1130
5.8	420
8.8	540
11.7	550
14.6	630

- (C) Calculate the apparent radius of gyration, $R_{G,\text{app}}$, for each concentration of protein.
- (D) Extrapolate to $\gamma_{\text{prot}} = 0$ and obtain the actual radius of gyration, R_G .
- (E) The molar mass of immunity protein is 9770 g mol^{-1} , and its partial specific volume, \bar{v}_{imm} , is $0.73 \text{ cm}^3 \text{ g}^{-1}$. Calculate its unhydrated volume and the radius a of a sphere with that volume.
- (F) What would be the radius of gyration of immunity protein if it were this sphere?

Absorption and Emission of Light

A valence electron in any molecule occupies an atomic orbital or a molecular orbital that has **energy levels** associated with it (Figure 12-5).⁸⁵ These energy levels have discrete magnitudes because of the quantum theory, and the steps between any two energy levels are also of discrete magnitude or quantized. The energy levels that have the smallest steps between them are the rotational energy levels. These energy levels correspond to the quantized kinetic and potential energy associated with the rotations around the bond in which a particular electron resides and with the bonds that are coupled to it. The steps between successive rotational energy levels are normally $0.5\text{--}50 \text{ J mol}^{-1}$ in magnitude, corresponding to the energy in a photon of wavelength 200 to 2 mm. The energy levels that have the next larger steps between successive stages are the **vibrational energy levels**. These energy levels reflect the quantization of the energy of the vibrations of the bond in which a particular electron resides and of neighboring bonds that are coupled to it. The steps between vibrational energy levels are normally $5\text{--}50 \text{ kJ mol}^{-1}$ in magnitude, corresponding to the energy in a photon of wavelength 20 to $2 \mu\text{m}$. The energy levels that have the next larger steps among them are the **electronic energy levels** of the molecule. The electronic energy levels relevant to these transitions are those of the atomic orbital or molecular orbital in which a particular electron resides and of the vacant atomic orbitals or molecular orbitals that are accessible to it. Steps between two of these electronic energy levels are normally $50\text{--}500 \text{ kJ mol}^{-1}$ in magnitude corresponding to the energy in a photon of wavelength 2000 to 200 nm. These three types of energy levels form nested sets (Figure 12-5). Within a given electronic energy level there are a series of associated vibrational energy levels, and within a given vibrational energy level there are a series of associated rotational energy levels.

In a particular molecule, at a given instant, a discrete set of atomic and molecular orbitals will be occupied by the valence electrons to produce the σ bonds, the π molecular orbital systems, and the lone pairs. For each atomic or molecular orbital occupied by an electron, a particular vibrational energy level will also be occupied, and the rotational motions within the molecule will determine which particular rotational energy levels are also occupied. Because the differences in energy between electronic energy levels are so large, the **equilibrium constants governing the occupation** by electrons of the successive electronic energy levels at temperatures experienced by living organisms are also large, and only the lowest electronic energy levels are significantly occupied. The electrons in a molecule in the ground state are always ($>99.99999\%$) distributed so as to fill in succession the levels of lowest electronic energy. As the differences in energy between vibrational energy levels are significant, the equilibrium constants govern-

Figure 12-5: Photophysical processes experienced by an electron in a covalent bond between two atoms.⁸⁵ The smooth curve S_0 is the potential energy of the molecular orbital of the covalent bond in which the electron resides as a function of the distance r between the two nuclei. The smooth curve S_1 is the potential energy that would be experienced if the electron were transferred to a particular unoccupied antibonding molecular orbital between the two atoms as a function of the distance between the two nuclei. Each well of potential energy has levels of vibrational energy (the parallel lines within each well) and levels of rotational energy (see expanded scale of the potential energy of the ground state to the left) associated with it. Absorptions by electrons of photons of energy equivalent to the differences in energy between vibrational energy levels (process **IR**) produces an infrared spectrum. When an electron in its occupied molecular orbital, the ground state, absorbs a quantum of electromagnetic energy sufficient to boost its energy high enough to enter the unoccupied molecular orbital, the excited state is created (process **A**). As the excited state relaxes, some of the absorbed energy is lost as heat. When the relaxed excited state emits light as the electron returns to the ground state (process **F**), the quantum of emitted fluorescent light has less energy (longer wavelength) than that of the quantum of light originally absorbed. If the spin of the electron inverts while it is in the excited state (process $S_1 \rightarrow T_1$), the electron enters a triplet excited state. The smooth curve T_1 is the potential energy of the electron in the bond in the triplet state as a function of bond length. The triplet excited state also relaxes by giving off heat. The phosphorescent light emitted from the relaxed triplet state (process **P**) has even less energy (even longer wavelength) than the fluorescence from the initial excited state, and the triplet excited state has an even longer lifetime. The bond lengths of the ground state, the excited singlet state, and the excited triplet state are indicated as 0r_e , ${}^1r_e^*$, and ${}^3r_e^*$. Adapted with permission from ref 85. Copyright 1977 W.A. Benjamin.

ing the occupation of the successive levels at temperatures experienced by living organisms are also significant. Consequently, in the ground state, the vibrational energy level that is occupied is usually (>90%) the lowest for each particular vibration. Because, however, their differences in energy are so small, rotational energy levels are widely occupied by the bonds in the different molecules in the solution.

A photon can encounter an electron in a molecule in such a way that its energy is absorbed. If the electron absorbs the energy of the oscillating electric field and then immediately emits the same photon back again without retaining any of its energy, the direction of the electromagnetic wave is altered so that its new direction of propagation bears no relationship to its incident direction while its wavelength remains the same. This is **elastic scattering**, and it is the phenomenon mainly responsible for X-ray diffraction, low-angle X-ray scattering, and light scattering.

If the electron that has absorbed the photon is in a bond that happens to change its vibrational energy level during the instant that it is excited, the subsequently scattered photon will have a wavelength that is shorter or

longer than that of the incident photon by a difference equivalent to the energy of the transition between the two vibrational energy levels (expanded scale in Figure 12-5). If the photon is absorbed by an electron in the excited state of a vibrational mode, it can carry away the energy of the transition to the ground state and be scattered with higher energy. If it is scattered by an electron in the ground state that enters an excited state during its residence, the photon will provide the energy for this transition and be scattered with lower energy. As a result, the energies of the scattered light vary symmetrically about the energy of the incident light. The intensities of the bands of scattered light with the longer wavelengths are greater than those of shorter wavelength because most vibrations are in the ground state before a photon is absorbed. The **Raman effect** that results is a set of small changes in wavelength that are experienced by a small percentage of the photons that are scattered by the electrons in the sample. As with light scattering itself, the Raman effect on scattered light is usually measured by sampling the light emitted by a sample perpendicular to the incident light. The incident light is from a laser, and it is intense and monochromatic. It is the spectrum of the

wavelengths of the scattered light that is determined. Although almost all of the scattered light is the same wavelength as the incident light, scattered light of other specific, sharply defined wavelengths is also present, and a Raman spectrum of this scattered light provides a catalogue of many of the transitions among the vibrational energy levels of the molecule.

The decision as to whether the photon is immediately scattered from the electron, in an event that is essentially instantaneous, or is absorbed by the electron for a longer period of time depends on how closely the energy of the photon matches one of the differences between the quantized energy levels available to the electron. If the energy of the photon that has just been absorbed by the electron is equal to the difference in energy between the vibrational energy level its bond occupied at the instant the photon was absorbed and a higher vibrational energy level accessible to it, the photon can be absorbed completely, and the vibrational energy of the bond occupied by the electron or that of a bond vibrationally coupled to it will increase by that step in energy (process **IR** in Figure 12-5). Most of the energy absorbed will not be emitted back radiatively as light but will be dissipated nonradiatively by intermolecular collision or by exciting coupled rotational motions the energy levels of which bridge the gap between the vibrational energy levels of the ground state and the excited state (Figure 12-5). Any light emitted radiatively due to a direct transition from the excited state back to the ground state has the same wavelength as the absorbed light but an altered direction and becomes distinguishable from elastically scattered light only by the delay in its reemission. The **absorption of infrared light** (in the range from 20,000 to 2000 nm, or 500 to 5000 cm^{-1})* produces transitions among vibrational energy levels, and a spectrum of infrared absorption has discrete maxima the energies of which correspond to transitions between pairs of vibrational energy levels.

If the energy of the photon absorbed by the electron is equal to the difference in energy between the molecular orbital or atomic orbital the electron occupies in the ground state and an unoccupied molecular or atomic orbital of higher energy, the photon can be absorbed (process **A** in Figure 12-5). The electron enters the unoccupied orbital, and an **electronically excited state** of the molecule is created. Because the excited state differs from the ground state in the distribution of its electrons among molecular and atomic orbitals, it should be thought of as a distinct, albeit similar, molecule. The

formation of the excited state can be followed by monitoring the disappearance of the absorption of light by the ground state⁸⁶ because the excited state, being a new molecule, has a different absorption spectrum. At the very least, in its most stable structure, this **new molecule**, the excited state, will have some bond lengths, bond angles, and bond energies that are different from those of the ground state because its bonding differs from that of the ground state. The instant the electron enters the new orbital, however, the molecule has the structure of the ground state. As the excited state relaxes in energy to the most stable structure available to it, the distance in energy between excited state and ground state shortens, and the excited electron loses energy. Because of the overlap required for excitation, the excited electron usually enters the excited state through one of its higher vibrational energy levels, and it simultaneously loses energy by a nonradiative passage to the lowest vibrational energy level. The net result of these relaxations is that the excited electron very rapidly (10^{-13} to 10^{-11} s) finds itself at an energy considerably below the energy it had achieved immediately after the light was absorbed.

Because the rotational and vibrational energy levels of the electronic excited state usually overlap rotational and vibrational energy levels of the ground state, the electron usually reenters the molecular or atomic orbital of the ground state by pursuing a path among the rotational and vibrational energy levels of excited state and ground state. In this case, the energy originally absorbed is dissipated nonradiatively as heat, and only the absorption of the light is detected. The absorption of ultraviolet and visible light (in the range between 200 and 2000 nm) produces transitions among electronic energy levels, and the result is a **spectrum of ultraviolet or visible absorption** that has maxima the energies of which correspond to the energies of electronic transitions in the molecule.

If, however, the energy levels of the ground state and the excited state overlap weakly, the excited electron can become trapped in the lowest vibrational energy level of the excited state long enough ($>10^{-9}$ s) to reenter the ground state with a bang rather than a whimper. The reentry of the excited electron into the ground state in such a single step requires that the energy it loses be emitted as a photon. This emission is either fluorescence or phosphorescence.

If it came from a covalent bond or a lone pair of electrons, then at the instant of excitation, the excited electron entering the new orbital has a spin opposite to the spin of the partner it left behind in its previous orbital. As it relaxes into the lowest vibrational energy of the excited state and as the excited state rearranges, the excited electron remains coupled to its old partner, and the excited state remains a singlet excited state. From a singlet excited state, the electron can rapidly return to the ground state because the excited electron can readily reenter its old orbital with a spin compatible with the single electron still there (process **F** in Figure 12-5) The

* It is customary for investigators using Raman spectroscopy or infrared spectroscopy to present absorption as a function of the inverse of the wavelength, referred to as the wavenumber (in centimeters^{-1}), which is directly proportional to the energy of the absorption. One advantage of this convention is that the two symmetrical displacements of the Raman effect for the same vibrational mode have the same numerical values when expressed in terms of wavenumber.

reentry is spin-allowed and rapid ($<10^{-7}$ s), and the emitted photon is **fluorescence**.

The energy of a photon of fluorescent light is necessarily less than the energy of the photon absorbed by the electron during excitation because of the nonradiative relaxations of the excited state that have occurred. **Fluorescent light** is light of a longer wavelength (usually visible light) emitted shortly after (within 10^{-7} s) a molecule has absorbed light of a shorter wavelength (usually ultraviolet light). The spectrum of the light absorbed is the **absorption spectrum**; the spectrum of the light emitted is the **emission spectrum**. Fluorescent light, as with scattered light and for the same reasons, is emitted in all directions relative to the incident light unless intramolecular interference occurs. It is usually measured perpendicular to the direction of the incident light. It can be measured under continuous excitation, or the excitation can be a flash ($<10^{-9}$ s in length), and the rate of decay of the fluorescence following the flash, indicative of its lifetime, can be measured.

If the electronically excited state is structured in such a way that the excited electron can become unpaired with the electron it left behind, it can enter a triplet excited state by **intersystem crossing**. The ground state of the triplet state is usually of lower energy than that of the singlet state. Once the triplet excited state has been occupied, the electron can return to the ground state only through a spin-disallowed process that is very slow (on the order of microseconds to seconds). The emitted light, or **phosphorescence** (process **P** in Figure 12-5), emerges from the solution over a relatively long period of time and has an even longer wavelength than the rapidly emitted fluorescence. Fluorescence is light emitted from singlet excited states; phosphorescence, from triplet excited states.

Both the direct and the Raman **infrared spectra of proteins** display absorptions of energy resulting from transitions between the quantized energy levels of molecular vibrations. The intensities of these absorptions are determined by **selection rules** that govern which transitions in vibrational energy are permitted and to what extent these transitions are able to absorb infrared light. Because the selection rules for direct absorption are different from the selection rules governing the Raman effect, direct infrared absorption spectra provide data that are complementary to Raman infrared spectra.

The most obvious and securely assigned absorptions in the infrared or Raman spectrum of a protein arise from excitations of the vibrations of the **amides** in the polypeptide backbone. A secondary amide such as *N*-methylacetamide, a simple model for the peptide bond, absorbs infrared energy of wavelength around 6000 nm (1650 cm^{-1}) into its C=O stretching vibration and of wavelengths around 6500 nm (1540 cm^{-1}) and around 8000 nm (1250 cm^{-1}) into a coupled C–N stretching and N–H bending vibration.⁸⁷ These three peaks of

absorbance are referred to as the **amide I band**, the **amide II band**, and the **amide III band**, respectively. The amide I band of absorbance is the strongest of the three and is the only one that is located in a region of the spectrum that does not contain significant absorptions from other groups in a protein (Figure 12-6).⁸⁸

Direct infrared spectroscopy of proteins in aqueous solution is severely compromised by the strong absorption of infrared light by water and other solutes. An infrared spectrum registered by the Raman effect, however, avoids these drawbacks. A **Raman infrared spectrum** is monitored as small differences in wavelength relative to the wavelength of the incident light. Consequently, the actual light registering each of the bands in the Raman spectrum is within the visible range, not the infrared range, and the problems of the absorption of infrared light by water and other solutes and by the container are avoided. Although the water in the solvent also produces Raman bands in the regions of its absorptions, they are much weaker than their direct absorptions of infrared light,⁸⁹ and the subtraction of background from the spectrum of the protein is much less drastic.

Raman infrared spectroscopy, however, has its own disadvantages. Two of those disadvantages are that the signals registering the Raman infrared spectrum are weak and that these small signals can be swamped by fluorescence. In addition, the presence of large particles such as fragments of membrane, by increasing the scattering from the solution, makes Raman spectroscopy even more difficult. Direct infrared absorption is unaffected by this latter problem, and infrared spectra of sus-

Figure 12-6: Direct infrared spectra in the amide I region of proteins with different mixtures of secondary structure.⁸⁸ (A) Human hemoglobin with its hemes in complex with CO at 130 mg mL^{-1} in 10 mM sodium phosphate, pH 7.4. (B) Bovine ribonuclease A at 50 mg mL^{-1} in 1% NaCl, pH 6.5. (C) Bovine immunoglobulin G at 50 mg mL^{-1} in 1% NaCl, pH 6.5. In each solution, the protein itself served to buffer the pH. The spectra were measured in a Fourier transform infrared spectrophotometer. The spectrum of 10 mM sodium phosphate or 1% NaCl, respectively, was subtracted from each infrared spectrum to obtain the spectrum of the protein alone. Even at these high concentrations of protein, the absorption of the water in the sample accounted for 96% of the total absorption at the wavelength where each of the proteins absorbed most strongly. The vertical dashed line at 1650 cm^{-1} is to aid in comparing the curves. Reprinted with permission from ref 88. Copyright 1990 American Chemical Society.

pensions of membranes can be readily measured.^{90–92} Measurements of the direct infrared spectrum of solid dehydrated protein or even a crystal of protein can also be made.^{93,94}

When a solution of protein is excited with a He–Ne laser, the Raman infrared spectrum of the scattered light (Figure 12–7)⁹⁵ displays a maximum arising from the amide I band of the folded polypeptide with a wavenumber of around 1650 cm^{-1} less than the wavenumber of the majority of the scattered light, which has the same wavenumber as the incident light ($15,802\text{ cm}^{-1}$, 632.8 nm). The amide III maximum at a wavenumber 1250 cm^{-1} less than that of the elastically scattered light and other maxima that can be assigned to vibrational transitions in some of the amino acids, such as phenylalanine, tyrosine, and methionine, are also observed.⁹⁶ By using difference spectra between a selectively deuterated protein and the same protein undeuterated, absorption bands in the Raman infrared spectrum from other amino acids, such as leucine, isoleucine, valine, alanine, glutamate, and aspartate, can be dissected out of the complete spectrum.⁹⁷ Difference Raman infrared spectra between proteins selectively labeled with ^{18}O oxygen and their unlabeled counterpart have also been reported,⁹⁸

Figure 12–7: Raman spectra of the intensity of the light scattered from (A) a solution of ribonuclease at 200 mg mL^{-1} and (B) a solution of amino acids at the same ratio that they are present in ribonuclease.⁹⁵ The samples were excited with a He–Ne laser ($\lambda = 632.8\text{ nm}$), and the intensity of the light scattered was measured as a function of wavenumber (centimeter^{-1}) in the neighborhood of the wavenumber of the elastically scattered light, which had a wavenumber identical to that of the incident light ($15,802\text{ cm}^{-1}$). The intensity of the scattered light is presented as a function of the difference between the wavenumber of the measured light and the wavenumber of the incident and elastically scattered light. As in the direct infrared spectrum (Figure 12–6), the amide I absorption is the most obvious, but other absorptions that can be assigned to various vibrational modes of the side chains of the amino acids, as well as the partially obscured amide III band, are clearly seen in the spectrum. Reprinted with permission from ref 95. Copyright 1970 Academic Press.

which can permit the observation of the vibrational transitions for a single bond among the thousands within a particular protein.

If the protein contains a functional group that absorbs the exciting visible light in an electronic transition, as does, for example, the heme in hemoglobin,⁹⁹ bands in the Raman infrared spectrum resulting from the absorption of energy by vibrations of the atoms within or adjacent to that functional group will be enhanced, and this enhanced spectrum is referred to as a **resonance Raman infrared spectrum**.¹⁰⁰ The maxima in a resonance Raman infrared spectrum can often be assigned to vibrations of particular bonds, such as an iron–dioxygen stretching vibration in oxygenated hemoglobin,⁹⁹ the oxygen–oxygen stretching vibration of the peroxy form of hemocyanin,¹⁰¹ the iron–oxygen stretching vibration of the ferryl intermediate of cytochrome *d* ubiquinol oxidase,¹⁰² or the copper–sulfur stretching vibrations in halocyanin.¹⁰³ When light of wavelength 200 or 206.5 nm , which is in the range where peptide bonds absorb strongly, is used to produce a resonance Raman infrared spectrum, the amide I, amide II, and amide III bands are selectively enhanced.^{104,105}

The amide I band in the direct infrared spectrum of a solution of a particular protein registers its **secondary structure**.^{88,90,106–108} The amide I band in the direct infrared spectra of a protein containing mainly α helix, for example, hemoglobin (87% α -helical), has a maximum at around 1655 cm^{-1} ; that of a protein rich in β sheet, for example, immunoglobulin G (67% β structure), has a maximum around 1635 cm^{-1} ; and that of a protein with a mixture of these two secondary structures, for example, ribonuclease A (23% α helix and 46% β structure), has a spectrum that seems to register this mixture (Figure 12–6).⁸⁸ Various algorithms have been derived for estimating the percentages of α helix, β structure, and β turn in a protein from the shape of the amide I band in its direct infrared spectrum.^{88,107} The amide I band in the direct infrared spectrum of a coiled coil of α helices also has a characteristic shape, diagnostic of this structure.¹⁰⁹

Unfortunately, as mentioned above, the amide I band falls in a region of the direct infrared spectrum where water absorbs strongly, and this **strong absorption by the solvent** and its vapor must be subtracted to obtain only the amide I band of the protein.⁸⁸ Deuterium oxide does not absorb strongly between 1700 and 1600 cm^{-1} , and direct infrared spectra of proteins in deuterium oxide rather than water display a readily measured amide I band.^{90,106} Unfortunately, it is difficult to exchange the protons with deuteriums on the amide nitrogens of the peptide bonds through the entire protein,¹⁰⁷ because those in the interior are inaccessible to solvent. As a result of this incomplete exchange and the fact that the amide I bands of deuterated peptide bonds are shifted by at least 5 cm^{-1} relative to those of undeuterated peptide bonds,¹⁰⁸ the resulting spectrum

of the mixture of exchanged and unexchanged peptide bonds is difficult to dissect accurately into the components arising from the different secondary structures.

An infrared spectrum registered by the Raman effect avoids these drawbacks, and the amide I band in such a spectrum also registers secondary structure.¹¹⁰ The wavelengths of the absorptions, however, differ from those in a direct infrared spectrum. α -Helical proteins have amide I bands with maxima around 1645 cm^{-1} while proteins composed entirely of β structure have amide I bands with maxima around 1670 cm^{-1} .⁸⁹ In resonance Raman infrared spectra produced by excitation at 205.6 nm , the amide III band is prominent and also registers secondary structure (λ_{max} for α helix at 1299 cm^{-1} and λ_{max} for β sheet at 1235 cm^{-1}).¹⁰⁵ Because of the various drawbacks of infrared spectroscopy with aqueous solutions of proteins, however, circular dichroism is more widely used to estimate percentages of secondary structure.

Circular dichroism is a consequence of the absorption of visible or ultraviolet light by a chiral solute such as a protein. As such, it relies on the excitation of electrons from occupied molecular orbitals into unoccupied molecular orbitals. The most widely used absorptions in spectroscopic studies of proteins by circular dichroism are the electronic absorptions of the amides of the polypeptide backbone between wavelengths of 180 and 240 nm. In this region, two electronic transitions account for the absorption of light.¹¹¹ One is a transition ($n \rightarrow \pi^*$) in which an electron leaves one of the lone pairs on the acyl oxygen (designated by n) and enters the vacant antibonding π molecular orbital of the amide (designated by π^*). This orbital is the one of highest energy of the three molecular orbitals of the π molecular orbital system (Figure 2-3). This $n \rightarrow \pi^*$ transition is responsible for the absorption of light at a wavelength of about 220 nm. The other transition ($\pi^\circ \rightarrow \pi^*$) is one in which an electron leaves the highest occupied nonbonding π molecular orbital of the amide (designated by π°) and enters the vacant antibonding π molecular orbital (Figure 2-3). This $\pi^\circ \rightarrow \pi^*$ transition is responsible for the absorption of light at a wavelength of about 200 nm.

Plane-polarized light is light characterized by an electric vector that oscillates within a plane. One way to describe plane-polarized light mathematically is to assume that it is produced by the sum of two electric vectors of equal amplitude emanating from a single point that is traveling at the speed of light in a straight line. While propagating, these two electric vectors spin in opposite directions, clockwise and counterclockwise at the same frequency (in revolutions second^{-1}) as the frequency of the light (Figure 12-8A).¹¹² The sum of these two spinning vectors produces an electric vector that oscillates in a plane containing the line of propagation to produce the plane-polarized light. These two components that spin in opposite directions around the axis defined by the line of propagation are called **circular polarizations**.

Figure 12-8: Principles of circular dichroism and optical rotation.¹¹² (A) View down a ray of light plane-polarized in the vertical direction looking from the source. The plane-polarized light can be considered to be the sum of two electric vectors, respectively, of right (R) and left (L) circularly polarized light. The electric vector of the plane-polarized light (M) remains fixed in orientation but oscillates in amplitude with a maximum at the point A. The electric vectors of each of the circular polarizations of the ray remain fixed in amplitude but circle in opposite directions at the same angular velocity. (B) Alteration of plane-polarized light during its passage through a solution containing a chiral solute. If the index of refraction of the solution for the left circular polarization (L') of the plane-polarized light is greater than that for the right circular polarization (R'), the left component will have a slower angular velocity than the right component, and the plane of the polarized light will be rotated to the right by an angle α . If the right circular polarization (R') of the plane-polarized light is absorbed more than the left circular polarization component (L'), the plane of the polarized light will broaden into an ellipse because when the two electric vectors are at 180° to each other (at B'), they no longer cancel. The ellipse is created by a composite electric vector (M') that rotates to the left if the absorption of the right circular polarization is greater and to the right if the absorption of the left circular polarization is greater. The maximum of the amplitude of the harmonic oscillation of this electric vector within the rotated plane is at the point A' and its maximum in the dimension at 90° to the rotated plane is at the point B'. The angle θ (Equation 12-33) is indicated. Adapted with permission from ref 112. Copyright 1967 Marcel Dekker.

When these two circular polarizations encounter a chiral object such as one of the functional groups of a protein in a solution, they are absorbed and retarded unequally. If only the amplitude of one component were decreased more than the amplitude of the other while the two components remained in phase, the plane of polarization of the emerging light would retain the same orientation, but its electric vector, which is the sum of the two components, would trace in cross section an ellipse rather than a flat, linear segment (Figure 12-8B). If the only the phase between the two components were

shifted while their amplitudes remained the same, the plane of polarization of the emerging light would rotate by an angle α , but the electric vector would still trace in cross section a flat, linear segment (Figure 12-8B). The first effect is circular dichroism; the second effect, **optical rotation**. Both effects are required to occur simultaneously in any circumstance, and as polarized light is rotated, it necessarily becomes elliptical and vice versa. This obligatory connection permits the spectrum of optical rotation as a function of wavelength to be calculated from the spectrum of circular dichroism as a function of wavelength and vice versa.¹¹²

The degree to which the emerging light has become elliptical can be measured, and it is expressed as an angle

$$\theta = \tan^{-1} \frac{OB'}{OA'} \quad (12-33)$$

where the ratio OB'/OA' is the ratio of the minor and major axes of the ellipse (Figure 12-8B). The **molar ellipticity** at a given wavelength λ , $[\theta]_\lambda$, is defined by the relationship

$$[\theta]_\lambda \equiv \frac{\theta}{l [\text{chromophore}]} \quad (12-34)$$

where $[\text{chromophore}]$ is the molar concentration of the functional group absorbing the light, referred to as the **chromophore**, and l is the path length of the sample chamber. By convention, the units of $[\theta]_\lambda$ are chosen to be degrees centimeter² (decimole of chromophore)⁻¹. A **circular dichroic spectrum** is a display of the amplitude of $[\theta]_\lambda$ as a function of wavelength.

The optical rotation α (Figure 12-8B) produced by the sample can be registered with a spectropolarimeter. It can also be normalized by the concentration of the chromophore responsible for it to produce the specific rotation $[\alpha]_\lambda$. A spectrum of the **optical rotatory dispersion** is simply the amplitude of $[\alpha]_\lambda$ plotted as a function of the wavelength of the polarized light. Because optical rotation arises from a shift in the relative phases of the two circularly polarized components (Figure 12-8B), it is proportional to the derivative with respect to wavelength of the electronic absorption from which it arises. This has the practical disadvantages of both turning each peak of absorption into two peaks, a positive one and a negative one distributed around the wavelength of maximum absorption, and broadening the signal. In a spectrum of optical rotatory dispersion arising from several maxima of absorption, the individual components are difficult to resolve.

A circular dichroic spectrum, however, is usually simpler to interpret. Unless excitonic coupling between two apposed chromophores of similar wavelengths of absorption is occurring, the individual bands in a circular dichroic spectrum of a protein are unsplit peaks that

coincide with absorption maxima in the absorption spectrum of the same protein. In uncomplicated situations, the circular dichroic spectrum simply registers the optical activity of each chiral contributor to the absorption spectrum. For example, most of the peaks in the absorption spectrum of cytochrome c_1 have only one corresponding **negative or positive peak** at the same wavelength in its circular dichroic spectrum (Figure 12-9).¹¹³ The peak of absorption from the pyridoxal phosphate in glycine hydroxymethyltransferase at 422 nm corresponds to a prominent peak of positive polarization at the same wavelength and of the same width in the circular dichroic spectrum, and corresponding peaks in the two corresponding spectra shift to 343 nm upon the addition of the substrate serine to the solution.¹¹⁴ Because adjacent bands of absorption often have different polarities, the circular dichroic spectrum can often reveal details in the absorption spectrum. For example, the two overlapping peaks at 480 and 530 nm in the absorption spectrum of cytochrome- c oxidase from *Thermus thermophilus* correspond to peaks at the same wavelengths of positive polarization and negative polarization, respectively.¹¹⁵ If excitonic coupling between two or more chromophores is occurring, however, the resulting bands in the circular dichroic spectrum will each be split into two or more components of both positive and negative amplitude, and this splitting complicates the situation.¹¹⁶

A polypeptide folded entirely as an α helix has a circular dichroic spectrum that is distinct from that of a polypeptide folded entirely in β structure. Both of these spectra are distinct from that of a polypeptide unfolded as a random coil (Figure 12-10).¹¹⁷ In the circular dichroic spectrum of a polypeptide folded as an α helix, the amido $\pi^\circ \rightarrow \pi^*$ transition at about 200 nm is split into a positive component ($\lambda_{\text{max}} = 191$ nm) and a negative component ($\lambda_{\text{max}} = 205$ nm). This splitting arises from the fact that each amide is held in the same orientation relative to the axis of the α helix.¹¹⁸ There is also the additional band of negative ellipticity at 225 nm from the $n \rightarrow \pi^*$ transition of the peptide bond, which, in combination with the band of negative ellipticity at 205 nm, gives the circular dichroic spectrum of the α helix its characteristic double minimum. The $\pi^\circ \rightarrow \pi^*$ transition from a polypeptide in either **β structure** or random coil is unsplit.

The tyrosines, phenylalanines, and tryptophans in a polypeptide absorb light of wavelength between 180 and 240 nm and have characteristic circular dichroic spectra.¹¹⁷ The contributions of the tyrosines, phenylalanines, and tryptophans in a protein to its circular dichroic spectrum can be numerically subtracted to reveal the circular dichroic spectrum of the amides of polypeptide backbone alone. Because the polypeptide is the main contributor to the circular dichroic spectrum between wavelengths of 180 and 240 nm, the unit in which the molar ellipticity is usually presented is decimolarity of peptide bonds (Figure 12-10).

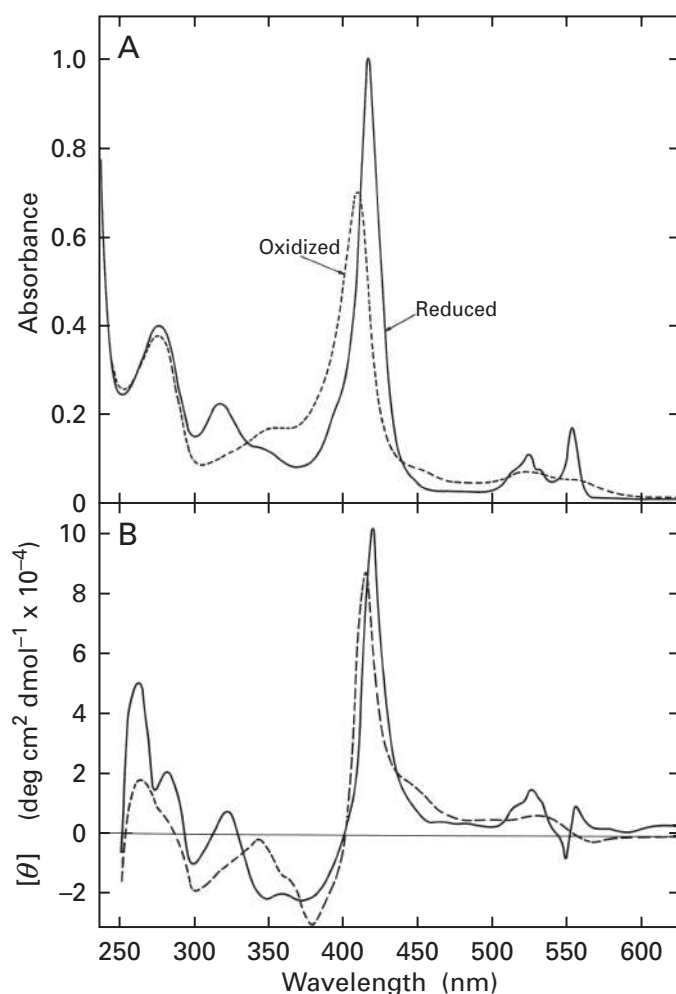

Figure 12-9: Correlation between an optical absorption spectrum (A) and the corresponding circular dichroic spectrum (B).¹¹³ Cytochrome c_1 was purified to homogeneity from bovine heart muscle. Solutions of the hemoprotein were prepared in its oxidized Fe(III) and reduced Fe(II) forms. (A) Optical absorption (absorbance) of the oxidized and reduced proteins as a function of wavelength (nanometers). In each case, the absorbance at wavelengths greater than 300 nm is due entirely to the heme of the hemoprotein. The intense bands of absorption at 400–420 nm are characteristic of hemes. (B) Molar ellipticities ($[\theta] \times 10^{-4}$) of the two solutions of the same two forms of the cytochrome c_1 , oxidized and reduced, as a function of wavelength. The molarities of the solutions were expressed as moles of peptide bond in each liter of solution, which seems inappropriate since the majority of the absorption arises from the heme. Nevertheless, the units for molar ellipticities are degrees centimeter² (decimole of peptide bond)⁻¹. For each band in the absorption spectrum, each of which has a positive value, there is a corresponding band in the circular dichroic spectrum, which is either positive or negative. For example, the band of absorption at 350 nm in the spectrum of the absorbance of the reduced cytochrome c_1 corresponds to a band of negative molar ellipticity in the circular dichroic spectrum. Reprinted with permission from ref 113. Copyright 1971 Academic Press.

The experimentally measured circular dichroic spectrum of the folded polypeptide in a protein can always be resolved numerically into three component spectra as similar as possible to those of pure α helix, pure β structure, and pure random coil. If it is assumed

Figure 12-10: Circular dichroic spectra that are used as reference spectra for α helix (dotted line), β structure (dashed line), and random meander (solid line).¹¹⁷ Molar ellipticity, $[\theta] \times 10^{-4}$ [degree centimeter² (decimole of peptide bond)⁻¹], is presented as a function of wavelength (nanometers). Myoglobin from *Physeter catodon*, dissolved in 0.1 M NaF at pH 7, is a protein that is almost entirely α -helical (Figure 4-18). It was used as a reference compound for α helix (dotted line). Poly(Lys-Leu-Lys-Leu) in 0.5 M NaF at pH 7 was used as a polypeptide that is purely β structure (dashed line). Poly(Pro-Lys-Leu-Lys-Leu) in a salt-free solution is completely structureless because of the prolines and the strong repulsions of the lysines. It is not, however, a typical random coil because of both of these features. Nevertheless, it was used as a model for a polypeptide that is purely random meander (solid line). Reprinted with permission from ref 117. Copyright 1980 Academic Press.

that these component spectra, obtained only by numerical analysis, do, nevertheless, accurately represent the contributions of α helix, β structure, and random meander to the entire spectrum, their relative amplitudes should provide the relative amounts of these three components in the actual molecule of protein.¹¹⁹

This simple expectation is diminished by several difficulties. Small peptides that assume particular types of **β turn** show significantly different circular dichroic spectra, that are each unique from that of a random coil, and dissecting out the contribution of each type of β turn to the spectrum of a particular protein is difficult,¹¹⁷ if not impossible. A related shortcoming is the confounding of random coils and random meanders. A random coil is an unfolded polypeptide continuously changing its structure by rotation around its various covalent bonds. **Random meander** is the path assumed by the backbone of a folded polypeptide that is neither an α helix, a β structure, nor a β turn. Random meander is static and respectively identical in all of the folded polypeptides in a solution of a given protein. The random coil of an unfolded polypeptide used as the standard in circular dichroism, unlike the α helix or β structure used as the standard, bears no relationship to the random meander

in a particular folded polypeptide. The random meander in a particular protein will produce a specific circular dichroic spectrum that is distinct from the common circular dichroic spectrum produced by all random coils and also distinct from the unique spectra produced by random meanders in other proteins.

Nevertheless, a least-squares method has been developed to fit the experimental circular dichroic spectrum of a protein, from which the contributions of tyrosine, tryptophan, and phenylalanine have been subtracted, to a calculated spectrum (Figure 12-11).¹¹⁷ The parameters of the **fitting procedure** are the fraction of α helix, the fraction of β structure, the fraction of random meander, and the fraction of each type of β turn. Because each measurement of molar ellipticity is based on decimoles of peptide bonds, it is assumed that the sum of these fractions is unity, that each point on the experimental spectrum is the sum of the molar ellipticity at that wavelength of the appropriate reference spectrum for the respective secondary structure multiplied by the fraction for that particular secondary structure, and that the reference spectrum for random meander is that of random coil. The least-squares procedure gives the respective values for the fractions of the four types of secondary structure that produce a calculated curve most closely reproducing the experimental curve. The fractions for each type of secondary structure estimated in this way for a set of proteins agreed quite closely with the fractions for each type of secondary structure in the respective crystallographic molecular models of these proteins.

One of the more important and informative uses of circular dichroism is to provide evidence that the structure of the protein has changed under particular circumstances. A **conformational change** is a change in the structure of the protein between two states of similar stability. For example, the conformational change of aspartate carbamoyltransferase that occurs upon the binding of its substrates and that is detected both crystallographically and as a change in sedimentation coefficient is also accompanied by significant changes in the circular dichroic spectrum of the protein.¹²⁰ Such changes in circular dichroic spectra coincident with a conformational change of a protein are commonly encountered. This fact increases the concern over the accuracy of secondary structural dissections by numerical analysis of circular dichroic spectra because crystallographic descriptions of conformational changes of proteins rarely involve significant changes in the content of α helix, β structure, β turns, or random meander or changes in their disposition over the sequence of the folded polypeptide. The changes in the circular dichroic spectrum of Na^+/K^+ -transporting ATPase during a conformational change caused by binding of its substrates are consistent with the transformation of 7% of its amino acids from α helix into β structure.¹²¹ When crystallographic molecular models of the two conformations between which the homologous conformational change occurs in

Figure 12-11: Circular dichroic spectra¹¹⁷ of (A) glyceraldehyde-3-phosphate dehydrogenase (phosphorylating) in 0.1 M NaF, pH 7, and (B) subtilisin in 0.2 M NaF, pH 7. Molar ellipticities, $[\theta] \times 10^{-4}$ [degree centimeter² (decimole of peptide bond)⁻¹], are presented as a function of wavelength (nanometers). The spectra were either directly measured (solid lines) or duplicated (dotted lines) by adding together spectra for α helix, β structure, β turn, and random meander (Figure 12-10). In the procedure used to duplicate the experimental spectrum, it was assumed that the proteins contain only α helix, β structure, β turn, and random meander. If f_{α} , f_{β} , f_T , and f_{RM} are the fractions of each of these secondary structures, it is assumed that the sum of these four numbers is 1 and that $f_{\alpha}(\theta^{\circ}_{\alpha}) + f_{\beta}(\theta^{\circ}_{\beta}) + f_T(\theta^{\circ}_T) + f_{RM}(\theta^{\circ}_{RM})$ is equal to the measured value of θ at every wavelength, where the θ° values are the molar ellipticities of the standard curves (Figure 12-10) at the same wavelength. A least-squares method was used to obtain the best values for f_{α} , f_{β} , f_T , and f_{RM} , and these four values were then used to construct the calculated curves presented in the panels. Note that f_{α} , f_{β} , f_T , and f_{RM} are parameters determined only by the structure of the protein and must have the same values for all wavelengths. For the spectrum of glyceraldehyde-3-phosphate dehydrogenase (phosphorylating), the best values of f_{α} , f_{β} , f_T , and f_{RM} were 0.31, 0.30, 0.22, and 0.17; for the spectrum of subtilisin, 0.30, 0.21, 0.21, and 0.28. Reprinted with permission from ref 117. Copyright 1980 Academic Press.

Ca^{2+} -transporting ATPase are examined,⁴⁰³⁻⁴⁰⁸ the content of α helix does change in the correct direction, but only by 2-3%. This rather small change in the amount of α helix is more consistent with the absence of a measurable shift in the amide I absorption in the infrared spectrum under the same circumstances.⁹⁰

As noted previously, most short **peptides** are structureless in water. The formation of α helices by those peptides synthesized to promote this secondary structure is routinely monitored by circular dichroism. It is also possible, by difference circular dichroic spectroscopy, to follow the assumption of a fixed structure by an otherwise structureless peptide when it binds to a protein.¹²²

Ultraviolet absorption spectra of proteins at wavelengths greater than 240 nm are dominated by the absorption of **phenylalanine** ($\lambda_{\text{max}} = 258 \text{ nm}$; $\epsilon_{258} = 197$), **cystine** ($\epsilon_{260} = 280$), **tyrosine** ($\lambda_{\text{max}} = 275 \text{ nm}$; $\epsilon_{275} = 1420$), and **tryptophan** ($\lambda_{\text{max}} = 280 \text{ nm}$; $\epsilon_{280} = 5600$).^{123,124} Tryptophan has the largest extinction coefficient and longest wavelength of maximum absorbance. Because of the strong absorption of tryptophan, the spectra of most proteins between 260 and 310 nm have the same shape as the spectrum of tryptophan alone with its maximum at 280 nm and its pronounced shoulder at 289 nm. Proteins with little or no tryptophan, however, have maxima of absorption shifted toward or coincident with the 275 nm maximum characteristic of tyrosine. The absorption of a protein at its particular maximum, somewhere between 275 and 280 nm, when properly corrected for the absorption due to the scattering of light by the solution, can be used as a rapid measurement of its concentration. Proteins that are posttranslationally modified with chromophores such as flavin, pyridoxal phosphate, or heme or bind noncovalently chromophores such as flavin, heme, metallic cations, coenzyme b_{12} , chlorophyll, pheophytin, or carotenoid, display absorption spectra that are characteristic of those chromophores (Figure 12–9). If one or more of the accessible tyrosines on the protein have been nitrated, their absorption spectra are shifted into the visible range ($\lambda_{\text{max}} = 430 \text{ nm}$) and their acid dissociation constants are increased ($\text{p}K_{\text{a}} = 6.5$), so that at neutral pH they are present mainly as the nitrophenolate, which absorbs strongly.¹²⁵

Either tryptophan or nitrotyrosine can be used as a spectral **reporter group**, the spectrum of which registers its environment or can monitor a conformational change of the protein.¹²⁶ For example, the absorption spectrum of nitrated Tyrosine 115 in micrococcal nuclease indicates that it is in a nonpolar environment in the absence of substrate but a polar environment in the presence of substrates.¹²⁵ This change in environment is also reflected in its accessibility to nitration by tetranitromethane. The conformational change of aspartate carbamoyltransferase that occurs on the binding of substrates can be detected by an upfield shift in the wavelength of the absorption of tryptophans in the protein¹²⁷ or of nitrated tyrosine side chains in its regulatory β subunits.¹²⁸

In addition to absorbing ultraviolet light, tryptophan is also both fluorescent and phosphorescent. The wavelength of the maximum **emission of fluorescence from tryptophan** varies from 300 to 350 nm.¹²⁹ The emis-

sion of fluorescence from indole itself varies between these limits systematically as a function of the polarity of the solvent; the more polar the solvent, the longer the wavelength of the emission, and the tryptophans in a protein that are the more buried display shorter wavelengths of maximum emission.¹²⁹ Consequently, the wavelength of its emission is used as a measure of the degree to which a tryptophan is buried within a protein. In the case of the absorption spectrum of tryptophan as opposed to its emission spectrum, the situation is reversed. The most buried tryptophans, in the most nonpolar environments, have been found to absorb light of the longest wavelength, on the red edge of the absorption band for tryptophan in the ultraviolet.¹³⁰

If a protein contains no posttranslationally or experimentally added chromophore, the emission of fluorescence from the protein will be dominated by that of its tryptophans. By the systematic removal of its tryptophans through site-directed mutation, the contribution of each of them to the total emission of fluorescence from the protein can be ascertained.^{131,132} A tryptophan can also be inserted into a particular location in a protein by site-directed mutation to monitor local changes in conformation.¹³³

The fluorescence from each of the tryptophans in a protein displays a characteristic wavelength of maximum emission and a characteristic intensity.¹³² When a protein is unfolded, its emission of fluorescence usually shifts to longer wavelengths as its buried tryptophans become exposed,^{131,134} but the intensity of the fluorescence can either increase¹³¹ or decrease.¹³⁴ These changes can be followed for individual tryptophans in appropriate mutants.¹³¹ Because all of the tryptophans in a protein are fully exposed to solvent upon unfolding, this observation states that the enclosing of a tryptophan by the native structure can either quench or enhance its fluorescence. Consequently, it is the particularity of the **local environment** around each tryptophan in the native protein that governs the intensity of its emission. For example, Tryptophan 94 in folded, native ribonuclease from *Bacillus amyloliquifaciens* has very little emission of fluorescence because one of its immediate neighbors is Histidine 18, which strongly quenches it.¹³⁵ The lowest intensity of emission (by a factor of greater than 3-fold) from the three tryptophans in lysozyme from T4 bacteriophage is that of Tryptophan 158, which is surrounded by a cystine and two methionines, the sulfurs of which are also efficient quenchers.¹³⁶ The amides of glutamine and asparagine are also efficient quenchers. This sensitivity to the particularity of the surroundings explains why tryptophans with the shortest wavelengths of maximum emission are not always the ones with the lowest intensity of emission.¹³²

If intersystem crossing is not significant, the excited state of a fluorescent functional group such as tryptophan can decay to the ground state by at least four **separate pathways**.¹³⁷

where the k_i are the rate constants for the respective processes. Equation 12-35 describes a radiationless decay of the energy of excitation through migration among rotational and vibrational energy levels or other piecemeal transfers to its surroundings as heat. Equation 12-36 describes the release of a portion of the energy of excitation as a photon of fluorescent light. Equation 12-37 describes the transfer of the energy of excitation to another molecule, the quencher. Although there are some molecules or ions, in particular those containing an unpaired electron, that can quench at distances beyond their van der Waals radii, most quenchers must collide with the fluorescent functional group when it is in the excited state to quench it. Equation 12-38 describes the radiationless transfer of the energy of excitation through space by resonance between the excited state and a nearby functional group capable of absorbing the energy. The excited electron is the donor, and the functional group to which the excitation is transferred is the acceptor.

The **quantum yield**, Q_0 , of a fluorescent chromophore is the number of photons appearing as fluorescence for every photon absorbed. When neither quencher nor acceptor is present,¹³⁷

$$Q_0 = \frac{k_F}{k_L + k_F} = k_F \tau_0 \quad (12-39)$$

The time over which 50% of the excited state disappears, or the half-life of the excited state, would be $(\ln 2)(k_L + k_F)^{-1}$, but the **lifetime of the fluorescence**, τ_0 , is defined as $(k_L + k_F)^{-1}$, the time in which the intensity decreases to $\exp(-1)$ of the initial intensity.

If a **collisional quencher** is added to the solution, it affects the quantum yield and lifetime of the excited state because every time a molecule of quencher collides with a molecule of excited state, there is a specific probability that the excitation energy will be transferred from the

excited state to the quencher. Each quencher has a unique efficiency for quenching a particular fluorescent chromophore. The result of this transfer of energy upon collision is that¹³⁷ the quantum yield of the fluorescent chromophore in the presence of the quencher, Q_Q , is decreased:

$$Q_Q = \frac{k_F}{k_L + k_F + k_Q[\text{quencher}]} \quad (12-40)$$

and

$$\frac{Q_Q}{Q_0} = \frac{1}{1 + \tau_0 k_Q [\text{quencher}]} \quad (12-41)$$

The observed lifetime of the quenched fluorescence, τ_Q , is

$$\tau_Q = \frac{\tau_0}{1 + \tau_0 k_Q [\text{quencher}]} \quad (12-42)$$

Phosphorescence, which is simply fluorescence from a triplet state, is also subject to quenching.

The ratio F_Q/F_0 is the ratio between the fluorescence observed in the presence of the quencher and the fluorescence observed in its absence. This ratio is necessarily equal to Q_Q/Q_0 . The ratio F_Q/F_0 can be readily measured with a fluorometer. When its reciprocal, F_0/F_Q , is plotted as a function of [quencher], a linear relationship is obtained, the slope of which is equal to $k_Q \tau_0$ (Figure 12-12).¹²⁹ The **bimolecular rate constant k_Q for the collision** of the quencher with the fluorescent functional group on a protein is the slope of this line divided by the lifetime τ_0 of the fluorescence of the unquenched excited state.

The fluorescence and phosphorescence of tryptophan can be quenched by large inorganic anions, such as Γ^- and NO_2^- ; by molecular oxygen; by unsaturated amides, such as acrylamide; and by ketones, such as 2-oxobutane.^{129,130,137,138} The bimolecular rate constant k_Q for the quenching reflects the accessibility of the quencher to the tryptophans.¹³⁸ If the quencher is a polar molecule confined to the aqueous phase, then the greater the rate constant for quenching, the more exposed is the tryptophan to that phase. On the basis of the observed rate constants k_Q for polar quenchers, the tryptophans in most proteins can be divided into three classes.¹³⁰

The tryptophans in the first class are **fully accessible** to the aqueous phase, and their fluorescence is readily quenched. The rate constants for the collisions between their singlet excited states and various polar quenchers are $2\text{--}10 \text{ M}^{-1} \text{ ns}^{-1}$ as expected from a diffusion-controlled process.

The fluorescence of the tryptophans in the third

class cannot be quenched ($k_Q < 0.01 \text{ M}^{-1} \text{ ns}^{-1}$)¹³⁶ because no collisions with the quenchers can occur within the lifetime of their excited states. Presumably, this is due to the fact that they are **buried**. This conclusion follows from the facts that such unquenchable tryptophans are observed in proteins that contain buried tryptophans in their crystallographic molecular models. For example, Tryptophan 138 in lysozyme from bacteriophage T4 is poorly quenched ($k_Q = 0.009 \text{ M}^{-1} \text{ ns}^{-1}$), and it is well buried in the molecular model of the protein.¹³⁶ Also, such unquenchable tryptophans are optimally excited by light of a longer wavelength.¹³⁰ The phosphorescence of these buried tryptophans, however, has a sufficiently long lifetime ($\tau_0 \cong 1 \text{ s}$) that it can be quenched. The bimolecular rate constants k_Q for the quenching of the phosphorescence of the tryptophans in the buried class are relatively small ($< 0.001 \text{ M}^{-1} \text{ ns}^{-1}$), and the quenching registered by these rate constants seems to result from extensive and momentary unfoldings of the folded polypeptide that occasionally provide access to the interior, but only for a short time.¹³⁰ These observations provide support for the concept that most parts of a protein are conformationally active and continuously expand and contract.

The intermediate, second class of tryptophans, and probably the most numerous, are those that are **partially buried** and have intermediate rate constants for quenching ($0.01\text{--}2 \text{ M}^{-1} \text{ ns}^{-1}$). Examples are Tryptophan 59 in ribonuclease T1 from *Aspergillus oryzae* ($k_Q = 0.3 \text{ M}^{-1} \text{ ns}^{-1}$),¹³⁸ Tryptophan 126 from lysozyme of T4 bacteriophage ($k_Q = 0.3 \text{ M}^{-1} \text{ ns}^{-1}$),¹³⁶ and Tryptophan 333 of phosphoglycerate kinase from *Saccharomyces cerevisiae* ($k_Q = 0.8 \text{ M}^{-1} \text{ ns}^{-1}$).¹³⁹

Oxygen provides an interesting exception to the behavior of most quenchers. The difference in its ability to quench accessible and buried tryptophans is much less than that observed with larger more polar quenchers (Figure 12-12).^{129,140} On the basis of this observation, it has been proposed that oxygen is small enough to insinuate its way through a molecule of protein in liquidlike diffusion among the tightly packed amino acids.

Changes in the accessibility of tryptophans to polar quenchers dissolved in the aqueous phase have been used to monitor conformational changes in the structure of a protein. In the case of succinate-CoA ligase (ADP-forming) from *E. coli*, the binding of ATP to the α subunit of the enzyme causes significant decreases in the accessibility of the tryptophans in the β subunit to acrylamide dissolved in the solution.¹⁴¹ This suggests that a conformational change propagated throughout the whole protein occurs upon the binding of ATP. The implication that both the α and β subunits change their structure in concert when ATP binds is consistent with the observation that they are intimately associated in the oligomeric structure of the protein (Figure 8-22).¹⁴² To follow the conformational change that occurs when the carboxy-terminal portion of colicin E1 from *E. coli* inserts into a

Figure 12-12: Collisional quenching of the fluorescence of tryptophans in several proteins by oxygen.¹²⁹ Solutions of the various proteins were placed in cuvettes in a fluorometer and excited with light of wavelength 280 nm. Fluorescence at 90° to the exciting beam was monitored at the wavelength of maximum emission for each protein (325–350 nm). The high concentrations of oxygen (molar) were produced by enclosing the cuvette in a chamber that could be pressurized to 105 kg cm⁻² O₂ gas and allowing the gas to equilibrate with the solution at various pressures. The proteins used were bovine α -chymotrypsin (■), rabbit fructose-bisphosphate aldolase (□), bovine immunoglobulin G (●), and bovine serum albumin (Δ). A solution of tryptophan (○) was used as an example of a fully exposed side chain. Lines were drawn on the basis of the expectation that F_0/F_0^{-1} as a function of [quencher] would be linear (Equation 12-41). Reprinted with permission from ref 129. Copyright 1973 American Chemical Society.

membrane, tryptophans were inserted at various positions in its amino acid sequence by site-directed mutation, and changes in the rate constants of quenching for these tryptophans were measured before and after insertion.¹⁴³

It is also possible for the energy of the relaxed excited state in excess over the energy of the ground state, which otherwise would be emitted as fluorescence, to be transferred intact through space by resonance to another chromophore in a radiationless process (Equation 12-38). This **fluorescence resonance energy transfer** (FRET) discharges the electronically excited state of the functional group that originally absorbed the

photon, the **donor**, and produces an electronically excited state in the functional group that receives the energy, the **acceptor**. Because this transfer of energy between donor and acceptor occurs by resonance, there must be a matching of energy and a matching of orientation between donor and acceptor. The energies are matched in the region of overlap between the absorption spectrum of the acceptor and the emission spectrum of the donor; the greater the overlap, the greater the probability that the energy will be transferred. The orientations are matched in the coincidence between the orientation of the transition dipole of the donor and the transition dipole of the acceptor; the greater the coincidence, the greater the probability that the energy will be transferred.

If the new excited state of the acceptor created by this transfer normally returns to its respective ground state by radiationless processes—in other words, if its quantum yield is zero—no fluorescent photon is emitted, and the only observations made are that the fluorescence of the donor is quenched and its lifetime is decreased. If the acceptor is also a fluorescent functional group, its excited state will release a fluorescent photon, consistent with its quantum yield. The photon released from the acceptor, however, will be of even longer wavelength than the one that would have been released from the donor (Figure 12–13)¹⁴⁴ because the excited state of the acceptor immediately following the transfer relaxes to a stable excited state, the energy of which, relative to the ground state of the acceptor, is less than the energy that was passed from donor to acceptor during the transfer. At those wavelengths in the emission spectrum of the donor that do not overlap the emission spectrum of the acceptor and are therefore not contaminated by the fluorescent emission of the acceptor, the fluorescence measured in the presence of the acceptor will be less than the fluorescence measured in its absence. The observed, uncontaminated fluorescence of the donor will be quenched in the presence of the acceptor by the ratio Q_A/Q_0 .

Suppose that a molecule of protein has a fluorescent chromophore that can act as a donor covalently attached or noncovalently bound to a particular location in its tertiary structure and a different chromophore that can act as an acceptor covalently attached or noncovalently bound to a different location. The various fluorescent compounds used to modify rhodopsin (Figure 12–14)¹⁴⁵ are typical of the donors and acceptors that are covalently or noncovalently attached to specific locations in a protein. In such a situation, the rate of the transfer of energy from the excited donor to the acceptor by resonance (Equation 12–38) is equal to $k_T f_A$ [excited donor], where f_A is the fraction of the sites on the protein for the acceptor that are occupied and [excited donor] is the molar concentration of the excited donor. As the acceptors are fixed to the molecules of protein that contain an excited donor at a constant fractional occupancy, the pseudo-first-order rate constant for the decay in the

Figure 12–13: Absorption spectra and emission spectra (inset) of 1-acetyl-4-(1-naphthyl)semicarbazide (solid lines), a typical fluorescent donor for observing transfer of energy by resonance, and a matched acceptor, dansyl-L-prolylhydrazide (dashed lines), both dissolved in ethanol.¹⁴⁴ The measurements of absorbance are made by monitoring the intensity of the light of continuously varied wavelength that passes through each solution. The measurements of emission are made by following the intensity of the light emitted at 90° to an incident beam as a function of wavelength while the chromophore is excited with light of wavelength equal to that of its maximum of absorption. The spectrum of the amount of light absorbed is expressed as an extinction coefficient (centimeter² micromole^{−1}) as a function of wavelength (nanometers). The amount of light emitted is expressed as fluorescence (in relative units) as a function of wavelength (nanometers). When donor and acceptor are located near each other, a portion of the excited states of the donor would have their energy of emission at 350 nm transferred radiationlessly by resonance to the overlapping absorption band of the acceptor, and this transfer would quench the fluorescence of the donor. The transferred energy would be emitted as fluorescence at 540 nm from the excited acceptors. Adapted with permission from ref 144. Copyright 1967 National Academy of Sciences.

concentration of excited donor through the transfer of energy to the acceptor is $k_T f_A$.

The **efficiency of transfer** E_T is defined as

$$E_T \equiv \frac{k_T f_A}{k_L + k_F + k_T f_A} \quad (12-43)$$

This is the fraction of the decay of the excited state due to transfer of energy by resonance, or the ratio between the quanta transferred and the quanta absorbed by the donor.¹⁴⁶ The quantum yield Q_A of the fluorescence of the donor in the presence of the acceptor is governed by a relationship analogous to Equation 12–40

Figure 12-14: Fluorescent, electrophilic reagents used to modify, covalently or noncovalently, three sites on rhodopsin.¹⁴⁵ *N*-[(iodoacetamido)ethyl]-1-aminonaphthalene-5-sulfonate anion **12-1** ($\lambda_{\text{abs}} = 350$ nm; $\lambda_{\text{emit}} = 495$ nm), *N*-[(iodoacetamido)ethyl]-1-aminonaphthalene-8-sulfonate anion **12-2** ($\lambda_{\text{abs}} = 350$ nm; $\lambda_{\text{emit}} = 495$ nm), and 5-(iodoacetamido)salicylate anion **12-3** ($\lambda_{\text{abs}} = 323$ nm; $\lambda_{\text{emit}} = 405$ nm) were used to modify a particular cysteine in the protein by alkylation. *N,N'*-Bis[1-(dimethylamino)naphthalene-5-sulfonato]-L-cystine **12-4** ($\lambda_{\text{abs}} = 350$ nm; $\lambda_{\text{emit}} = 520$ nm) and *N,N'*-bis[fluoresceinyl(isothiocarbamido)]cystamine **12-5** ($\lambda_{\text{abs}} = 495$ nm; $\lambda_{\text{emit}} = 518$ nm) were used to modify a different cysteine in the protein by disulfide exchange. 9-Hydrazinoacridine **12-6** ($\lambda_{\text{abs}} = 440$ nm; $\lambda_{\text{emit}} = 470$ nm) and proflavin **12-7** ($\lambda_{\text{abs}} = 470$ nm; $\lambda_{\text{emit}} = 512$ nm) were used as ligands for a particular site on the protein with a high affinity for aromatic cations. All wavelengths (λ) are wavelengths of maximum absorption or maximum emission. In each instance the fluorescent functional group selectively attached to the protein was used as a donor of resonant energy to 11-*cis*-retinal, a natural, covalent posttranslational modification (Table 3-1) of the protein that absorbs maximally at 500 nm.

$$Q_A = \frac{k_F}{k_L + k_F + k_T f_A} \quad (12-44)$$

from which it follows¹⁴⁵ that

$$E_T = 1 - \frac{Q_A}{Q_0} = 1 - \frac{F_A}{F_0} \quad (12-45)$$

where F_A/F_0 is the ratio between the fluorescence observed in the presence and that observed in the absence of the acceptor.

The lifetime of the excited state τ_A in the presence of acceptor is governed by a relationship analogous to Equation 12-42

$$\tau_A = \frac{\tau_0}{1 + \tau_0 k_T f_A} \quad (12-46)$$

from which it follows that

$$E_T = 1 - \frac{\tau_A}{\tau_0} \quad (12-47)$$

The efficiency of transfer can be assessed by measuring either the decrease in steady-state fluorescence (F_A/F_0 ; Equation 12-45) or the **decrease in the lifetime of the excited state** produced by the acceptor (τ_A/τ_0 ; Equation 12-47), but the latter measurement is more accurate than the former. The efficiency is calculated from the emission or the lifetime of the donor in the presence of the acceptor and the emission or the lifetime of the donor in the protein that has not been modified with the acceptor or in which the acceptor has been bleached.¹⁴⁵

The efficiency of the transfer of energy, E_T , is determined by the distance r between the center of the transition dipole of the donor and the center of the transition dipole of the acceptor by the relationship

$$E_T = \frac{f_A r^{-6}}{f_A r^{-6} + R_0^{-6}} \quad (12-48)$$

where R_0 is the distance at which the efficiency of transfer would be 50% if the site for the acceptor were fully occupied. Consequently, the **distance between the centers of the dipoles of the donor and the acceptor**

$$r = R_0 \left[\frac{f_A(1 - E_T)}{E_T} \right]^{1/6} \quad (12-49)$$

In theory^{146,147}

$$R_0^6 = \frac{9 (\ln 10) K^2 Q_0 J}{128 \pi^5 \tilde{n}^4 N_A} \quad (12-50)$$

where Q_0 is the quantum yield of the donor (dimensionless), \tilde{n} is the refractive index of the medium between the donor and the acceptor (dimensionless), and N_A is Avogadro's number (moles⁻¹). The **overlap integral** J (centimeters⁶ mole⁻¹)^{145,146} is that between the fluorescence emission spectrum $I(\lambda)$ of the donor (in relative units) and the spectrum of the extinction coefficient $\varepsilon(\lambda)$ of the acceptor (in liters mole⁻¹ centimeters⁻¹) normalized by the total fluorescence of the donor

$$J = \frac{\int I(\lambda) \varepsilon(\lambda) \lambda^4 d\lambda}{\int I(\lambda) d\lambda} \quad (12-51)$$

where λ is the wavelength.* This integral quantifies the match between the energies of the donor and acceptor required for the resonance. The integral J is calculated numerically from the absorption spectrum of the acceptor and the emission spectrum of the donor (Figure 12-13), which should be gathered from donor and acceptor when they are in solution attached individually to the protein.

The **orientation factor** K^2 (dimensionless) is defined by

$$K^2 \equiv (\cos \theta_T - 3 \cos \theta_D \cos \theta_A) \quad (12-52)$$

where θ_T is the angle between the transition dipoles of donor and acceptor and θ_D and θ_A are the angles between the transition dipoles of the donor and acceptor, respectively, and the vector between the centers of those dipoles.¹⁴⁸ The transfer of energy is between these transition dipoles of the donor and acceptor, and this factor quantifies the match between the orientations of the donor and acceptor required for the resonance. If the orientations of the transition dipoles are not fixed

because the chromophores are free to adopt a number of different orientations, K^2 is the average of Equation 12-52 over those orientations.

The first requirement for every application of the transfer of energy by resonance is to have a protein in which a donor of energy and an acceptor of that energy are both located at defined positions within its structure. It turns out that measuring the transfer of energy is easy but placing the donors and acceptors at unique and exclusive locations on the protein is difficult. Often, either an **intrinsic donor or an intrinsic acceptor** or both, placed by evolution either covalently or noncovalently at a unique location on the protein, is relied upon to circumvent at least half of the difficulty.

Examples of such evolutionarily positioned donors and acceptors are fluorescent substrates or fluorescent analogues of substrates that bind to the active site of an enzyme, fluorescent ligands that bind to a specific site on a protein, and posttranslationally incorporated functional groups such as coenzymes that happen to be fluorescent or transition metal ions the complexes of which absorb at convenient wavelengths.¹⁴⁹ Tryptophans are often used as donors of resonant energy. Those found naturally in the protein can be used one by one as unique donors by preparing the respective site-directed mutants, each of which retains only one of them.¹⁵⁰ Nitrotyrosine¹⁵¹ or kynurenine,¹⁵² a covalent modification of tryptophan, can be used as acceptors of resonant energy from a tryptophan.

Often cysteines in the protein are used as convenient nucleophiles to be covalently modified by **fluorescent electrophilic reagents** (Figure 12-14). Sometimes, one of the cysteines in a protein, because of its peculiar reactivity, can be selectively modified with one fluorescent reagent and another cysteine can then be modified with another.^{153,154} Cysteines can be placed at specific positions in a protein by site-directed mutation and then selectively modified with appropriate fluorescent reagents.¹⁵⁵ A fluorescent reagent can be attached to a specific glutamine on the surface of a protein by use of the enzyme protein-glutamine γ -glutamyltransferase, which exchanges the ammonia of the glutamine with a primary amine on the reagent.^{24,156} It is also possible to use synthetically produced fluorescent α amino acids and in vitro systems for incorporating unnatural amino acids at specific positions in its amino acid sequence to produce a protein with a fluorescent functional group located at a single, designated point in its native structure.^{157,158}

The **bilayer of phospholipid** in which membrane-bound proteins are embedded also provides a location in which to locate a fluorescent donor or acceptor. The bilayer can be turned into a sheet of fluorescent donors or fluorescent acceptors by dissolving hydrophobic fluorophores^{159,160} in the liquid hydrocarbon at its center or by covalently attaching fluorophores to the phospholipids from which it is formed.¹⁶¹ Because the bilayer

* In the equation presented by Latt et al.,¹⁴⁶ there is a misleading factor of 1000 that serves to correct liters mole⁻¹ to centimeters³ mole⁻¹, a correction that would automatically be made during the cancellation of units. This is an excellent example of the absolute necessity of including units and making sure that they cancel properly whenever any calculation is performed in the physical sciences.

forms a sheet of hydrocarbon and because the molecules of a particular protein all float at the same depth within this sheet of hydrocarbon, the molecules of donor or acceptor dissolved within it end up in a fixed location relative to the rest of the protein. A matched acceptor or donor, respectively, can then be attached covalently to a specific location on the protein, and transfer of energy between the molecules of donor or acceptor within the bilayer and the acceptor or donor on the protein can be monitored.

The orientation factor K^2 is the most uncertain parameter in Equation 12–50.¹⁴⁵ In any given situation, K^2 has a specific numerical value but its value cannot be measured directly. If both donor and acceptor were free enough to assume all possible relative orientations with equal probability, K^2 would be $\frac{2}{3}$.¹⁴⁵ If one of the two were fixed and the other could assume all possible relative orientations, K^2 would have a value between $\frac{1}{3}$ and $\frac{4}{3}$.¹⁴⁵ If both donor and acceptor, however, are fixed in their relative orientations, for example, both rigidly bound to a molecule of protein, K^2 can have a value anywhere between 0 and 4.0. Because R_0 , and hence r , depends for its value on $(K^2)^{1/6}$, the uncertainty of K^2 affects the value of r by more than $\pm 12\%$ only when it is greater than $\frac{4}{3}$ but far more dramatically when it is less than $\frac{1}{3}$.

The more freedom the donor, the acceptor, or both of them have to assume different orientations by rotation around unhindered bonds between them and the rigid portion of the protein, the closer the value of K^2 comes to $\frac{2}{3}$. An estimate of the orientational freedom of donor or acceptor can be made from the rate and extent of the depolarization of its fluorescent emission. If either the donor or acceptor is excited with linearly polarized light, the light emitted as fluorescence immediately, that is, before the chromophore has had time to reorient, will also be polarized. The polarity of the emitted light, however, will decay over the lifetime of the excited state as it reorients. The rate of this decay and the final residual polarity of its fluorescence provide an estimate of the orientational freedom of the donor or acceptor.

From these **estimates of orientational freedom**, a distribution of the probability for particular values of K^2 can be calculated.¹⁶² For example, from the depolarization of the fluorescence from the 5-(*N,N*-dimethylamino)naphthalenesulfonyl group attached to rhodopsin as a donor to the retinal rigidly fixed in the center of the protein, the value for K^2 could be estimated to fall between 0.08 and 1.8 with a confidence of 90%,¹⁵⁶ and from the depolarization of the fluorescence from the pyrene group attached covalently as a donor to the active site of acetylcholinesterase and the depolarization of the fluorescence from the propidium bound as an acceptor at another site on the protein, the value for K^2 could be estimated to fall between 0.25 and 2.2.¹⁴⁸ For donor or acceptor or both to display depolarization, however, they must be reorienting fairly freely anyway, and such estimates of ranges for K^2 may not be significantly more

accurate than simply using $\frac{2}{3}$ for the value of K^2 . For example, predicted distances between four pairs of donors and acceptors positioned on specific amino acids in phosphoglycerate kinase from yeast, a protein for which a crystallographic molecular model is available, were no more reliable when K^2 was estimated from depolarizations than when $\frac{2}{3}$ was used for K^2 .¹⁵⁵

If both donor and acceptor are rigidly bound by the protein at a **fixed orientation** relative to each other, then neither will have any orientational freedom and no limits can be placed on K^2 other than from 0 to 4.¹⁶³ For example, in the crystallographic molecular model of deoxyribodipyrimidine photo-lyase from *Anacystis nidulans*, the angle between the transition dipoles of the flavin adenine dinucleotide and the 8-hydroxy-5-deazaflavin bound to the protein is 36° . From this angle and the angles of the dipoles to the vector between the two chromophores (Equation 12–52), a value of K^2 of 1.6 could be calculated.¹⁶⁴ For the same protein from *E. coli*, however, the angle between the transition dipoles of the flavin adenine dinucleotide and the methylene tetrahydrofolic acid, which takes the place of the 8-hydroxy-5-deazaflavin in the latter crystallographic molecular model, is almost 90° , causing K^2 to be almost 0. Even though the distances between the chromophores in these two proteins are the same (1.7 nm), the efficiency of the transfer of energy by resonance for the protein from *A. nidulans* is 97% while that from *E. coli* is 62%. When K^2 of $\frac{2}{3}$ was used to calculate the distance between the flavin adenine dinucleotide and the tetrahydrofolic acid in the protein from *E. coli*, in the absence of a crystallographic molecular model, the value obtained was 2.2 nm instead of the actual distance of 1.7 nm.¹⁶⁵

The efficiency of the transfer of energy by resonance between Tyrosine 14 and Tyrosine 55 in steroid Δ -isomerase from *Pseudomonas testosteroni* is less than 25% even though these tyrosines are only 0.6 nm apart in the crystallographic molecular model. Consequently, K^2 must be less than 0.003, a fact from which it was concluded that these two tyrosines were held rigidly by the protein in a relative orientation incompatible with efficient transfer even over such a small distance.¹⁶⁶ Had a value of $\frac{2}{3}$ been used for K^2 in the calculation, the distance between these two tyrosines would have been estimated to be greater than 1.5 nm.

The original enthusiasm for measurements of the transfer of energy by resonance was the potential it offered for **measuring the distance between two locations in a protein** the crystallographic molecular model for which is not available.¹⁴⁵ For example, if the donor were attached by the unique stoichiometric covalent modification of a particular amino acid in the sequence of the protein and the acceptor were specifically attached by the unique modification of another amino acid in the sequence, it would be possible to estimate the distance between the donor and acceptor in the folded polypeptide and hence the distance between the two modified

amino acids. In support of this intention, Equations 12–48 and 12–50 have been shown to be consistent with the observed transfers of resonant energy between a donor and an acceptor at the two ends of short synthetic peptides of proline.¹⁴⁴ The distance between donor and acceptor was varied by varying the number of prolines in the peptides to demonstrate that the dependence of efficiency upon distance was as the sixth power. If K^2 was assumed to be $\frac{2}{3}$, the calculated distances between donor and acceptor agreed fairly well (within 25%) with the distances measured from molecular models of these modified peptides. Many estimates of distances between locations in proteins have been made from measurements of the transfer of energy by resonance.

One way to evaluate the **reliability of such estimates** is to compare a distance estimated in this way with the distance observed in a subsequently obtained crystallographic molecular model. The distance between Cysteine 199 and Cysteine 343 in cyclic AMP-dependent protein kinase was estimated to be 3.1–5.2 nm on the basis of the transfer of energy by resonance between two different pairs of donor and acceptor,¹⁵⁴ but in the subsequently reported crystallographic molecular model¹⁶⁷ the distance between the sulfurs of these two cysteines is only 2.12 nm. The distance between the two Cysteines 283 in dimeric creatine kinase from rabbit muscle was estimated to be 4.8–6.0 nm from measurements of the efficiency of transfer for five different pairs of donor and acceptor,¹⁶⁸ but in the subsequently reported crystallographic molecular model of the protein,¹⁶⁹ these cysteines are only 3.33 nm apart. The distance between Lysine 84 on one of the subunits in an α_3 catalytic trimer and the closest Lysine 84 on a subunit in the other α_3 catalytic trimer in aspartate carbamoyltransferase (Figure 9–37) was estimated to be 3.3 nm on the basis of transfer of energy by resonance between a pyridoxamine phosphate and a pyridoxal phosphate attached to the respective side chains.^{170,171} This estimate conveniently splits the difference between the distances of 2.1 and 3.8 nm observed in subsequent crystallographic molecular models of the two respective conformations of the protein.^{172–174} The distance between the binding site for acetylcholine on acetylcholine receptor and the bilayer of phospholipids of the membrane in which it is located was estimated to be 3.0–4.0 nm from measurements of the transfer of energy by resonance between a donor covalently attached to choline and two different acceptors dissolved in the hydrocarbon of the bilayer,¹⁶⁰ and the distance to the closest surface of the bilayer estimated crystallographically is 3.0 nm.¹⁷⁵

A more suspect evaluation of the reliability of distances estimated from the transfer of energy by resonance are comparisons of them with those observed in a crystallographic molecular model available at the time the measurements were made. The distances estimated from the transfer of energy to chloramphenicol bound at the active site of chloramphenicol *O*-acetyltransferase

from Tryptophan 86 and Tryptophan 152, respectively, were both 1.5 nm when K^2 was set at $\frac{2}{3}$, and the distances in the crystallographic molecular model are 1.72 and 1.66 nm, respectively.¹⁵⁰ The distances estimated from the transfer of energy between the amino terminus and Lysines 15, 26, 41, and 46 in bovine pancreatic trypsin inhibitor were 3.4, 2.2, 2.1, and 2.3 nm, respectively, and the distances in the crystallographic molecular model are 3.17, 1.68, 1.80, and 2.17 nm, respectively.¹⁷⁶ The distance between Tyrosine 99 and Tyrosine 138 in the complex between calmodulin and four calcium ions was estimated from the transfer of energy to be between 1.4 and 1.9 nm,¹⁵¹ and the distance in the crystallographic molecular model is 1.2 nm.¹⁷⁷ The distance between a cysteine substituted for Phenylalanine 239 and Cysteine 343 in cyclic-AMP dependent protein kinase was estimated from the transfer of energy to be 4.1 nm,¹⁷⁸ and the distance in the crystallographic molecular model is 3.7 nm.¹⁷⁹

Aside from the uncertainty of the values of K^2 , one of the main difficulties in measuring distances by transfer of energy is that the donors and acceptors are often attached covalently to the protein by using reagents that end up placing the chromophore on a **flexible tether** a significant distance from the amino acid to which it is attached. For example, the reagents used to modify rhodopsin (Figure 12–14) place the centers of the chromophores 0.4–1.2 nm away from the electrophilic carbon or sulfur that is directly attached to the nucleophilic amino acid that has been modified. The fluorescent (5-sulfonaphthalen-1-yl) amino group and the fluorescent (7-nitrobenz-2-oxa-1,3-diazol-4-yl) amino group that were used as donor and acceptor, respectively, in estimates of distances between locations in the complex between DNA, deoxymononucleotide, and the Klenow fragment of DNA-directed DNA polymerase from *E. coli*, were attached to various atoms in the complex by tethers that were each about 1.2 nm in length.¹⁸⁰ If both donor and acceptor are attached through such long tethers, the distance between them can be significantly different from the actual distance between the two amino acids to which they are attached. One approach to adjusting the estimates of distance for these added lengths is to assume that the fluorescent functional group and its tether extend unrestrained outwards from the surface of the protein and correct for this extra distance geometrically.¹⁸¹ The difficulty with this approach is that the fluorescent functional group may adsorb to the surface of the protein or insert into a crevice on the surface.¹⁵³

Many of the failures of the measurements of distance to agree very closely with subsequent or even prior crystallographic determinations may result from technical shortcomings. Too frequently the necessary parameters such as quantum yield and spectral overlap are not measured directly but are based on prior published values. Measurements in the ultraviolet are often compromised

by contaminants in the solutions. It has already been mentioned that steady-state measurements of fluorescence are much less accurate than direct measurements of lifetimes of the fluorescence. Nevertheless, because of the uncertainties concerning the orientations of the dipoles of donor and acceptor, the degree of their orientational freedom, and the relationship of the distance between them and the distance between their points of attachment, because of the modest success of such estimates, and because crystallographic molecular models have become far more common, measurements of the transfer of energy by resonance are used infrequently to estimate distances. They are, however, still widely used for other purposes, because they have the advantage of providing information about a protein while it is in solution.

The transfer of energy by resonance is used to detect **conformational changes** in a protein. For example, the efficiency of the transfer of energy by resonance between Tryptophan 133 and a (5-sulfonaphthalen-1-yl)amino group attached through a tether to Cysteine 93 in dolichylphosphate β -D-mannosyltransferase increased from 42% to 66% upon the binding of the substrate dolichyl phosphate.¹⁸² From this observation, it was concluded that a conformational change occurs in the protein upon the binding of the substrate, and from the magnitude of the change in the efficiency of the transfer of energy, it was estimated that the distance between Tryptophan 133 and Cysteine 93 decreased about 0.3 nm during this conformational change. From similar observations, conformational changes producing shifts in the apparent positions of donors and their acceptors of 0.3, 0.3, 0.5, and 1.2 nm have been observed for the binding of DNA to transcription factor AP-1,¹⁸³ the exchange of Na^+ for K^+ in the active site of Na^+/K^+ -exchanging ATPase,¹⁸⁴ the exchange of Ca^{2+} cations for Mg^{2+} cations in troponin,¹⁸⁵ and the binding of a bisubstrate analogue to adenylate kinase, respectively.¹⁸⁶

For all of the same reasons, associating a **change in the distance between two locations** on a protein with the change in the transfer of energy by resonance is just as uncertain as estimating a distance between them. Upon the binding of the $\beta(1\rightarrow4)$ trimer of *N*-acetylglucosamine to lysozyme from chicken, the distance between a kynurenine at position 62 and Tryptophan 108 appeared to decrease by 0.5 nm when calculated from the change in the efficiency of transfer.¹⁵² It is unlikely, however, that such a large conformational change occurs on the binding of the oligosaccharide because no such differences (<0.04 nm) in the distance between these two amino acids is observed between the crystallographic molecular models of unliganded lysozyme and lysozyme to which the $\beta(1\rightarrow4)$ tetramer of *N*-acetylglucosamine is bound.¹⁸⁷ It is possible that crystal packing constrains both the liganded and unliganded conformations to the same structure in the crystal even though their structures are so different in solution. It is more likely, however, that the relative orientations of the donor or the acceptor or both are changed upon the association of the ligand, not

the distance between them. In the case of the sliding clamp of bacteriophage T4 DNA-directed DNA polymerase, however, it is thought that the ring of subunits composing the protein must split open so that a molecule of DNA can enter the hole in its center, and changes in the efficiency of the transfer of energy by resonance between donors and acceptors on different subunits equivalent to changes in distances of up to 1.5 nm are thought to reflect real changes in distance upon the opening of the ring and its subsequent intimate embrace of the DNA.¹⁸⁸

The transfer of energy by resonance is also used to monitor the association between a molecule of protein modified with a donor and another molecule of protein modified with an acceptor. The catalytic α subunit of cyclic AMP-dependent protein kinase has been modified with a tethered fluorescein and the regulatory β subunit with a tethered rhodamine. During the heterologous association of the two subunits, the fluorescence of the fluorescein decreases by about 30% as the rhodamine, an acceptor of the energy of its excited state, is brought into its vicinity.¹⁸⁹ Such assays based on the decrease in the fluorescence of a donor produced by an acceptor upon formation of a complex have been used to follow the association of cytochrome *c* and cytochrome-*c* oxidase¹⁹⁰ and the association of myosin and actin.¹⁹¹

Changes in the efficiency of the transfer of energy by resonance resulting from changes in the molar concentrations of the participants can also be used to measure the **dissociation constant** for a complex between two proteins or the complex between a protein and a nucleic acid. The dissociation constant between cytochrome *c* and cytochrome-*c* oxidase¹⁹⁰ and the dissociation constant between Rho-GDP dissociation inhibitor and GTP-binding protein Cdc42¹⁹² have been determined by monitoring changes in the efficiency of the transfer of energy, as has the equimolar stoichiometry of the complex between the sliding clamp and the clamp holder of DNA-directed DNA polymerase from bacteriophage T4.¹⁹³ Both the dissociation constant and the kinetics of the association between DNA and transcription factor AP-1^{183,194} have been monitored by changes in the transfer of energy by resonance.

Dissociation constants are also measured by monitoring changes in fluorescence that do not involve transfer of energy by resonance. For example, the enhancement of the fluorescence of poly(deoxy-1,*N*⁶-ethenoadenylic acid), a fluorescent analogue of poly(adenylic acid), upon the association of RecA protein from *E. coli* has been used to determine the dissociation constant and the kinetics of the association between the protein and the nucleic acid.¹⁹⁵

The transfer of energy by resonance has also been used to monitor changes in the structure of DNA produced by a protein. By modifying the immediately adjacent 3' end of one strand and 5' end of the other strand of a molecule of double-stranded DNA with a donor and an

acceptor, respectively, the increase in fluorescence of the donor when the two strands are dissociated has been used to monitor the unwinding of DNA catalyzed by ATP-dependent DNA helicase Rep from *E. coli*¹⁹⁶ and the exchange of one strand in a duplex of DNA for another catalyzed by RecA protein from *E. coli*.¹⁹⁷ By labeling short, double-stranded molecules of DNA with a donor at one end and an acceptor at the other, the decrease in the distance between donor and acceptor during the bending of the DNA caused by the binding of high mobility group protein Z from *Drosophila melanogaster* could be monitored.¹⁹⁸

Another manifestation of fluorescence that can be used to assess the proximity of two sites in a molecule of protein is the formation of an excited-state dimer or **excimer**. If upon its formation, the excited state of a suitable chromophore, for example, a pyrenyl group, is immediately adjacent to another one of the same chromophore, for example, another pyrenyl group, the excited state will form a dimer with its unexcited twin. Such a dimeric excited state, because of the greater opportunities for dissipation of the energy of the excited state radiationlessly, emits light of longer wavelength. For example, a pyrenyl group when excited at 344 nm emits light of wavelengths 378, 398, and 417 nm, but its excimer emits light of wavelength 470 nm. The observation of excimer fluorescence from a protein modified at two different amino acids with an appropriate chromophore is evidence that in the native structure of the protein those two amino acids are immediately adjacent to each other, even though they are distant from each other in its sequence.^{199,200}

Problem 12–10: Hepatitis B virus produces severe inflammation of the liver. The mature, infectious virion is composed of three spherical, concentric layers. The outer layer is a continuous envelope of membrane the phospholipid bilayer of which came from the plasma membrane of the cell out of which the virion budded and the protein of which was encoded by viral DNA. The inner layer is a sphere of condensed, double-stranded viral DNA (3.2 kb) encoding the viral genome. The middle layer is a capsid enclosing the viral DNA. This viral capsid is an oligomeric protein composed of multiple copies of the same folded polypeptide, 183 amino acids in length. The amino acid sequence of this polypeptide is

The first 145 amino acids of the polypeptide fold to form the compact subunit that creates the viral capsid, and the last 40 amino acids interact with the viral DNA to provide counterions for the phosphodiester of the DNA and assist in condensing and packaging it.

A recombinant form of the gene encoding the viral capsid has been constructed for studies of its assembly. This recombinant gene, carried on the plasmid ptacHBc144, is under the control of the lacUV5 promoter and directs the expression in *Escherichia coli* of a polypeptide 154 amino acids long. The amino-terminal sequence of this polypeptide is TMITDSLEFH–, and the carboxy-terminal sequence is –IS. Between these two terminal sequences, which result from the cloning strategy, is the sequence of the polypeptide of the viral capsid from Isoleucine 3 to Proline 144. The expressed recombinant polypeptide lacks the carboxy-terminal portion of the subunit that interacts with the viral DNA. Nevertheless, it folds as it is being expressed in *E. coli*, and the resulting subunit then assembles, also within the bacterium, to form an oligomer similar to the viral capsid in the intact, infectious virion. This recombinant, empty, unenveloped viral capsid can be purified, and the purified protein is composed of only the one polypeptide, which is not post-translationally modified. This native, empty oligomeric protein is referred to as the HBe viral capsid.²⁰¹

The molar mass of the polypeptide of the HBe viral capsid at a net charge number of zero, calculated from the amino acid sequence of the expressed protein, is 17,369.9 g mol^{–1}.

- The actual molar mass of a folded polypeptide differs from its molar mass at zero net charge depending on the conditions. Give reasons other than posttranslational modification for this difference.
- Estimate the magnitude of the effect of these factors (plus or minus how many grams mole^{–1}) on the molar mass of the subunit of the HBe viral capsid. What would be the appropriate choice of significant figures for expressing the molar mass of the subunit?

The HBe viral capsid was submitted to sedimentation equilibrium at 2800 rpm, 20 °C, in 0.15 M NaCl and 50 mM tris(*N*-hydroxymethyl)aminomethane hydrochloride, pH 7.0 ($\rho_{\text{sol}} = 1.00494 \text{ g cm}^{-3}$).

- Why was the sodium chloride present?

At sedimentation equilibrium, the absorbance at 290 nm (A_{290}) within the sample chamber showed the following dependence on the radial distance (r) from

the center of rotation.²⁰¹ Reprinted with permission from ref 201. Copyright 1995 American Chemical Society.

- (D) Calculate the molar mass of the HBe viral capsid. In this calculation, use the approximation of Equation 8-21. The partial specific volume of the protein, calculated from its amino acid composition, is $0.743 \text{ cm}^3 \text{ g}^{-1}$. Note that

$$\frac{d \ln C_{\text{prot}}}{dr^2} = \frac{d \ln \epsilon_{290}}{dr^2} + \frac{d \ln A_{290}}{dr^2} = \frac{d \ln A_{290}}{dr^2}$$

where ϵ_{290} is the extinction coefficient for the protein at 290 nm.

- (E) On what measurements of the concentration of protein does this calculation of molar mass rely?

A similar recombinant version of the viral capsid of hepatitis B virus has been embedded in amorphous ice, and electron micrographs of that protein have been submitted to image reconstruction. The following are two views of that reconstruction.²⁰² Reprinted with permission from ref 202. Copyright 1994 Elsevier B.V.

- (G) Exactly how many folded polypeptides are there in the HBe viral capsid? What is its exact molar mass?
- (H) The standard sedimentation coefficient at 20 °C in water, $s_{20,w}^0$, of the HBe viral capsid is 44 S. Calculate its frictional coefficient.

- (I) On the basis of this frictional coefficient, if the viral capsid were a smooth, unhydrated sphere, what would be its radius?

The HBe viral capsid was examined by scanning transmission electron microscopy. The inset in the figure is a selected field from one of these micrographs containing three HBe viral capsids.²⁰¹ Reprinted with permission from ref 201. Copyright 1995 American Chemical Society.

Each image obtained in this procedure is a projection of the three-dimensional molecule onto a two-dimensional plane. The image is in negative contrast so the protein appears as a light object on a dark background, and the degree of contrast at any point in the plane is directly proportional to the amount of protein contributing to that projected point. These images can be scanned, and the two-dimensional distribution of contrast can be converted into a radial distribution of density if it is assumed that the viral capsid is spherically symmetric. A graphical representation of this radial distribution of density in kilodaltons nanometer⁻³ is presented in the figure.

- (J) Why does the density of protein decrease gradually beyond a radius of 12 nm rather than abruptly as it would if the protein were a smooth sphere?
- (K) On the basis of this distribution of protein density, what is the maximum value for the radius of the HBe viral capsid?
- (L) What would be the frictional coefficient for a spherical molecule of protein with this radius?
- (M) What reasons could explain why the actual frictional coefficient of the HBe viral capsid is larger than this maximum theoretical frictional coefficient?

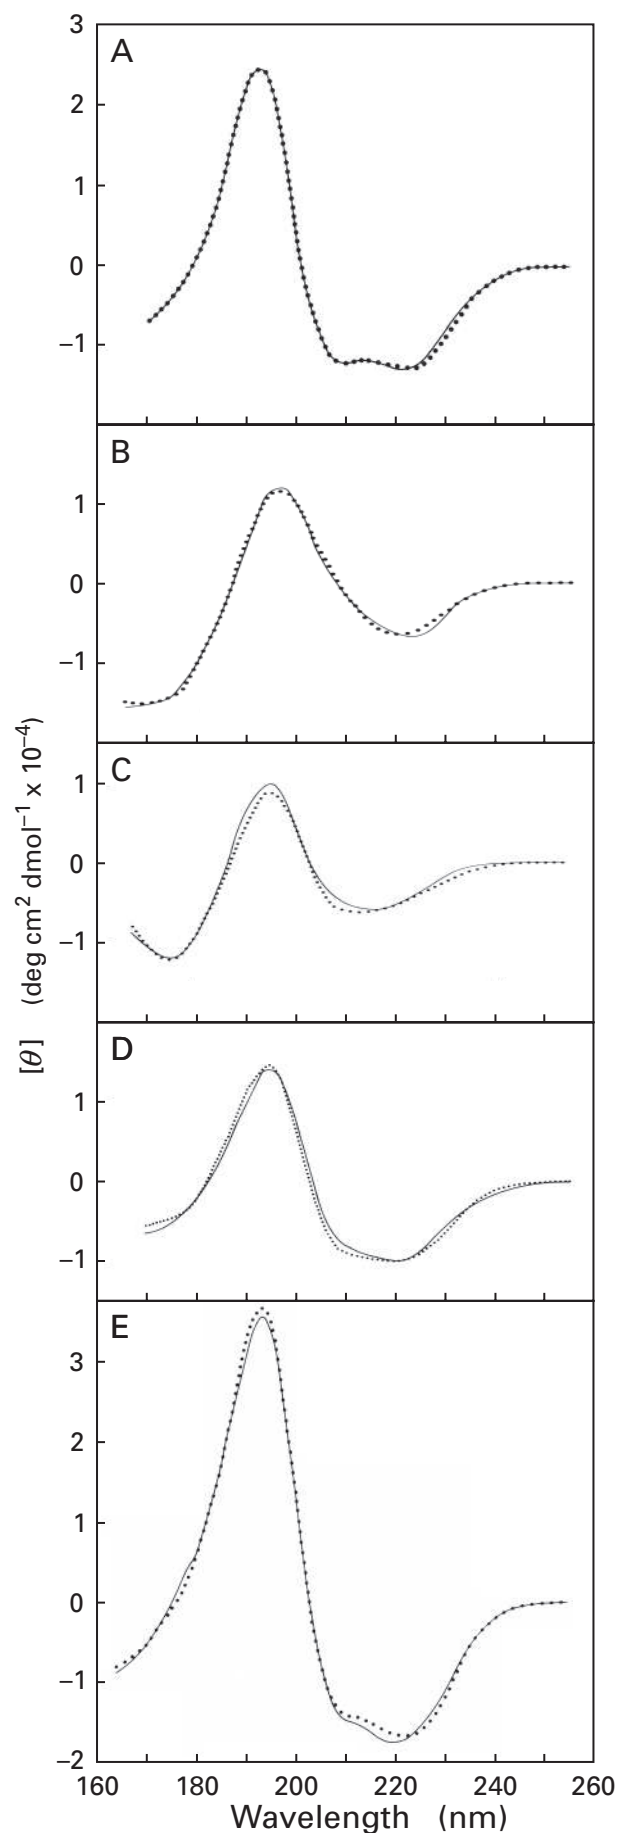

The following is the circular dichroic spectrum of the HBe viral capsid and a list of the values of the molar ellipticity [degrees centimeter² (decimole of peptide bond)⁻¹] at three selected wavelengths.²⁰¹ Reprinted with permission from ref 201. Copyright 1995 American Chemical Society.

The values for the molar ellipticities at these same three wavelengths for the three standard curves in Figure 12-10, which represent pure α helix, pure β structure, and pure random meander, are

λ (nm)	$[\theta]_{\alpha}$ (deg cm ² dmol ⁻¹ × 10 ⁻⁴)	$[\theta]_{\beta}$ (deg cm ² dmol ⁻¹ × 10 ⁻⁴)	$[\theta]_{RM}$ (deg cm ² dmol ⁻¹ × 10 ⁻⁴)
223	-2.75	-0.97	+0.31
210	-2.67	-0.78	-0.78
198	+3.85	+3.85	-3.96

- (N) Assume that the folded polypeptide of the HBe viral capsid contains only α helix, β structure, and random meander, and formulate a set of three simultaneous equations relating the three unknowns f_{α} , f_{β} , and f_{RM} , the respective fractions of each type of secondary structure in the protein. Do not use as an equation the assumption that the sum of these three fractions is 1.
- (O) Solve this set of equations for f_{α} , f_{β} , and f_{RM} .
- (P) Why is it so surprising that the values of f_{α} , f_{β} , and f_{RM} add up to 1 anyway?
- (Q) On the basis of these numerical values of f_{α} , f_{β} , and f_{RM} , why is one required to conclude that the viral capsid of southern bean mosaic virus (Figure 9-27) and the viral capsid of hepatitis B virus do not share a common ancestor even though their overall structures are similar?

Problem 12–11: The circular dichroic spectra of several proteins are shown to the left.¹¹⁷ The solid lines are the observed spectra; the dotted lines are theoretical fits to the data. Reprinted with permission from ref 117. Copyright 1980 Academic Press.

- Using the letters in each panel to designate each protein, rank them in order from the one with the most α helix and the least β structure to the one with the most β structure and least α helix.
- Consider the protein with the most α helix. What would be the maximum percentage of α helix it could have?
- Consider the protein with the least α helix. What would be the maximum percentage of β structure it could have?

Problem 12–12: Suppose that $R_0 = 1.7$ nm for the transfer of energy by resonance between a donor and an acceptor on a protein and that the efficiency of the energy transfer between donor and acceptor is 0.79. When a ligand that binds to the protein is added, the efficiency of energy transfer decreases to 0.64. What is the apparent change in the distance between donor and acceptor that occurs upon binding of the ligand?

Nuclear Magnetic Resonance^{203,204}

Many atomic nuclei display rotational motion known as **nuclear spin**. Because nuclear spin is quantized, its angular velocities can assume only those magnitudes dictated by **spin quantum numbers**. Among many other atomic nuclei, those of ^1H , ^{13}C , ^{15}N , ^{19}F , and ^{31}P have only two spin quantum numbers, $+\frac{1}{2}$ and $-\frac{1}{2}$. These dictate two specific angular velocities of the same magnitude but of opposite polarity. These two angular velocities are the two **spin states** of these nuclei. As any one of these nuclei is a charged particle by virtue of its protons, either of these angular velocities creates a magnetic field of the respective polarity aligned with the axis of the nuclear spin. When such a nucleus is placed in an **external, homogeneous magnetic field** of a given polarity, its axis tends to align with the direction of the applied field, and its spin states, because they are of opposite polarity to each other, become different in energy. This **difference in energy**, ΔE , is directly proportional to the **magnetic flux density** B_i (tesla) at the location of nucleus i ; and as in optical spectroscopy, the difference in energy determines the frequency ν_i (hertz) of electromagnetic energy that is absorbed by nucleus i :

$$\Delta E = \frac{\gamma_i h B_i}{2\pi} = h\nu_i \quad (12-53)$$

where h is Planck's constant and γ_i is the magnetogyric ratio (radians tesla⁻¹ second⁻¹) for nucleus i , which is

determined only by the type of nucleus, ^1H , ^{13}C , ^{15}N , ^{19}F , or ^{31}P , that it is (Table 12–2). The frequency ν_i at which nucleus i absorbs in an applied external field is its **Larmor frequency**.

At readily accessible magnetic flux densities (<25 T), the difference in energy between the two spin states of one of these nuclei is less than 0.5 J mol^{-1} , which is the energy contained in a photon of wavelength greater than 3×10^8 nm and frequency less than or equal to 1000 MHz. This is in the **radiofrequency range of electromagnetic energy**.

A solution of molecules contains discrete **populations of atomic nuclei** in which each and every nucleus is chemically identical. For example, if the naturally present deuterium is ignored, a solution of *p*-xylene

uniformly and completely labeled with ^{13}C carbon would contain one discrete population of ^1H hydrogen nuclei composed from the four hydrogens attached to the phenyl ring in each molecule of *p*-xylene, a discrete population of ^1H hydrogen nuclei composed from the six hydrogens attached to the methyl groups in each molecule of *p*-xylene, a discrete population of ^{13}C carbon nuclei composed from the carbons of the methyl groups, a discrete population of ^{13}C carbon nuclei composed from the para carbons of the ring, and a discrete population of ^{13}C carbon nuclei composed from the meta carbons of the ring. The nuclear spin of each nucleus in a given population of nuclei can be represented as a vector of unit length parallel to the axis of its spin. The **net magnetization** of a given population of nuclei is the vector sum of its individual nuclear spins. In an applied magnetic field, although the individual nuclear spins show only a tendency to align with the field, the net magnetization of each population of nuclei is aligned exactly with the direction of the field. In an applied magnetic field, each of these discrete populations of nuclei in the solution has a corresponding Larmor frequency for the nuclear magnetic resonance absorption associated with it.

When a population of chemically identical fundamental particles, such as electrons or atomic nuclei, is exposed to electromagnetic radiation of a wavelength equivalent in energy to the difference between two energy levels accessible to the particles, the electromagnetic radiation catalyzes the movement of the members of that population of particles between these two energy levels. The reason is that the electromagnetic radiation is in **resonance** with the transition between the two energy levels. Photons with this energy will be absorbed during this process only if, at the time of irradiation, the popu-

lation of particles occupying the lower energy level is greater than the population occupying the higher energy level. The absorption of photons, however, necessarily increases the population in the higher energy level at the expense of the population in the lower energy level. When the populations in the two resonating energy levels become equal to each other, absorption can no longer occur, and a state of **saturation** is reached.*

In the electronic transitions and vibrational transitions of electrons in atomic and molecular orbitals (Figure 12-5), the energy levels are sufficiently different that almost all unexcited electrons are in the state of lower energy, and relaxation back to the state of lower energy is sufficiently rapid ($>10 \text{ ns}^{-1}$)⁸⁶ that absorption of a particular wavelength of light by a given population of chemically identical electrons rarely displays saturation. In nuclear magnetic resonance, however, the energy difference between the two spin states that can be achieved with the available magnetic flux densities is so small ($<0.5 \text{ J mol}^{-1}$) that the equilibrium constant K_{sp} between the two spin states for a population of identical nuclei at normal temperatures (300 K) is very close to 1 ($1 < K_{\text{sp}} < 1.0002$). This means that the difference in the concentrations of the nuclei in the two spin states at equilibrium will be less than 200 ppm. The difference between the populations in the two energy levels set in resonance is small enough and the **rate of relaxation** of a nucleus in the level of higher energy back to the level of lower energy is slow enough ($\geq 1 \text{ s}^{-1}$) that saturation occurs readily. This causes the amplitude of the observed absorption of the electromagnetic energy in nuclear magnetic resonance spectroscopy to be sensitive to the rate of relaxation of the populations of individual nuclei from the state of saturation to the state of equilibrium. The faster the population relaxes, the more energy it can absorb. For this relaxation to occur, the excess energy that has been absorbed has to be dissipated.

The **chemical shift** of the nuclear magnetic resonance absorption of a population of nuclei is a measure of the frequency of the electromagnetic energy at which the absorption appears in the spectrum. The chemical shift of the absorption of a particular population of nuclei is determined by the chemical environment of the chemically identical nuclei that compose the population. The electrons surrounding a given nucleus circulate in response to the applied magnetic field as a current would in a copper coil. This current decreases the local magnetic flux density B_i experienced by the nucleus and establishes its characteristic Larmor frequency (Equation 12-53). The chemical shift δ_i of a nuclear magnetic resonance absorption from a population of chemically iden-

tical nuclei i is the normalized difference between its Larmor frequency ν_i , the frequency at which it absorbs, and the frequency ν_{std} at which the population of a standard nucleus absorbs:

$$\delta_i = \frac{\nu_{\text{std}} - \nu_i}{\nu_{\text{std}}} = \frac{B_{\text{std}} - B_i}{B_{\text{std}}} \quad (12-54)$$

The units used for chemical shift are **parts per million** (ppm) relative to the absorption of the standard nucleus in a particular reference compound because the local differences in magnetic flux density are never greater than about 0.0002 (200 ppm) of the applied field. Chemical shift cannot be expressed in absolute units of energy because the energy difference between a particular absorption and that of the standard varies with the magnitude of the applied field (Equation 12-53). The magnitude of the chemical shift provides chemical information about the disposition of the electrons in the environment surrounding the nucleus, in other words, the molecular structure in its vicinity.

Nuclear magnetic resonance spectroscopy measures the same phenomenon as optical spectroscopy. In an external magnetic field every nucleus of spin $\frac{1}{2}$ has two energy levels. Depending on the flux density of the applied magnetic field and the type of nucleus, electromagnetic energy of a discrete wavelength (frequency) somewhere between $2 \times 10^{10} \text{ nm}$ (15 MHz) and $3 \times 10^8 \text{ nm}$ (1000 MHz) will be absorbed by a particular population of identical nuclei in the process of exciting nuclei in the population of the spin state with lower energy to the spin state with higher energy. In theory, these absorptions of energy by each discrete population could be recorded as a function of wavelength to obtain a spectrum, as is done with an optical absorption spectrum. **Continuous wave (CW) nuclear magnetic spectrometers** approximate this ideal. They measure the absorption of energy of a fixed frequency as the flux density of the applied magnetic field is varied slowly and continuously, and they record the variation in the intensity of the radiofrequency signal as it is absorbed by the sample. This measurement produces a scan of absorption as a function of the flux density of the magnetic field. The direct proportionality between magnetic flux density and frequency (Equation 12-53) permits the spectrum of absorption to be presented as a function of frequency. Maxima of absorption appear in the spectrum at the Larmor frequencies of the different populations of nuclei in the sample. Nuclei of the different elements differ dramatically in their ability to absorb radiofrequency energy (Table 12-2) and hence the intensities of their maxima.

Almost all instruments used today, however, are **Fourier transform (FT) nuclear magnetic resonance spectrometers**. In such a spectrometer there is a radio-transmitter that generates radiowaves of a set frequency, for example 600 MHz, referred to as the **carrier fre-**

* Because the absorption of electromagnetic energy is the consequence of resonance and because the resonance is so much closer to equilibrium in nuclear magnetic resonance spectroscopy than in optical spectroscopy, nuclear magnetic resonance spectroscopists often use the word "resonance" in place of the word "absorption".

Table 12-2: Nuclear Properties²⁰³ of Nuclei with Spin Quantum Number $\frac{1}{2}$

nucleus	magnetogyric ratio ($\text{rad T}^{-1} \text{s}^{-1} \times 10^8$)	frequency of maximum absorption at 1 T (MHz)	relative amplitude of absorption at constant field
^1H	2.675	42.577	1.000
^{13}C	0.673	10.705	0.016
^{15}N	-0.271	4.315	0.001
^{19}F	2.517	40.055	0.834
^{31}P	1.083	17.231	0.066

quency ν_0 . The radiowaves generated by the radiotransmitter are propagated in a direction x perpendicular to the direction z of the fixed magnetic field so that the magnetic fields of the radiowaves oscillate in the dimension y at the carrier frequency. The net magnetization of a given population of nuclei is precisely aligned with the z axis.

The magnetic field of the instrument is adjusted (Equation 12-53) so that the span of the Larmor frequencies of the various populations of nuclei to be examined, for example, all of the populations of ^1H hydrogen in the sample, is centered on the carrier frequency. The sample is excited with a strong (50 W) pulse of radiowaves at the carrier frequency. The pulse, however, is so short (5–50 μs) that a set of radiowaves is produced of almost equal intensity within a continuous range of frequencies encompassing the Larmor frequencies of the various populations of nuclei. If the proper length of the pulse is chosen by trial and error, the net magnetization of each of the populations of nuclei will be diverted from its alignment with the applied field in the z direction to an alignment with the oscillating magnetic field of the pulse in the y direction. A pulse of the proper duration is a **90° pulse**, referring to the fact that it has moved all of the net magnetizations by 90°. The 90° pulse is strong enough to saturate by resonance each population of nuclei as well as divert the alignment of its net magnetization.

At the end of the pulse, when only the applied field in the z direction remains, the net magnetization of each population of nuclei begins to precess in the x,y plane around the z axis at its Larmor frequency. As they lose their saturation, each of the various populations of these **precessing nuclei** emits a radio signal at its Larmor frequency, just as a population of excited electrons emits fluorescent light of a frequency equivalent to the difference in energy between the excited state and the ground state upon its relaxation. Because this emission decays as the saturation is lost both through the emission itself and through normal relaxation, it is referred to as a **free induction decay**. The free induction decay, which is registered from the conclusion of the 90° pulse until it has relaxed to nothing, is the only direct measurement made

by the spectrometer and must contain all of the data necessary to produce a spectrum. The free induction decay is registered by a radio receiver that is tuned to the carrier signal so that the output produced by the receiver is the modulations of the frequency of the carrier signal that each population of nuclei produces. Consequently, the signal that is registered from each population by the receiver is at the frequency of the difference between its Larmor frequency and the carrier frequency, which happens to be proportional to its chemical shift from the carrier frequency (Equation 12-54). After it has been submitted to a suitable linear combination of its real and imaginary terms, the **Fourier transform** of the total free induction decay from the receiver, which is the sum of all the free induction decays from all of the populations of nuclei, has positive maxima at the chemical shifts of each of the populations of nuclei relative to the carrier frequency. This Fourier transform reproduces a continuous wave spectrum of absorption from the same sample.

The absorption of a population of chemically identical nuclei is usually split into a series of peaks producing a symmetrical pattern around its mean resonant frequency. This splitting is due to **spin-spin coupling**, also referred to as J coupling. It arises from the fact that any adjacent spinning nucleus A, covalently linked to the nucleus X being observed, acts as a small magnet that induces the electrons between it and the nucleus X to circulate. This induced current alters the local magnetic field B_i at the nucleus X. Within the whole population of molecules, the various nuclei A assume both of their spin states randomly and almost equivalently, but each particular nucleus X in the population can be spin-coupled to a particular nucleus A in only one of those two spin states. This divides the population of nuclei X into two different groups, each group having each of its corresponding nuclei A in only one of its two available spin states.

The spin-spin **coupling constant**, J_{AX} , is the magnitude of the magnetic effect of nucleus A on nucleus X. Because spin-spin coupling is a function only of the intrinsic magnetic fields of the neighboring nuclei, coupling constants are not a function of the magnitude of the applied field, and their values (which are invariant differences in energy) are expressed quantitatively as the number of hertz by which the magnetic field of nucleus A splits the frequency of the absorption of nucleus X into two peaks of different frequency. Because spin-spin coupling is relayed by the electrons in the covalent bonds connecting the nuclei, it decreases in magnitude with the number of bonds separating them. For example, the values of J for the spin-spin coupling of ^1H hydrogen nuclei through two bonds can be as large as 15 Hz, and for coupling of ^1H hydrogen nuclei through three bonds, as large as 12 Hz, but for coupling of ^1H hydrogen nuclei through four bonds, the values are less than 1 Hz.

In addition to being determined by the number of bonds separating the two coupled nuclei, the value of the

spin-spin coupling constant J also depends on the angles at which two nuclei are held with respect to each other. For example, for two ^1H nuclei coupled through two bonds, the range of values is 10–15 Hz if the bond angle is close to the sp^3 tetrahedral angle of 109° , but the value of the coupling constant falls to 2–3 Hz at the sp^2 angle of 120° . In three-bond coupling, the value of the spin-spin coupling constant depends on the **dihedral angle** between the two nuclei along the bond connecting the two neighboring atoms to which they are attached:

12-9

The coupling constant J_{AX} is at its maximum when the dihedral angle is 0° or 180° and at its minimum when the dihedral angle is 90° or 270° . At these latter angles, the spin-spin coupling constant can be almost zero. The maxima at 0° and 180° for such coupling between the nuclei of two ^1H hydrogens is about 10 Hz, and between the nuclei of a ^1H hydrogen and a ^{13}C carbon, about 8 Hz.²⁰³

Two populations of nuclei, X and A, can also be coupled by a nuclear Overhauser effect. A **nuclear Overhauser effect** of the population of nuclei A on the population of nuclei X is any change in the net spin state of the population of nuclei X produced by a change in the net spin state of the population of nuclei A. For example, a nuclear Overhauser effect can be the consequence of either an alteration in the relaxation rate between the two spin states accessible to the members of the population of nuclei X or the consequence of an alteration in the levels of occupation of the two spin states within the population of nuclei X caused by a change in the net spin state of the population of nuclei A. A change in the net spin state of the population of one nucleus produced by a change in the net spin state of the population of another nucleus results from dipolar interactions between the two respective nuclei. A **dipolar interaction** is a function of, among other things, the distance between the two nuclei, r , and its magnitude is proportional to r^{-3} . The change in the spin state of nucleus X by nucleus A caused by a dipolar interaction is a second order perturbation, and hence it is proportional to r^{-6} . The transfer of energy between two transition dipoles by resonance is also a dipolar interaction and has the same dependence on distance (Equation 12-48). Because of the inverse dependence on the sixth power of the distance, nuclear Overhauser effects are significant only if the nucleus X and the nucleus A in a particular molecule are close to each other.

Because a nuclear Overhauser effect is not transmitted by changes in the static, local magnetic field of nucleus X brought about by a change in the spin state of

nucleus A, there is no requirement that the two nuclei be associated by covalent bonds as there is with spin-spin coupling. Nuclear Overhauser effects can indicate that the two nuclei involved are adjacent to each other in the tertiary structure of a protein even though they may be distant from each other in its primary structure. As with the transfer of energy by resonance, however, there are factors other than the distance between the nuclei associated with the dipolar interactions producing nuclear Overhauser effects, causing the intensity of a nuclear Overhauser effect not to be directly proportional to the inverse of the sixth power of this distance.²⁰⁵

Because nuclear Overhauser effects are manifested only as changes in the net spin state of the population of one nucleus under the influence of a change in the net spin state of the population of the other, no change occurs in the chemical shift of either nucleus involved in the nuclear Overhauser coupling as there was with spin-spin coupling. Rather, a nuclear Overhauser effect is registered as a **change in the intensity of the absorption** for nucleus X. For example, if the net rate of relaxation of the population of nucleus X is increased by the change that has occurred in the net spin state of the population of nuclei A, then the amplitude of the absorption for nucleus X will increase. If the occupation of the two spin states available to the members of the population of nuclei X is caused to become more equal by the change that has occurred in the net spin state of the population of nuclei A, then the amplitude of the absorption for nucleus X will decrease.

In large, relatively rigid macromolecules such as proteins, nuclear Overhauser effects between ^1H hydrogen nuclei are usually a consequence of the transfer of saturation.²⁰⁶ **Transfer of saturation** is the transfer of a portion of the saturation of one population of nuclei, nuclei A, to another population of nuclei, nuclei X. For transfer of saturation to occur, each of the individual nuclei X must be adjacent in space to a nucleus A. Transfer of saturation results from the summation of a large number of individual exchanges of spin state between a nucleus A and a nucleus X. The two adjacent nuclei simultaneously and reciprocally exchange their spin states in opposite directions with essentially zero change in the total energy of the two exchanging nuclei. During each exchange, the spin state of that particular nucleus X becomes what was the spin state of the particular nucleus A and vice versa. As a result of a large number of such exchanges of spin state at the atomic level, a portion of the saturation of the population of nuclei A is transferred to the population of nuclei X. The driving force is the resulting increase in entropy. A sequence of such transfers of saturation among a number of populations of adjacent nuclei can cause the saturation of one population of nuclei to spread outward over populations of nearby nuclei.

Spin diffusion is this outward spread of saturation from the saturated population of nuclei A. For spin diffu-

sion to occur, the populations of the nuclei in the vicinity of the nuclei A must be unsaturated so they are able to assume the saturation transferred from the population of nuclei A. It is the saturation of only the population of nuclei A that permits the diffusive force to be observed, just as the creation of a gradient of concentration permits the diffusive force to be observed.

Spin diffusion by transfer of saturation can be observed in an experiment analogous to the transfer of energy by resonance. The population of nuclei A is irradiated at the radio frequency with which its spins resonate and with sufficient amplitude to saturate its absorption, which equalizes the number of nuclei in its two spin states. The stimulating radiation is then turned off. The population of nuclei A will slowly relax back to its equilibrium distribution by losing the excess energy it has gained. One of the ways the population of nuclei A may relax is by transferring saturation to the population of nuclei X, if within the molecule nucleus X is close to nucleus A. If the absorption of the population of nuclei X is measured after a time, t_m , sufficient for some of the saturation in the population of nuclei A to be transferred to the population of the nuclei X, the absorption of the population of nuclei X will have decreased relative to its absorption in the absence of transfer of saturation because the population of nuclei X will have been moved closer to saturation.

An example of a nuclear Overhauser effect that was the consequence of spin diffusion was observed during a spectroscopic study of cytochrome *c* from *Katsuwonus pelamis*.²⁰⁷ The heme in cytochrome *c*, as it is a large aromatic ring (2-4), produces a substantial toroidal magnetic field when its π electrons circulate as a **ring current** in the presence of the applied magnetic field. The δ_2 methyl group of Leucine 68 (Figure 7-9C) resides adjacent to the heme in the region of this local field that is opposed to the applied field, and the chemical shift (-2.7 ppm) of the absorption of its three equivalent ^1H hydrogens is even less than that of the reference absorption. This substantial displacement isolates this peak of absorption from the absorptions of the rest of the methyl ^1H hydrogens in the protein. When the population of the δ_2 methyl ^1H hydrogens on Leucine 68 was saturated by preirradiation at the frequency of its chemical shift, the absorptions of four other populations of ^1H hydrogens were found to decrease. These were assigned to ^1H hydrogens neighboring the δ_2 methyl group of Leucine 68 in the crystallographic molecular model of the protein.

The initial nuclear magnetic resonance spectra of proteins were of ^1H hydrogen nuclei in molecules dissolved in $[^2\text{H}]\text{H}_2\text{O}$. They were **one-dimensional spectra of absorption** as a function of chemical shift. Even a small protein of 100 amino acids has more than 700 hydrogens in it, most of them unique and most of their absorptions split by spin-spin coupling. It is not surprising, therefore, that such spectra contain, by and large, several broad, unresolved absorptions, each resulting from the overlap

of hundreds of individual absorptions.²⁰⁸ The ranges in which these overlapping absorptions occur can be assigned to particular classes of nuclei: those of methyl ^1H hydrogens on leucines, isoleucines, valines, alanines, and threonines ($\delta = 0.9\text{--}1.5$ ppm); methylene ^1H hydrogens ($\delta = 1.5\text{--}3.5$ ppm); α ^1H hydrogens on each amino acid ($\delta = 3.5\text{--}5.5$ ppm); the ^1H hydrogens on the peripheries of the aromatic rings of tryptophans, phenylalanines, histidines, and tyrosines ($\delta = 6.4\text{--}7.4$ ppm); and the unexchanged amido ^1H hydrogens of the peptide bonds and glutamines and asparagines ($\delta = 7.0\text{--}9.0$ ppm).

The central difficulty in nuclear magnetic resonance spectroscopy of even a small protein is that in a one-dimensional spectrum of absorption as a function of chemical shift, regardless of the nucleus chosen, the peaks of absorption from the individual nuclei overlap and cannot be distinguished from each other, let alone assigned. It has been possible, however, to dissect the nuclear-magnetic resonance spectra of small molecules of protein^{209,210} into their individual components by using the **two-dimensional spectroscopy** that has been developed by Ernst and his colleagues^{211,212} and the **three-dimensional spectroscopy** that has been developed by Bax and his colleagues (Table 12-3).

All of the techniques of multidimensional nuclear magnetic resonance spectroscopy rely upon the technique of **frequency labeling**, which is a direct elaboration of Fourier transform nuclear magnetic spectroscopy. To label the absorption of a population of nuclei *i* with its Larmor frequency, two successive 90° pulses are used. Following the first 90° pulse applied in the *x* direction, the net magnetization of the population of nuclei *i* is aligned with the *y* axis and then begins to precess in the *xy* plane around the *z* axis at its Larmor frequency. After a period of time t_1 , a second 90° pulse in the *x* direction is applied. The second pulse is in phase at the carrier frequency ν_0 with the first pulse to insure that

$$\nu_0 t_1 = n \quad (12-55)$$

where *n* is an integer. In this way, the carrier frequency acts as an internal clock. This second 90° pulse diverts only the *y* component of the precessing net magnetization at that instant into the *z* direction but leaves the *x* component at that instant in the *xy* plane. Consequently, the amplitude of the remaining net magnetization in the *xy* plane after the second 90° pulse is equal to $M_i \sin 2\pi \nu_i t_1$ where M_i is the amplitude of the net magnetization from the population of nuclei *i* before the second pulse and ν_i is its Larmor frequency. Because

$$M_i \sin(2\pi \nu_i t_1) = M_i \sin[2\pi(\nu_i t_1 - n)] = M_i \sin[2\pi(\nu_i - \nu_0)t_1] \quad (12-56)$$

^aBoxes enclose the three or four coupled atoms that both produce the peak or peaks and determine the three or four chemical shifts, one for each of the three or four atoms, in the three or four respective dimensions. ^bThe three-dimensional peaks from the α ¹³C carbon and the β ¹³C carbon are separate peaks on the same field, each coupled respectively to the same amide ¹⁵N nitrogen and amide ¹H hydrogen or to the same combination of acyl ¹³C carbon and α ¹H hydrogen, respectively, in the other two dimensions. ^cThe three dimensions are ¹³C carbon, ¹³C carbon, and ¹H hydrogen. The ¹H hydrogens coupled to one or the other of the two ¹³C carbons appear on the three-dimensional field at the chemical shifts of the other ¹³C carbon and their own ¹³C carbon. ^dThe coupling between the amide ¹H hydrogen and the α ¹H hydrogen is the usual strong three-bond *J* coupling between adjacent ¹H hydrogens. This coupling can be relayed through the α ¹³C carbon or can be enhanced by using HOHAHA. ^eThe coupling between the α ¹³C carbon and amide ¹⁵N nitrogen is relayed through the acyl ¹³C carbon. ^fThe three-dimensional peaks from the α ¹H hydrogen and the β ¹H hydrogens are separate peaks each coupled respectively to the same amide ¹⁵N nitrogen and amide ¹H hydrogen through the acyl ¹³C carbon.

after the second 90° pulse, the amplitude of the net magnetization of the population of nuclei i precessing at its Larmor frequency in the xy plane has become a function of the length of the interval t_1 between the pulses. Furthermore, as t_1 is varied, this amplitude will vary harmonically with a frequency $\nu_i - \nu_0$, which is directly proportional to the chemical shift (Equation 12-54) of the population of nuclei i if the applied magnetic flux density B_{app} is such that the carrier frequency ν_0 is equal to the frequency at which the standard nuclei absorb, ν_{std} .

Immediately following the second 90° pulse, the free induction decay of the excited sample is gathered in the usual way. The Fourier transform of the output of the radio receiver produces a nuclear magnetic spectrum. The amplitude of each peak in the spectrum, however, because it was derived only from the net magnetization remaining in the xy plane, has become a harmonic function of t_1 with a frequency $\nu_i - \nu_0$. If spectra are gathered at systematically increasing values of t_1 , the amplitude of each peak will vary with a frequency proportional to its chemical shift (Figure 12-15).²⁰³ Each peak has become **labeled with its own Larmor frequency**, and this labeling is manifested in the **amplitude modulation** of its peak in the spectrum with a frequency equal to the difference between its Larmor frequency and the carrier frequency. In a spectrometer with a carrier signal of 600 MHz, the values of $\nu_i - \nu_0$ for ^1H hydrogens are less than 6000 Hz, and in a spectrometer with a carrier signal of 150 MHz, the values of $\nu_i - \nu_0$ for ^{13}C carbon are less than 15,000 Hz, so the systematically increasing lengths of the

Figure 12-15: Amplitude modulation of the absorption of a nucleus produced during correlated spectroscopy.²⁰³ The absorption of a particular population of identical nuclei produces a peak in the spectrum of absorption as a function of the chemical shift δ_2 after $f(t_1, t_2)$ has been submitted to Fourier transformation only in the second dimension. Each trace is this spectrum of absorption as a function of the chemical shift δ_2 at a different t_1 . The amplitude of the peak of absorbance records the harmonic precession of the nuclear spin relative to the carrier frequency during the interval t_1 . Reprinted with permission from ref 203. Copyright 1995 John Wiley and Sons Ltd.

intervals t_1 must be in the range of tens of microseconds to milliseconds to produce reliable modulations of the amplitudes.

A simple two-dimensional spectrum is an extension of this procedure of frequency labeling. A series of free induction decays from the sample are gathered at systematically increasing intervals t_1 . The time dimension of each free induction decay is designated as t_2 . The complete set of this series of free induction decays defines a function that is two-dimensional in time, $f(t_1, t_2)$. The information in the first dimension of this function is encoded in the modulations of the amplitudes (**AM**) of the signals from the individual populations of nuclei, and the information in the second dimension is encoded in the modulations of the frequency (**FM**) of the free induction decays. A two-dimensional Fourier transform of this function extracts the frequencies of these modulations in the two dimensions. The two-dimensional Fourier transform of the function $f(t_1, t_2)$ is a two-dimensional function in frequency, which when divided by the carrier frequency (Equation 12-54) is a two-dimensional function in chemical shift, $f(\delta_1, \delta_2)$.

If none of the populations of nuclei in the sample is spin-spin-coupled to any other, the amplitude of the signal from each population of nuclei is modulated only by its own Larmor frequency, and $f(\delta_1, \delta_2)$ has peaks only when $\delta_1 = \delta_2$. In such a case, the **diagonal of the two-dimensional spectrum** replicates the one-dimensional nuclear magnetic resonance spectrum, and nothing has been gained. If, however, one population of nuclei is spin-spin-coupled to another population of nuclei, the modulations of the amplitudes of their precessions are transferred between themselves during the second 90° pulse, and each of their precessions becomes labeled not only with its own Larmor frequency but also with the Larmor frequency of the other population of nuclei to which it is spin-spin-coupled.

The Fourier transform picks out these coupled frequencies, and on the two-dimensional field, in addition to the one-dimensional spectrum along the diagonal, there are **off-diagonal cross-peaks**. Each of these cross peaks is located on the field at a chemical shift δ_1 of one population of nuclei and a chemical shift δ_2 of another population of nuclei to which the first population is spin-spin-coupled. Because spin-spin coupling is fully reciprocal, these cross-peaks are distributed symmetrically about the diagonal of the two-dimensional field. Correlated spectroscopy (COSY) is the technique that has just been described. A two-dimensional **correlated spectrum** is a two-dimensional spectrum in which the off-diagonal cross-peaks arise from spin-spin couplings between different populations of nuclei and identify populations of spin-spin-coupled nuclei by their chemical shifts. It is these off-diagonal cross-peaks that pull out individual absorptions from the one-dimensional spectrum, spread them into two dimensions, and permit them to be observed individually.

A two-dimensional correlated spectrum (Figure 12-16)²¹⁰ is a presentation of absorption as a function of two values of chemical shift (in parts per million), δ_1 and δ_2 . Each off-diagonal cross-peak in the spectrum has the same value of the chemical shift δ_2 as a peak buried in the one-dimensional spectrum and the same value of the chemical shift δ_1 as another peak buried elsewhere in the one-dimensional spectrum but connected to the first by spin-spin coupling. The result is that two individual absorptions unresolved in the one-dimensional spectrum are simultaneously drawn out of it and placed in isolation from all of the other absorptions otherwise overlapping them. This provides the **resolution**. The **information** provided by an off-diagonal cross-peak is that the two nuclei responsible for these two now isolated absorptions are connected through covalent bonds that mediate spin-spin coupling.

The off-diagonal region displayed in Figure 12-16 has a range for δ_2 (6.5–10.6 ppm) that includes the chemical shifts for the **amido ^1H hydrogens** of the polypeptide backbone and a range for δ_1 (1.7–6 ppm) that includes the chemical shifts of the **^1H hydrogens on the α carbons** of the amino acids in the protein. The diagonal, one-

dimensional spectrum is just beyond the lower right hand corner of the figure. Each cross-peak within the panel arises from the spin-spin coupling between the amido ^1H hydrogen of one of the amino acids in the protein and its own α ^1H hydrogen. Each cross-peak has pulled the absorption of each amido ^1H hydrogen and the absorption of its adjacent α ^1H hydrogen out of the unresolved one-dimensional spectrum so that they can be individually observed. Each cross-peak also assigns numerical values for the individual chemical shifts (δ_1 and δ_2) of the two nuclei of each of these pairs of spin-spin-coupled ^1H hydrogens and states that the two ^1H hydrogens with these two chemical shifts are connected to each other by three covalent bonds. This region of a two-dimensional (^1H - ^1H) correlated spectrum is a **fingerprint** for the protein because almost every amino acid in its sequence is represented by a single cross-peak,* and the distribution of the cross-peaks on the field is unique to that protein.

* Glycines, because they have two diastereotopic α ^1H hydrogens, usually produce two cross-peaks of the same chemical shift in the amido ^1H hydrogen dimension, and prolines, because they have no α ^1H hydrogens, produce none.

Figure 12-16: Two-dimensional (^1H - ^1H) correlated nuclear magnetic resonance spectrum of a 20 mM solution of basic pancreatic trypsin inhibitor ($n_{\text{aa}}=58$) in $^1\text{H}_2\text{O}$ at pH 4.6 and 68°C .²¹⁰ The spectrum is presented on a two-dimensional field with axes of the two respective chemical shifts. Each cross-peak is represented topographically as mountains are represented topographically on a map. Each cross-peak is a set of closed curves within closed curves. As in a map of electron density (Figure 4-12), each curve connects points of equal amplitude in the Fourier transform $f(\delta_1, \delta_2)$; the more closed curves, the greater the amplitude of the peak. The spectrum has three dimensions, the two chemical shifts δ_1 and δ_2 , in the x and y dimensions in the plane of the page, and the amplitude of the Fourier transform, in the z dimension normal to the page and represented in the contours. The region of the spectrum presented contains the cross-peaks created by spin-spin couplings between the ^1H hydrogen on each α carbon (vertical axis) and the ^1H hydrogen on the respective, immediately adjacent amido nitrogen (horizontal axis). The spectrum is a fingerprint for the protein, and each cross-peak assigns the respective chemical shifts of the two coupled nuclei. Every peak in this region of the spectrum has been assigned to one of the amino acids in the sequence of the protein. All of the amino acids in the sequence are represented, with the exception of the four prolines (which have no α hydrogens), Glycine 37, and Arginine 1. Lysine 46, because the chemical shift of its absorption coincides with that of $[^1\text{H}]\text{H}_2\text{O}$ and is suppressed along with that of the $[^1\text{H}]\text{H}_2\text{O}$, is also missing from the spectrum. Reprinted with permission from ref 210. Copyright 1982 Academic Press.

Many **improvements** have been made to the original correlated spectrum. There are many sophisticated and intricate elaborations of the sequence of the pulses of oriented radiowaves that narrow the cross-peaks, eliminate background, and enhance dramatically the signals from weakly absorbing nuclei such as ^{13}C and ^{15}N . Each of these elaborations is identified by its own acronym (Table 12–4). Because the nucleus of ^{12}C has no magnetic moment and the nucleus of ^{14}N has a spin quantum number of 1, the proteins examined are now almost always modified so that all of their nitrogens are ^{15}N and all of their carbons are ^{13}C by expressing them in bacteria grown on $[\text{N}^{15}]\text{NH}_4^+$ as their sole source of nitrogen and on a $[\text{C}^{13}]$ nutrient as their sole source of carbon. In this way, cross-peaks from these enriched proteins produced by heteronuclear spin–spin coupling can be observed. For example, the heteronuclear spin–spin coupling between an **amido ^{15}N nitrogen** and its own **amido ^1H hydrogen**, enhanced by an HSQC pulse sequence (Figure 12–17),²⁵¹ provides an alternative fingerprint of the protein in which every amino acid is also represented. Two-dimen-

sional correlated spectroscopy has been expanded to three dimensions (Table 12–3). The cross-peaks in these spectra (Figure 12–18)²¹³ are produced by spin–spin coupling among three nuclei, usually of two or three different elements. By expanding the dimensions, these procedures are able to resolve absorptions that overlap in two dimensions just as two dimensions separate absorptions that overlap in one dimension. Each cross-peak in such spectra assigns chemical shifts simultaneously to three or four individual nuclei.

Each of the cross-peaks in the two-dimensional (^1H – ^1H) correlated spectrum of basic pancreatic trypsin inhibitor (Figure 12–16) and the two-dimensional (^{15}N – ^1H) HSQC correlated spectrum of dihydrofolate reductase (Figure 12–17) has been labeled with the position in the sequence of the protein of the amino acid containing the two nuclei that produced it. The spectra themselves do not come with labels, and each of these **assignments** has been performed by tracing connections among cross-peaks that affiliate nuclei in the polypeptide backbone through spin–spin coupling and by assigning the type of each amino acid from the pattern of

Table 12–4: Methods for Improving Cross-Peaks in Two-Dimensional and Three-Dimensional Nuclear Magnetic Resonance Spectra

acronym	full name	improvement
HMQC ^{231,232}	heteronuclear multiple-quantum coherence	increases amplitude of cross-peaks arising from coupling involving nuclei with small magnetogyric ratios such as ^{13}C and ^{15}N (Table 12–2)
HSQC ²³³	heteronuclear single-quantum coherence	
HSMQC ²³⁴	heteronuclear single–multiple-quantum coherence	
DQF ^{235,236} MQF ²³⁷	double quantum filtered multiple quantum filtered	removes unwanted noise from spectrum
HOHAHA ^{238–240}	homonuclear Hartmann–Hahn	increases amplitude of cross-peaks and extends, by relaying coherence, the number of bonds through which coupling can produce a cross-peak
TOCSY ^{238,241}	total correlation spectroscopy (same method as HOHAHA)	
HMBC ^{242,243}	heteronuclear multiple bond correlation	extends the number of bonds through which coupling can produce a cross-peak
PS ²⁴⁴	pseudo single quantum	narrows the line widths of the cross-peaks
random fractional deuteration ^{245,246}		replacement of 50% of the ^1H hydrogens in a protein with ^2H hydrogens at random narrows the widths of the cross peaks in correlated spectroscopy and increases the amplitude and the number of the detectable nuclear Overhauser effects from larger proteins
TROSY ²⁴⁷	transverse relaxation-optimized spectroscopy	narrows the line widths of the cross-peaks
CRINEPT ²⁴⁸	cross relaxation insensitive nuclei enhanced polarization transfer	increases amplitude of cross-peaks arising from coupling involving nuclei with small magnetogyric ratios such as ^{13}C and ^{15}N
SBC ^{249,250}	single bond correlation	permits spin–spin coupling between ^{13}C and ^{15}N to be used for two-dimensional spectrum

Figure 12-17: Two-dimensional (^1H - ^{15}N) HSQC correlated nuclear magnetic resonance spectrum of a 2 mM solution of human dihydrofolate reductase ($n_{\text{aa}} = 186$) expressed in *E. coli* grown on [^{15}N]NH $_4$ Cl as its sole source of nitrogen and dissolved at pH 6.5 and 25 °C.²⁵¹ Each of the spin-spin couplings between an amido ^{15}N and an amido ^1H at each of the positions in the backbone of the polypeptide creates one of the cross-peaks in the spectrum. The range of chemical shift for ^{15}N (vertical axis) spans the chemical shifts for the amido ^{15}N in the protein, and the range of chemical shift for ^1H (horizontal axis) spans the chemical shifts for amido ^1H in the protein. The two-dimensional spectrum is a fingerprint for the protein, and each cross-peak assigns pairs of chemical shifts to the respective coupled amido ^{15}N and amido ^1H hydrogens. Each cross-peak is labeled by the amino acid in the sequence of the protein to which it has been assigned. The pairs of peaks each having the same chemical shift in the ^{15}N dimension (connected by horizontal lines) are those arising from the spin-spin coupling of the two respective distinct ^1H hydrogens on each amido nitrogen in the primary amides of the glutamines and asparagines in the protein. They are also labeled by the amino acid to which they have been assigned. Reprinted with permission from ref 251. Copyright 1992 American Chemical Society.

affiliations among cross-peaks that trace connections out into each side chain.

Connections among nuclei along the polypeptide backbone are usually traced^{252–255} in a systematic sequence of sections through three-dimensional correlated spectra (Figure 12–18). The large set of three-dimensional spectra available for **tracing the connections among nuclei** (Table 12–3) is redundant, so that when connections are obscured by the overlap of peaks or when a particular cross-peak is missing (for example, Lysine 46 in Figure 12–16), the trace can take an alternative path. The result of such a trace is that all of the nuclei—¹hydrogens, ¹³carbons, and ¹⁵nitrogens—in long segments of polypeptide backbone are consecutively connected to each other and each individually assigned a chemical shift.

The respective positions of these segments of connected nuclei in the amino acid sequence of the protein are then established by tracing connections from the nuclei out into each side chain (Figures 12–19 through 12–22). Each of these paths of **connections out into a side chain** usually starts at one of the cross-peaks in a fingerprint of the protein. For example, the relayed

spin-spin coupling among the ^1H hydrogens of each side chain registered in a two-dimensional (^1H - ^1H) TOCSY spectrum (Figure 12-19)²⁵⁶ begins at the cross-peak between the amido ^1H hydrogen and the α ^1H hydrogen (Figure 12-16). The coupling between the α ^{13}C carbon and the β ^{13}C carbon of each side chain registered in a three-dimensional (^{13}C - ^{15}N - ^1H) CBCA(CO)NH correlated spectrum (Figure 12-20)²⁵⁷ begins at the cross-peak between the amido ^{15}N nitrogen and the amido ^1H hydrogen (Figure 12-17) of the next amino acid in the sequence (Table 12-3). Connections among ^1H hydrogens of a side chain (Figure 12-19) or ^{13}C carbons of a side chain (Figure 12-20) can be extended to their own ^{13}C carbons or ^1H hydrogens, respectively, with two-dimensional (^1H - ^{13}C) HSQC correlated spectra (Figure 12-21).²⁵⁸ When two-dimensional spectra (Figure 12-19) become too crowded to trace connections, they can be expanded in a third dimension (Figure 12-22)²⁵⁹ to resolve the individual cross-peaks.

Each side chain has a characteristic **pattern of connections** among nuclei of characteristic chemical shifts that identifies it in the spectrum. For example, glutamate has two β^1 hydrogens that have smaller chemical shifts than its two α^1 hydrogens (Figure 12–19). Isoleucine has

^1H hydrogens on a δ methyl group and a γ methyl group as well as two ^1H hydrogens on a γ methylene, all in the aliphatic range of chemical shifts (Figures 12–19 and 12–22). Lysine has ^1H hydrogens on a β methylene, a γ methylene, and a δ methylene in the aliphatic range but two ^1H hydrogens on an ε methylene with chemical shifts around 3 ppm (Figures 12–19 and 12–22). Threonine and serine have β ^1H hydrogens with larger chemical shifts (around 4 ppm), and threonine has γ ^1H hydrogens with chemical shifts characteristic of a methyl group (Figures 12–19 and 12–22). From these patterns, from the sequence of the connections along the backbone (Figure 12–18), and from the amino acid sequence of the protein, it is usually possible to identify the long, unbroken segments of connections among the atoms of the backbone that run through the spectra with segments in the amino acid sequence of the protein and thereby assign the cross-peaks to specific positions in the amino acid sequence, much as the pattern of protrusions from the polypeptide backbone in a map of electron density allows segments of the amino acid sequence to be identified.

The final results of this process are that each cross-peak on the various two- and three-dimensional correlated spectra has been assigned to the two or three nuclei in the amino acid sequence of the protein that produce it and that the nucleus of almost every ^1H hydrogen, ^{13}C carbon, and ^{15}N nitrogen in the protein has been assigned a specific chemical shift. By themselves these assignments are not very informative. They are, however, an indispensable prelude to using nuclear magnetic resonance to provide insight into the dynamics of a protein, to produce its molecular model, to measure the acid dissociation constants of its side chains, and to follow the rates of exchange of its protons with protons in the solution.

When the spin state of a particular population of chemically identical nuclei is saturated by the absorption of electromagnetic energy at its Larmor frequency and then allowed to relax back to its equilibrium distribution, the rate of its relaxation contains information about the **dynamics of the structure** in which each of these nuclei is contained. For example, the relaxation of a particular population of identical nuclei of amido ^{15}N nitrogens, each at the same position in the polypeptide backbones of the identical molecules of a protein in a solution, is dominated by the dipolar interactions between the nuclei of the ^{15}N nitrogens in that population and the nuclei of the directly attached ^1H hydrogens on each of the individual amido nitrogens. The rate at which the bonds between the ^{15}N nitrogens and the ^1H hydrogens in those two particular populations reorient relative to the magnetic field determines the rate of the relaxation of the population of ^{15}N nitrogen nuclei. From an analysis of this rate of relaxation, information about the rate of this reorientation can be extracted.^{260,261} This information is expressed as an **order parameter** S^2 , which assumes a value of 1 when

the ^{15}N – ^1H bond is fixed rigidly in the protein so that it reorients at the same rate at which the entire molecule of protein reorients by its normal rotational and translational diffusion and which assumes a value of 0 when it is so loosely attached to the protein that it reorients completely independently of the reorientation of the molecule of protein. Therefore, the order parameter S^2 is a measure of the flexibility of a particular position within a molecule of the protein.

Two-dimensional spectra of proteins in which each amido ^{15}N nitrogen in the polypeptide backbone has been assigned its position in the amino acid sequence can be used to measure relaxation rates of these individual ^{15}N nitrogens and calculate values of the order parameter S^2 for each. Most of the values of the order parameter S^2 for these ^{15}N nitrogens are near 1 (≥ 0.8) because most of the polypeptide backbone of a molecule of protein is rigidly fixed within the tertiary structure, but there are **flexible segments** that can be identified by the smaller values (0.4–0.6) of the order parameter S^2 of the amido ^{15}N nitrogens they contain.^{262,263} These segments are often flexible loops on the surface of the molecule of protein and correspond to segments in a crystallographic map of electron density that are so flexible that they do not appear in the map or to segments the atoms of which have high B -factors.²⁶³ High values of these B -factors indicate that the segment is also flexible in the crystal. The informative exceptions are those in which the order parameters are low but the segment appears to be rigid in the crystallographic molecular model and its constituent atoms have low B -factors. These exceptions indicate that the crystal packing has confined an otherwise flexible segment of polypeptide.

Order parameters can also be obtained for bonds between ^{15}N nitrogens and ^1H hydrogens in side chains. For example, the order parameters for bonds between ^{15}N nitrogens and ^1H hydrogens in the side chains of tryptophans buried in the core of the protein are usually greater than 0.8, but those for the bonds between ^{15}N nitrogens and ^1H hydrogens in the side chains of arginines on the surface of a protein can be as small as 0.05.²⁶³ Unfortunately, there is no simple correlation between values of the order parameter S^2 and the rates at which the flexible segments or two side chains are fluctuating relative to the entire molecule, and motions slower than the rotational diffusion of the entire molecule of protein do not register in the order parameter.

In the rare instances in which a flexible segment of the folded polypeptide assumes only two significantly occupied conformations of about equal occupancy, each nucleus in the flexible segment will have a different chemical shift in each conformation. If these chemical shifts are different enough, each pair of nuclei that is spin–spin-coupled will produce two cross-peaks in a two-dimensional spectrum, each with the chemical shifts of the respective nuclei in the **two respective conformations**.²⁶⁴ In such cases, it is possible to obtain a rate

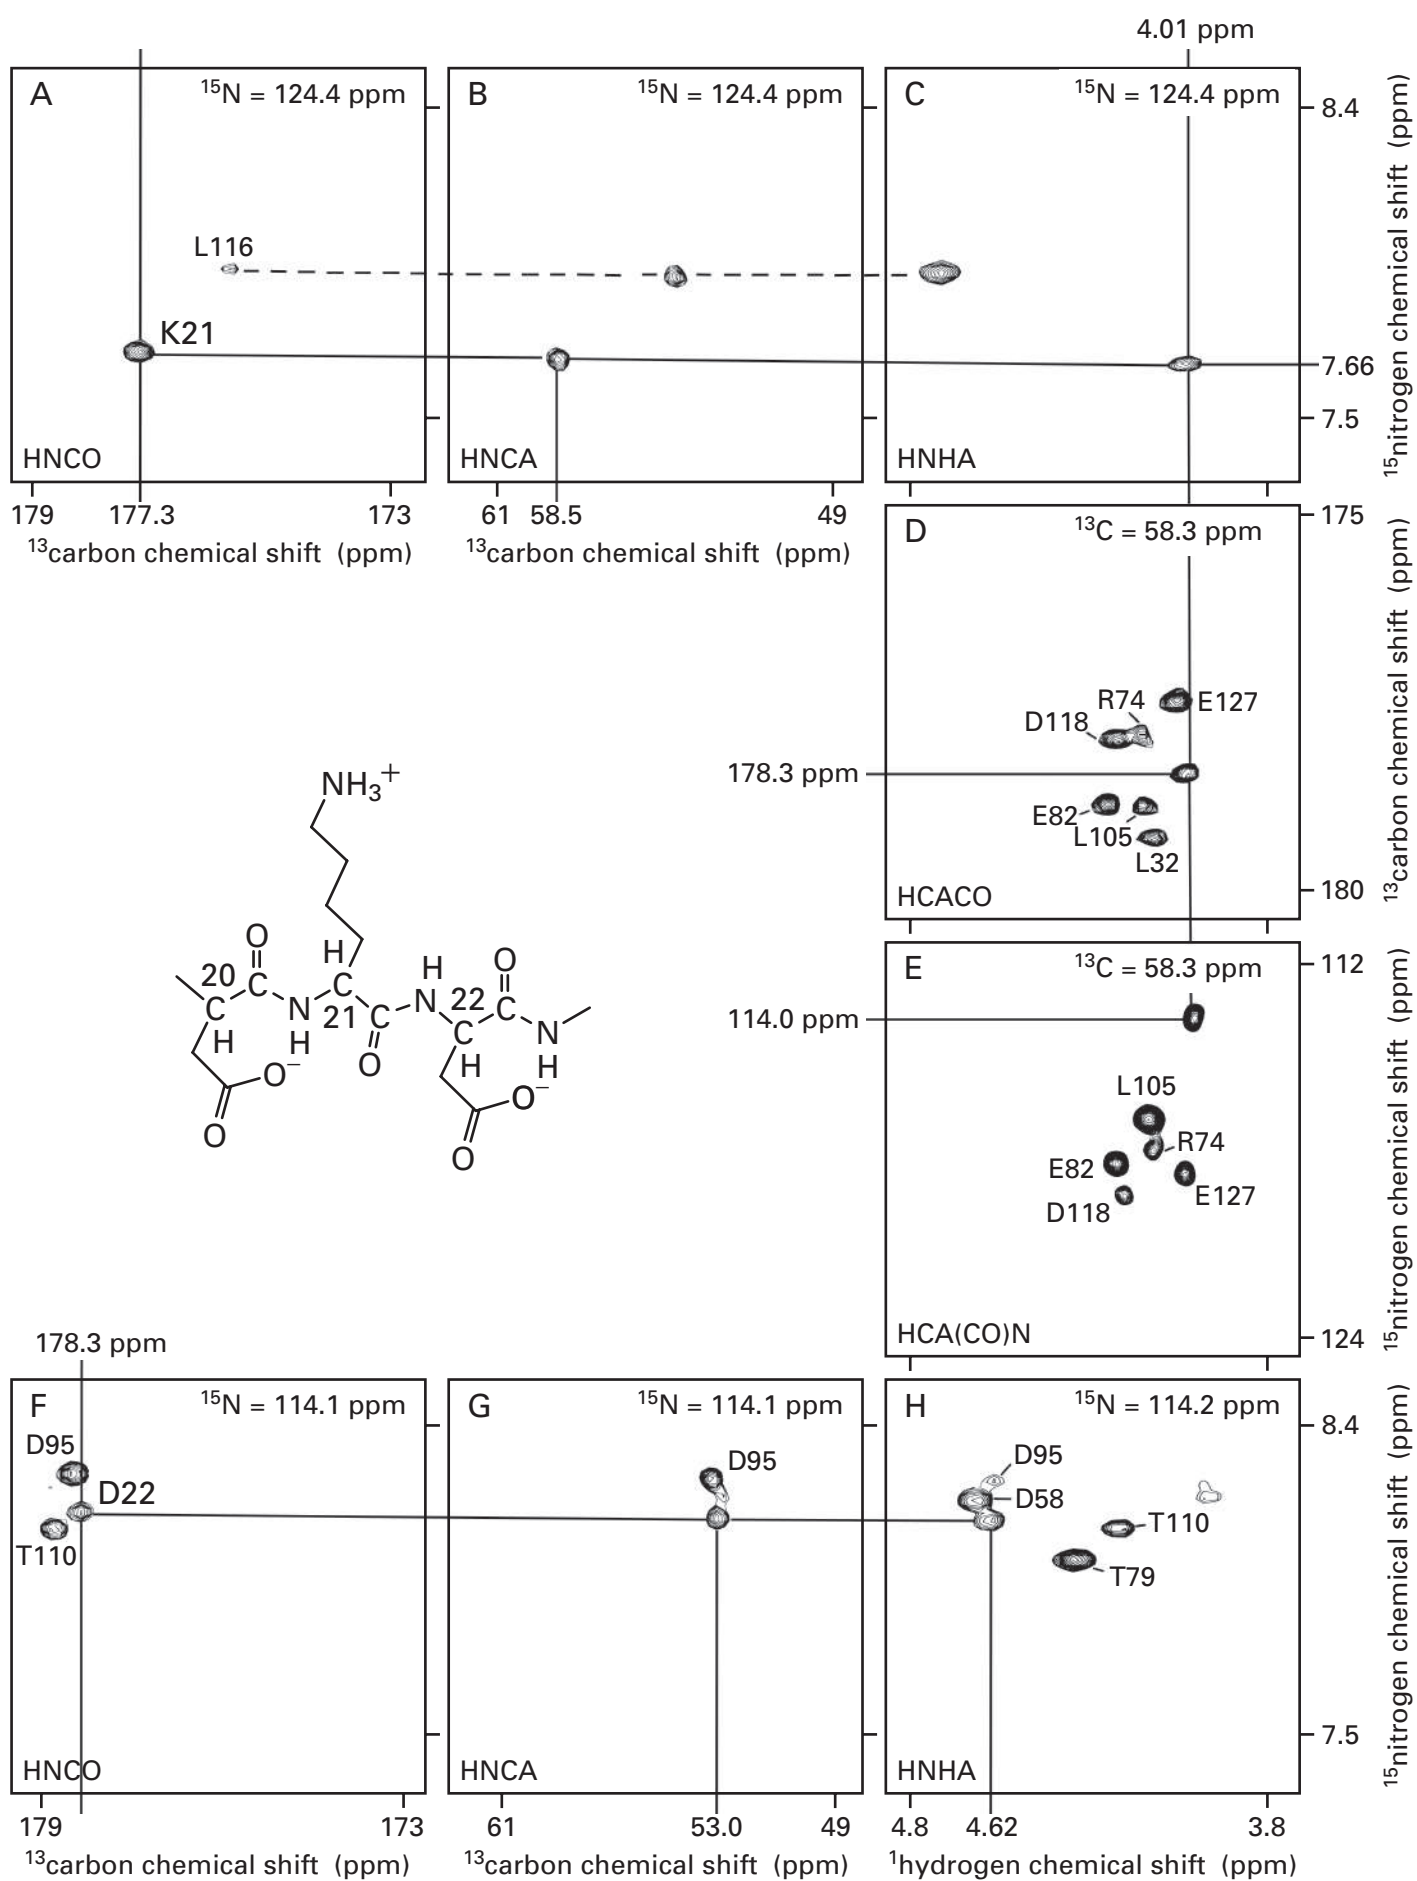

Figure 12–18: Sequential assignment of the chemical shifts for the ^1H hydrogens, ^{13}C carbons, and ^{15}N nitrogens in a polypeptide backbone by use of three-dimensional nuclear magnetic resonance spectra.²¹³ The complementary DNA encoding calmodulin from *D. melanogaster* ($n_{\text{aa}} = 148$) was expressed in *E. coli* grown on $^{15}\text{N}[\text{NH}_4\text{Cl}]$ and $^{13}\text{C}_6[\text{glucose}]$ as sole nitrogen and carbon sources, so that the protein was uniformly and completely (>95%) labeled with ^{15}N nitrogen and ^{13}C carbon. Spectra were recorded from a 1.5 mM solution of calmodulin in a 93:7 mixture of $^1\text{H}_2\text{O}$ to $^2\text{H}_2\text{O}$ at pH 6.3 and 47 °C. Individual panels (A–H) are two-dimensional sections through a series of three-dimensional nuclear magnetic resonance spectra (Table 12–3) of the protein. In panels A, B, and C, the sections through the respective three-dimensional spectra are only wide enough to contain cross-peaks from ^{15}N nitrogens the chemical shifts of which are 124.4 ± 0.2 ppm, which includes the chemical shift of the amido ^{15}N nitrogen of Lysine 21. Each of these three sections has as its vertical axis the chemical shift of ^1H hydrogen between 7.4 and 8.5 ppm, the region covering the chemical shifts of ^1H hydrogens on amido nitrogens. (A) Section containing the cross-peak produced by the spin–spin coupling connecting the amido ^1H hydrogen of Lysine 21, the amido ^{15}N nitrogen of Lysine 21, and the acyl ^{13}C carbon of Aspartate 20. This section has as its horizontal axis the chemical shift for ^{13}C carbon between 172 and 180 ppm, the region covering the chemical shifts of acyl ^{13}C carbons. This cross-peak is located by the chemical shift of the acyl ^{13}C carbon of Aspartate 20 (177.3 ppm) and assigns the chemical shift of the amido ^1H hydrogen of Lysine 21 as 7.66 ppm. (B) Section containing the cross-peak produced by the spin–spin coupling connecting the amido ^1H hydrogen, the amido ^{15}N nitrogen, and the α ^{13}C carbon of Lysine 21. The section has as its horizontal axis the chemical shift for ^{13}C carbon between 47 and 64 ppm, the region covering the chemical shifts of the α ^{13}C carbons. The position of this cross-peak, located by the value for the chemical shift of its amido ^1H hydrogen (horizontal line), assigns the chemical shift of the α ^{13}C carbon of Lysine 21 as 58.5 ppm. (C) Section containing the cross-peak produced by the spin–spin coupling connecting the amido ^1H hydrogen, the amido ^{15}N nitrogen, and the α ^1H hydrogen of Lysine 21. This section has as its horizontal axis the chemical shift for ^1H hydrogen between 3.7 and 4.9 ppm, the region covering the chemical shifts of α ^1H hydrogens. The position of this cross-peak, located by the value of the chemical shift of its amido ^1H hydrogen (horizontal line), assigns the chemical shift of the α ^1H hydrogen of Lysine 21 as 4.01 ppm. In panels D and E, the sections through the respective three-dimensional spectra are only wide enough to contain cross-peaks from ^{13}C carbons the chemical shifts of which are 58.3 ± 0.3 ppm, which includes the chemical shift of the α ^{13}C carbon of Lysine 21 (assigned in panel B). Each of these two sections has as its horizontal axis the chemical shift for ^1H hydrogen between 3.7 and 4.9 ppm, the region covering the chemical shifts of α ^1H hydrogens. (D) Section containing the cross-peak produced by the spin–spin coupling connecting the α ^1H hydrogen, the α ^{13}C carbon, and the acyl ^{13}C carbon of Lysine 21. This section has as its vertical axis the chemical shift for ^{13}C carbon between 174 and 181 ppm, the region covering the chemical shifts of acyl ^{13}C carbons. The position of this cross-peak, located by the value of the chemical shift of its α ^1H hydrogen (vertical line), assigns the chemical shift of the acyl ^{13}C carbon of Lysine 21 as 178.3 ppm. (E) Section containing the cross-peak produced by the spin–spin coupling connecting the α ^1H hydrogen of Lysine 21, the α ^{13}C carbon of Lysine 21, and the amido ^{15}N nitrogen of Aspartate 22. This section has as its vertical axis the chemical shift for ^{15}N nitrogen between 111 and 125 ppm, the region covering the chemical shifts of amido ^{15}N nitrogens. The position of the cross-peak for Lysine 21, located by the value of the chemical shift of its α ^1H hydrogen (vertical line), assigns the chemical shift of the amido ^{15}N nitrogen of Aspartate 22 as 114.0 ppm. (F–H) Sections through three-dimensional spectra containing cross-peaks for Aspartate 22 corresponding respectively to the sections in panels A–C that contain cross-peaks for Lysine 21. The sections in panels F, G, and H are only wide enough to contain cross-peaks from ^{15}N nitrogens, the chemical shifts of which are 114.1 ± 0.2 ppm, which includes the chemical shift of the amido ^{15}N nitrogen of Aspartate 22 assigned in panel E. The value of the chemical shift of the amido ^{15}N nitrogen of Lysine 21 (124.4 ppm) that was used to set the position of the slabs in panels A, B, and C was assigned with a section corresponding to panel E but with the section for the sequential assignment of the chemical shifts of the nuclei in Aspartate 20 rather than Lysine 21. The cross-peak in panel F produced by spin–spin couplings connecting the amido ^1H hydrogen of Aspartate 22, the amido ^{15}N nitrogen of Aspartate 22, and the acyl ^{13}C carbon of Lysine 21 was located with the chemical shift of the acyl ^{13}C carbon of Lysine 21 assigned in panel D. The position of the cross-peak from Lysine 21 in panel A was located with the chemical shift of the acyl ^{13}C carbon of Aspartate 20 assigned in a section for the sequential assignment of the nuclei in Aspartate 20 corresponding to that in panel D for Lysine 21. Cross-peaks from Leucine 116 appear in panels A, B, and C because the chemical shift of its amido ^{15}N nitrogen is 124.2 ppm. Cross-peaks from Leucine 32, Arginine 74, Glutamate 82, Leucine 105, Aspartate 118, and Glutamate 127 appear in panels D and E because the chemical shifts of their α ^{13}C carbons are 58.2, 58.1, 58.2, 58.5, 58.5, and 58.5 ppm, respectively. Cross-peaks from Aspartate 58, Threonine 79, Aspartate 95, and Threonine 110 appear in panels F, G, and H because the chemical shifts of their amido ^{15}N nitrogens are 113.9, 114.0, 114.2, and 114.4 ppm, respectively. Reprinted with permission from ref 213. Copyright 1990 American Chemical Society.

constant for the exchange of the flexible segment between the two conformations. For example, a loop between Alanine 9 and Leucine 24 in dihydrofolate reductase from *E. coli* exchanges between its two conformations²⁶⁵ at a rate of 35 s^{-1} . The heterologous association between two molecules of protein also causes changes in the chemical shifts of nuclei that end up in the interface. These changes produce pairs of cross-peaks, one from the unassociated protein and one from the associated protein. These changes in chemical shift identify the amino acids involved in the interface,²⁶⁶ and rates of exchange of the participants between free and bound states can be calculated from such spectra.²⁶⁷

A nuclear magnetic resonance molecular model of a protein is produced from a list of the individual nuclear Overhauser effects between its ^1H hydrogens. The thousands of nuclear Overhauser effects that occur between pairs of the thousands of unique ^1H hydrogens in a protein

are resolved from each other by using two-dimensional and three-dimensional nuclear Overhauser enhanced spectroscopy (NOESY) just as the individual absorptions of each of the thousands of nuclei in a protein are resolved by using two-dimensional and three-dimensional correlated spectroscopy.

A two-dimensional **nuclear Overhauser enhanced spectrum** is a two-dimensional spectrum in which the off-diagonal cross-peaks arise from nuclear Overhauser effects between two different populations of ^1H hydrogen nuclei and identify by their chemical shifts those pairs of ^1H hydrogen nuclei that are connected by those respective nuclear Overhauser effects. A two-dimensional nuclear Overhauser enhanced spectrum (Figure 12–23)^{268,269} is produced in the same way as a two-dimensional correlated spectrum, except that after the second 90° pulse has labeled the precession of the net magnetization of each population of nuclei with its Larmor frequency by

modulating the amplitude of its precession in the xy plane (Figure 12–15), there is a fixed delay or **time of mixing**, t_m , of 50 ms to several hundred milliseconds to allow the saturation of each population of nuclei, which has been labeled with its own characteristic Larmor frequency, to diffuse outward, mixing with the spin states of nuclei in its vicinity. After this fixed delay, a third 90° pulse initiates the collection of the free induction decay from the sample during t_2 .

In the two-dimensional spectrum that results, there is a cross-peak produced by the transfer of some of the saturation from the population of nuclei A, which has been labeled with its own Larmor frequency, to the population of nuclei X, each of which is adjacent to a nucleus A in a molecule of the protein. As a result, the

Figure 12-19: Two-dimensional (^1H - ^1H) TOCSY nuclear magnetic resonance spectrum of a 2 mM solution of ferrocycytochrome c_2 from *Rhodobacter capsulatus* ($n_{\text{aa}} = 116$) dissolved in a 90:10 mixture of $^1\text{H}_2\text{O}$ and $^2\text{H}_2\text{O}$, respectively, at pH 6 and 30 °C.²⁵⁶ The spectrum contains peaks resulting from the relay of spin-spin coupling from the amido ^1H hydrogen of each amino acid out along the atoms in its side chain. Each cross-peak is labeled with the letter of the Greek alphabet designating the carbon of the side chain on which the ^1H hydrogen producing it resides. Each sequence of cross-peaks resulting from these relayed spin-spin couplings (vertical lines) is anchored on the cross-peak connecting the spins of the amido ^1H hydrogen and the α ^1H hydrogen of an amino acid (Figure 12-16). Each sequence identifies cross-peaks arising from relayed coupling between the amido ^1H hydrogen and other hydrogens in the side chain of that amino acid and assigns chemical shifts (the values of the ordinate of each cross-peak) to each of those other hydrogens. For example, the chemical shifts of the α , β , γ , and δ_3 ^1H hydrogens of Isoleucine 19 are 4.12, 1.42, 0.66, and -0.22 ppm, respectively, and those of the α ^1H hydrogen and the two β ^1H hydrogens of Cysteine 13 are 4.90, 1.67, and 0.67 ppm, respectively. Each cross-peak between an amido ^1H hydrogen and an α ^1H hydrogen anchoring each of the relayed connections is labeled with the amino acid on which they reside. Reprinted with permission from ref 256. Copyright 1990 American Chemical Society.

population of nuclei X becomes labeled with the Larmor frequency of the population of nuclei A as well as its own Larmor frequency, and in the two-dimensional nuclear Overhauser enhanced spectrum that results, there is an off-diagonal cross-peak at chemical shift δ_2 of nucleus X and chemical shift δ_1 of nucleus A. Transfer of saturation, however, is reciprocal, and the saturation reciprocally and coincidentally transferred from the population of nuclei X to the population of nuclei A, which is labeled with the Larmor frequency of nuclei X, produces an off-diagonal peak at chemical shift δ_2 of nucleus A and chemical shift δ_1 of nucleus X. Each of these two symmetrically displayed peaks connects nucleus A and nucleus X by a nuclear Overhauser effect and identifies the two nuclei connected by their chemical shifts. Each of the hundreds of symmetrically displayed peaks in a nuclear Overhauser enhanced spectrum (Figure 12-23) makes its own respective connection between two ^1H hydrogens, each identified by its chemical shift.

A specific example illustrates the spin diffusion resulting from these individual transfers of saturation. A cross section through a two-dimensional nuclear Overhauser enhanced spectrum of bovine acrosin inhibitor IIA, at the chemical shift δ_1 equivalent to the Larmor frequency of the amido ^1H of Alanine 37 (8.45 ppm), contains cross-peaks at the chemical shifts δ_2 of the amido ^1H s of Asparagine 34, Cystine 36, and Phenylalanine 38; of the α ^1H s of Cystine 36 and Alanine 37; and of the β ^1H s of Cystine 36 and Alanine 37 (Figure 12-24)²⁷⁰ because the saturation transferred to each of these populations of ^1H nuclei retains the amplitude modulation, labeling it with the Larmor frequency of the population of the nuclei of the amido ^1H s of Alanine 37. Consequently, in the dimension of chemical shift δ_1 cross-peaks are located at the chemical shifts of these other populations

Figure 12-21: Two-dimensional (^1H - ^{13}C) HSQC correlated nuclear magnetic resonance spectrum of a solution of human transforming growth factor $\beta 1$ (homodimer of subunits 112 aa in length) expressed in Chinese hamster ovarian cells grown on a mixture of [^{14}C]amino acids and dissolved in a 95:5 mixture of [^1H]H $_2\text{O}$ and [^2H]H $_2\text{O}$, respectively, at pH 4.2 and 45 °C.²⁵⁸ The region of the spectrum presented covers the range of chemical shift for ^1H hydrogen (horizontal axis) and ^{13}C carbon (vertical axis) of the methyl groups of threonine, valine, leucine, and isoleucine. Each cross-peak is produced by the spin-spin coupling between a methyl ^{13}C carbon and its three ^1H hydrogens. Each is labeled with the amino acid in the sequence of the protein to which it has been assigned and the Greek letter designating the position of the methyl group within that amino acid. The inset is the boxed region within the full spectrum expanded in the dimension of the chemical shift of ^{13}C carbon to resolve peaks that overlapped in the full spectrum. Figure 12-20: Strips from sections of a three-dimensional (^{13}C - ^{15}N - ^1H) CBCA(CO)NH nuclear magnetic resonance spectrum of a 1 mM solution of human interleukin-13 ($n_{\text{aa}} = 113$) expressed in *E. coli* grown on [^{15}N](NH $_4$) $_2$ SO $_4$ and [$^{13}\text{C}_6$]glucose as sole sources of nitrogen and carbon and dissolved in a 90:10 mixture of [^1H]H $_2\text{O}$ and [^2H]H $_2\text{O}$, respectively, at pH 6.0 and 25 °C.²⁵⁷ Each section through the three-dimensional spectrum from which each strip is taken is centered on the chemical shift of the amido ^{15}N nitrogen of the respective amino acid. A strip is then taken from the resulting two-dimensional section. Each strip is aligned vertically with its neighbors and is designated at its bottom by the amino acid from which the pair of cross-peaks (connected by vertical lines) arises. Each strip is centered on the chemical shift of the amido ^1H hydrogen of the next amino acid in the sequence of the protein (Table 12-3) so the horizontal axis of each strip is the chemical shift of ^1H hydrogen. Each strip is wide enough to include the cross-peak produced by the spin-spin coupling connecting the α ^{13}C carbon of the amino acid, the amido ^{15}N nitrogen of the next amino acid and the amido ^1H hydrogen of the next amino acid as well as the cross-peak produced by the spin-spin coupling connecting the β ^{13}C carbon of the amino acid, the amido ^{15}N nitrogen of the next amino acid, and the amido ^1H hydrogen of the next amino acid. The two cross-peaks in each strip appear in the same section and have the same value on the horizontal axis because they are both coupled to the same respective amido ^{15}N nitrogen and amido ^1H hydrogen on the next amino acid. Therefore, each strip is anchored on a cross-peak in the two-dimensional (^1H - ^{15}N) HSQC correlated nuclear magnetic resonance spectrum (Figure 12-17) providing the fingerprint of the protein, albeit on the cross-peak of the next amino acid, and each cross-peak assigns a value for the chemical shifts of the α ^{13}C carbon and the β ^{13}C carbon of the amino acid preceding the amino acid producing the cross-peak in the fingerprint. Reprinted with permission from ref 257. Copyright 2001 Elsevier B.V.

Figure 12-22: Sections from three-dimensional (^1H - ^{13}C - ^1H) HCCH-TOCSY nuclear magnetic resonance spectra of a 2 mM solution of human interleukin-1 β ($n_{\text{aa}} = 153$) expressed in *E. coli* grown on ^{15}N and ^{13}C as the sole sources of nitrogen and carbon and dissolved in $^2\text{H}_2\text{O}$ at pH 5.4 and 36 °C.²⁵⁹ Each section through the three-dimensional spectrum is 0.6–0.8 ppm in width centered on the ^{13}C chemical shift noted in its upper left corner. These chemical shifts serve to identify each section. Each cross-peak is produced by the spin–spin coupling of two hydrogens on the side chain of a particular amino acid often relayed through multiple bonds. One of the two hydrogens is on the ^{13}C providing the third dimension. The sections through the three-dimensional spectrum centered on chemical shifts for ^{13}C of 17.6 and 22.2 ppm, respectively, contain cross-peaks arising from the absorptions of the ^{13}C carbons in the δ and γ positions of leucines, the β positions of valines, and the β position of an alanine with chemical shifts in each of these ranges. The cross-peak produced by the self-coupling of the ^1H hydrogen on each of these selected ^{13}C carbons lies on the diagonal. Every cross-peak along each horizontal line is coupled, respectively, to this ^{13}C and ^1H , each labeled with its eventual assignment. Each cross-peak is labeled by the position of the other coupled hydrogen in the side chain, and each cross-peak assigns the chemical shift of that other hydrogen. The sections through the three-dimensional spectrum centered on chemical shifts for ^{13}C of 39.9 and 40.9 ppm, respectively, contain cross-peaks arising from the absorptions of the ^{13}C carbons in the β positions of isoleucines with chemical shifts in each of these ranges. The cross-peaks produced by the self-coupling of the ^1H hydrogens on each of these selected β carbons lie on the diagonal. Every cross-peak along each horizontal line is coupled, respectively, to this β ^{13}C and β ^1H , each labeled with its eventual assignment. Each cross-peak is labeled by the position of the other coupled hydrogen in the side chain, and each cross-peak assigns the chemical shift of that other hydrogen. The sections through the three-dimensional spectrum centered on chemical shifts for ^{13}C of 55.0, 56.7, 58.0, and 58.6 ppm, respectively, contain cross-peaks arising from the absorptions of the ^{13}C carbons in the α positions of amino acids with chemical shifts in each of these ranges. The cross-peaks produced by the self-coupling of the α ^1H hydrogens on each of these selected α ^{13}C carbons lie on the diagonal. Every cross-peak along each horizontal line is coupled, respectively, to this α ^{13}C and α ^1H , each labeled with its eventual assignment. Each cross-peak is labeled by the position of the other coupled hydrogen in the side chain, and each cross-peak assigns the chemical shift of that other hydrogen. Reprinted from ref 259. of ^1H hydrogens. The existence of these cross-peaks states that all of these ^1H hydrogens are in the vicinity of the amido ^1H hydrogen of Alanine 37 in the tertiary structure of the protein. As the length of the fixed delay t_m was increased, the intensity of the cross-peaks increased as more and more of the amplitude modulation of the population of the nuclei of amido ^1H hydrogens of Alanine 37 was transferred to the populations of neighboring nuclei.

Two **problems with nuclear Overhauser effects** that are the consequence of spin diffusion are that they are complicated by the spectral density function²⁰⁵ inherent to the dipolar interaction and that they are usually not confined to nuclei immediately adjacent to the source of the diffusing spin but spread outward from the source in rather complex pathways that cannot be delineated unless the detailed structure of the molecule is already known.^{206,271,272} The time t_m between the second and the third 90° pulses must be chosen by trial and

error to maximize the amount of transfer to immediately adjacent nuclei while minimizing the spread to more distant locations (Figure 12-24). Because the nuclear Overhauser effect results from a dynamic, inhomogeneous process, no reliable absolute measurements of particular distances between nuclei can be made. An intuition of relative distances between the nuclei can be gained, however, by following the changes in the intensity of the nuclear Overhauser effects as a function of the time interval t_m . If a nuclear Overhauser effect is one that develops early in the progress of spin diffusion, the two nuclei connected by that nuclear Overhauser effect are presumed to be close to each other (<0.5 nm) in the folded polypeptide.²⁷⁰

In the full two-dimensional nuclear Overhauser spectrum of a protein (Figure 12-23A), the one-dimensional spectrum of the individual absorptions of the ^1H hydrogens lies along the diagonal. The nuclear

Figure 12-23: Two-dimensional (^1H - ^1H) nuclear Overhauser enhanced spectra. (A) Full spectrum of a solution of ribosomal protein S17 from *Bacillus stearothermophilus* ($n_{\text{aa}} = 86$) dissolved in a 90:10 mixture of $^1\text{H}_2\text{O}$ and $^2\text{H}_2\text{O}$, respectively, at pH 6.5 and 25°C .²⁶⁹ In this spectrum, a cross-peak appears whenever the absorptions of two ^1H hydrogens are connected by a nuclear Overhauser effect. The two chemical shifts of each cross-peak are those of the two respective ^1H hydrogens. Because most ^1H hydrogens on adjacently bonded atoms are close enough to be connected by a nuclear Overhauser effect as well as spin-spin coupled through the bonds, most of the cross-peaks in a correlated spectrum of the protein are also present here. There are, however, more cross-peaks. The additional ones connect ^1H hydrogens on atoms adjacent in space but not connected by covalent bonds. Several regions are highlighted within boxes on the full spectrum: $d_{\text{N,N}}$, connections between ^1H hydrogens on different amide nitrogens; $d_{\alpha,\text{N}}$, connections between α ^1H hydrogens and amide ^1H hydrogens; $d_{(\beta,\gamma,\delta),\text{N}}$, connections between ^1H hydrogens on β , γ , or δ carbons and amide ^1H hydrogens; $d_{\alpha,\omega}$, connections between ^1H hydrogens on two different α carbons; and $d_{(\beta,\gamma,\delta),(\beta,\gamma,\delta)}$, connections between two different β , γ , or δ ^1H hydrogens. Reprinted from ref 269. Copyright 1996 American Chemical Society. (B) Expansion of the $d_{\alpha,\text{N}}$ region of spectrum A. Each cross-peak is a connection produced by a nuclear Overhauser effect between the α ^1H hydrogen on one amino acid and the amide ^1H hydrogen on another. The identity of the amino acids on which the paired ^1H hydrogens are located is determined by the chemical shifts at which the cross-peak is situated. Those that connect consecutive amino acids in the sequence of the protein are labeled to illustrate the fact that most but not all of the nuclear Overhauser effects in this region are local and uninformative. Reprinted from ref 269. Copyright 1996 American Chemical Society. (C) Spectrum of a 2 mM solution of the γ -carboxyglutamate-rich domain of human factor IX ($n_{\text{aa}} = 47$) dissolved in a 90:10 mixture of $^1\text{H}_2\text{O}$ and $^2\text{H}_2\text{O}$, respectively, at pH 5.3 and 35°C .²⁶⁸ The region of the spectrum displayed contains cross-peaks between ^1H hydrogens on aromatic rings (horizontal axis) and ^1H hydrogens on methyl groups (vertical axis). Because aromatic amino acids have no methyl groups, most of the cross-peaks in this region, unlike those in panel B, connect amino acids distant from each other in the sequence of the protein. The cross-peaks are identified in the respective dimensions by the number of and position in the amino acids containing the two ^1H hydrogens. Reprinted with permission from ref 268. Figure 12-24: Diffusion of saturation, labeled with its Larmor frequency, from a nucleus of ^1H hydrogen into surrounding nuclei of ^1H hydrogen as a function of the length of the fixed delay t_m .²⁷⁰ Each trace is a cross section through a two-dimensional (^1H - ^1H) nuclear Overhauser enhanced spectrum of a 16 mM solution of acrosin inhibitor IIA from bovine seminal plasma ($n_{\text{aa}} = 57$) in $[\text{H}]_2\text{O}$ at pH 5.3 and 47 °C. Each cross section cuts through one of the two-dimensional spectra at a chemical shift δ_1 of 8.45 ppm, which is the chemical shift of the amido ^1H hydrogen on Alanine 37. Other ^1H hydrogens connected to this hydrogen by nuclear Overhauser effects are represented by cross-peaks in the dimension of ^1H hydrogen chemical shift δ_2 (horizontal axis). They are labeled by the ^1H hydrogen to which they have been assigned by the individual values of their chemical shifts. The large peak labeled A37NH is the self-connection of the amido ^1H hydrogen of Alanine 37. Each cross section is from a two-dimensional spectrum gathered with a different fixed delay t_m , noted to its left in milliseconds. Reprinted with permission from ref 270. spin-spin-coupled to a ^{13}C carbon or a ^{15}N nitrogen the chemical shift of which falls within a narrow range of values are registered. For example, only the ^1H hydrogens connected by nuclear Overhauser effects to ^1H hydrogens on ^{13}C carbons with chemical shifts of 13.3 ppm are registered in the left strip in Figure 12-25. The nuclear Overhauser effects in such spectra are assigned to particular pairs of hydrogens on the basis of the two chemical shifts of each cross-peak (Figure 12-23B,C) or the two chemical shifts of the cross-peak and the chemical shift of a ^{13}C carbon or ^{15}N nitrogen to which one or the other of the ^1H hydrogens is spin-spin-coupled. These chemical shifts were determined during the initial assignments of chemical shifts to all of the nuclei in the protein.

As many pairs of hydrogens coupled by nuclear Overhauser effects as possible are identified and catalogued. For example, 531 pairs of ^1H hydrogens were identified as being connected by nuclear Overhauser effects in spectra of the major cold-shock protein ($n_{\text{aa}} = 70$) from *E. coli*;²⁷⁶ 1281 pairs, in spectra of glutaredoxin 2 ($n_{\text{aa}} = 215$) from *E. coli*;²⁷⁷ and 3125 pairs, in spectra of phosphoglycerate mutase ($n_{\text{aa}} = 205$) from *Schizosaccharomyces pombe*.²⁷⁸ As is usually the case, these connections were spread unevenly over the amino

Figure 12-25: Three-dimensional (^1H - ^{13}C - ^1H) NOESY-HMQC spectra of a 2 mM solution of human interleukin-4 ($n_{\text{aa}} = 129$) that had been expressed in *E. coli* grown on $[\text{H}_4]\text{SO}_4$ and $[\text{H}_3]\text{glycerol}$ as sole sources of nitrogen and carbon and that was dissolved in $[\text{H}_2]\text{O}$ at pH 4.5 and 20 °C.²⁷³ The three strips are from two-dimensional sections through the three-dimensional spectra. The three two-dimensional sections, cut in the ^{13}C carbon dimension, contain cross-peaks from ^{13}C carbons with chemical shifts of 13.3, 16.6, and 6.7 ppm, respectively, which are the chemical shifts of the ^{13}C carbons in the δ methyl group of Isoleucine 10, one of the γ methyl groups of Valine 29, and the δ methyl group of Isoleucine 80. Each strip from each of these two-dimensional sections is centered on the chemical shift (horizontal axis) of the ^1H hydrogens of the respective methyl group. The most intense cross-peak on each strip is the self-connection of those hydrogens and is not labeled. The vertical axis defines the chemical shifts of the other hydrogens connected to the respective methyl hydrogens by nuclear Overhauser effects. Each of these cross-peaks, identified by its chemical shift, is labeled with the amino acid and the position in that amino acid at which the ^1H hydrogen producing the nuclear Overhauser effect is located. Reprinted from ref 273. Copyright 1994 Elsevier B.V.

acid sequences of these proteins with as few as 5–10 involving ^1H hydrogens on one particular amino acid to as many as 160 involving ^1H hydrogens on another.²⁷⁷ The latter values are extraordinarily impressive because no one hydrogen in a protein can have more than about 20–25 hydrogens within 0.5 nm of it, and the ^1H hydrogens on methyl groups are indistinguishable from each other in chemical shift and do not register as separate ^1H hydrogens. It is from this **catalogue of pairs of connected ^1H hydrogens** that a molecular model is built.

It is the nuclear Overhauser effects between ^1H hydrogens that are on amino acids two or more positions away from each other in the amino acid sequence of a protein that provide the information on which the molecular model is based. Nuclear Overhauser effects between ^1H hydrogens within the same amino acid or on immediately adjacent amino acids are usually uninformative because the covalent structure requires that they occur.

Usually, only about 50% of the assigned nuclear Overhauser effects arise from ^1H hydrogens that are on amino acids two or more positions away from each other in the amino acid sequence of a protein.^{276–279} Certain regions of a two-dimensional nuclear Overhauser enhanced spectrum, such as the one containing connections between α ^1H hydrogens and amido ^1H hydrogens, are dominated by pairs of ^1H hydrogens that are on amino acids at adjacent positions in the amino acid sequence (labeled cross-peaks in Figure 12–23B), while other regions, such as the one containing connections between aromatic ^1H hydrogens and aliphatic ^1H hydrogens (labeled cross-peaks in Figure 12–23C), are dominated by pairs of ^1H hydrogens distant from each other in the primary structure but adjacent to each other in the tertiary structure of the protein. It is these latter types of nuclear Overhauser effects that draw together two distant hydrogens as the covalent structure of the protein is folded into the molecular model.

A **nuclear magnetic resonance molecular model** is a molecular model of the covalent structure of the protein folded by the builder of the model into a tertiary structure in which the maximum number of ^1H hydrogens observed to be connected by short-range nuclear Overhauser effects end up close (≤ 0.5 nm) to each other. It is possible to start with a molecular model of the extended polypeptide in a computer and use molecular dynamics and simulated annealing, modified so that the potential function includes the constraints of the nuclear Overhauser effects, to produce a preliminary molecular model, similar to the preliminary crystallographic molecular model that results from inserting the molecular model of the polypeptide into the map electron density.

The validity of this initial molecular model can be assessed by examining its secondary structure. Just as α helices and β structure can be recognized in a map of electron density, segments of the polypeptide that are α helices or β structure in the actual molecule of protein can be recognized by **patterns in the observed nuclear Overhauser effects** (Figure 12–26).²⁷⁰

The most dominant pattern is that of the ^1H hydrogens in an **α helix**. In an α helix, nuclear Overhauser effects systematically connect hydrogens in each amino acid to those in amino acids three positions and four positions (Figure 6–6) away from it in the amino acid sequence.^{280–282} An α helix holds the consecutive nitrogen–hydrogen bonds of the amides of the backbone close to each other, and these short distances promote transfer of saturation. For example, in the two-dimensional nuclear Overhauser enhanced spectrum of the anaphylatoxin from human complement factor 3a, 36 of the 44 nuclear Overhauser effects observed between amido ^1H hydrogens on spatially adjacent amino acids were those for amino acids in α helices, while only 46 of the 77 amino acids in the protein are in α helices.²⁸³

In **parallel β structure**, ^1H hydrogens in a string of successive amino acids in the sequence are connected in

Figure 12–26: Diagonal plot of the nuclear Overhauser effects observed between different amino acids in the amino acid sequence of acrosin inhibitor IIA from bovine seminal plasma.²⁷⁰ Each nuclear Overhauser effect was established by the existence of a cross-peak in a two-dimensional nuclear Overhauser enhanced spectrum of the protein that had two chemical shifts identical to the respective chemical shifts of particular ^1H hydrogens on the two different amino acids. The two axes are the numbering of the amino acids in the sequence of the protein, and a square represents a connection between the two positions in the sequence. Solid squares represent nuclear Overhauser effects between ^1H hydrogens on α carbons or amido ^1H hydrogens from the respective amino acids; hatched squares, between a ^1H hydrogen on an α carbon or amido ^1H hydrogen on one amino acid and a ^1H hydrogen on the side chain of the other; squares with \times , between ^1H hydrogens on the side chains of both amino acids. Patterns of connections can be recognized in the plot that define three turns of α helix from positions 34 to 45 and one turn of α helix from positions 8 to 11, and three segments from positions 52 to 55, 27 to 23, and 29 to 33 define three strands of antiparallel β structure in a pleated sheet. Reprinted with permission from ref 270. Copyright 1985 Academic Press.

pairs to ^1H hydrogens in another string of successive amino acids in the order in which those spectrally connected pairs of amino acids occur in the sequence. In **antiparallel β structure**, the pairs of amino acids are connected in the reverse order to the order in which they occur in the sequence. For example, connections between amino acids at positions 20 and 17, 21 and 16, 22 and 15, 23 and 14, 24 and 13, and 25 and 12 defined an antiparallel β hairpin in α -amylase inhibitor HOE-467A from *Streptomyces tendae*.²⁸⁴

Other patterns indicating the organization of the tertiary structure of the actual molecule of protein can also be recognized in the spectra. For example, patterns similar to those for antiparallel β structure, in which ^1H hydrogens in one segment of amino acids are connected in reverse order to ^1H hydrogens in another segment of amino acids, can identify two adjacent, antiparallel

Figure 12-27: Nuclear magnetic resonance molecular model of the amino-terminal domain ($n_{\text{aa}} = 92$) of the ADP regulatory protein of *E. coli*.^{293,294} The nuclear Overhauser effects observed in spectra of the protein were used as constraints in a computing program written to build a tertiary structure from a model of the polypeptide with optimal bond lengths and bond angles by first bringing as many hydrogens connected by nuclear Overhauser effects to within 0.5 nm of each other and then adjusting the structure to obtain the optimal length for designated hydrogen bonds and optimal dihedral angles and to eliminate overlap of atomic volumes. An ensemble of superposed structures is presented in stereo, each of which is equally compatible with the constraints imposed. The positions of a structural Zn^{2+} cation (Zn) in the various superposed structures are indicated by adjacent crosses. Reprinted with permission from ref 293. Copyright 1996 American Chemical Society.

α helices. In this instance, however, the patterns are discontinuous because only ^1H hydrogens within the interface between the two α helices are connected by nuclear Overhauser effects.²⁸⁵⁻²⁸⁷

Just as the preliminary crystallographic molecular model is then submitted to refinement against the data set, the preliminary nuclear magnetic resonance molecular model is submitted to **refinement** with the nuclear Overhauser effects as constraints. In addition to nuclear

Overhauser effects, other constraints can be applied to the process of refinement. Designated donors and acceptors of hydrogen bonds in α helices and β structure can be assigned ideal lengths.²⁸⁸ Dihedral angles within the structure can be constrained to particular ranges by values of observed coupling constants.^{289,290} If the protein contains a paramagnetic metallic cation, the effect of that cation on the relaxation rates of ^1H hydrogens in the protein can provide estimates of the distances between each of those ^1H hydrogens and the metallic cation.²⁹¹

In the final refined nuclear magnetic resonance molecular model, segments of **random meander** connecting clearly defined segments of secondary structure will often be less well defined even though there is crystallographic or chemical evidence that they do assume specific structures.^{292,293} This problem is emphasized by the practice of presenting a nuclear magnetic resonance molecular model as an ensemble of structures, each of which satisfies the constraints of the nuclear Overhauser effects (Figure 12-27).^{293,294} In such representations, the certainty of the structures of α helices and β structure is set in sharp contrast to the uncertainty of the structure of the random meander. Although such a representation implies that these poorly defined segments are more flexible and less rigidly confined than the central regions of regular secondary structure, crystallographic molecular models of the same protein often show no evidence of such flexibility.²⁹⁵ It is possible to distinguish whether or not the poor definition of these regions of random meander results from dynamic flexibility by examining the rates of relaxation of the ^{15}N nitrogens in these regions. These rates of relaxation are sensitive to thermal motion and can be used to identify segments of polypeptide that are dynamically flexible in the actual molecule of protein. In the absence of evidence for flexibility, it must be assumed that the poor definition of random meander is a consequence of an insufficiency of constraints in the data.

In refined nuclear magnetic resonance molecular models, it is those regions of the protein that are within or sandwiched between α helices or β structure that are the most precisely defined. There are, however, regions of the secondary structure that are poorly defined by nuclear magnetic resonance. Hydrogens known to be within short segments of secondary structure, such as **β turns** or 3_{10} helix, participate in so few nuclear Overhauser effects that those that are observed are often inadequate to define the structure of these segments.²⁹⁶

Molecules of **water** confined to particular locations on the surface of the protein can be incorporated into the molecular model on the basis of the nuclear Overhauser effects between their ^1H hydrogens and ^1H hydrogens of the amino acids by using rotating-frame Overhauser enhanced spectroscopy (ROESY).²⁹⁷ Molecules of water, however, at locations buried within the structure of the molecule of protein have residence times long enough to be observed directly by their nuclear Overhauser effects.

These two types of locations for molecules of water, exterior and interior, are usually found to occupy the same positions in the nuclear magnetic resonance molecular model that they do in the crystallographic molecular model of the same protein.²⁹⁸ The position of metallic cations in the molecular model can be established by substituting the natural cation with a cation of nuclear spin $\frac{1}{2}$. For example, the Zn^{2+} cations normally bound to the amino-terminal domain of regulatory protein GAL4 from *S. cerevisiae* ($n_{\text{aa}} = 62$) were replaced with $^{113}\text{Cd}^{2+}$ cations, and spin-spin couplings between the $^{113}\text{Cd}^{2+}$ cations and the β ^1H hydrogens on the cysteines that covalently bind them (6–19) produced a two-dimensional correlated spectrum.²⁹⁹

The fundamental problem with building a molecular model from nuclear Overhauser effects is that those nuclear Overhauser effects do not define a distance between two ^1H hydrogens because the relative rates of spin diffusion are too dependent on the character of the unique surroundings around each nucleus to obtain reliable estimates of distances. The distances in the final refined model between pairs of ^1H hydrogens connected by nuclear Overhauser effects are always quite different even though almost all of them can be made less than 0.5 nm.²⁸⁸ When distances between ^1H hydrogens connected by nuclear Overhauser effects are measured in a crystallographic molecular model of the same protein,²⁹⁶ there is usually little correlation between the actual distance between the hydrogens and the strength of the nuclear Overhauser effect at the optimal mixing time t_m . Those nuclear Overhauser effects observed only after extended mixing times do arise from hydrogens that are farther apart, but the range of those longer distances is broad, and consequently they are not very useful.²⁹⁶ If a nuclear Overhauser effect is observed between two ^1H hydrogens after an optimal mixing time t_m , it can only be assumed that they are less than 0.5 nm apart,^{205,272} but there are usually notable exceptions even to this limit.^{296,300–302}

In effect, the existence of a nuclear Overhauser effect allows the investigator to connect the two hydrogens in a molecular model of the covalent structure of the polypeptide with a rubber band that is elastic enough to stretch to a distance equivalent to about 0.5 nm. If enough of these rubber bands were inserted into a molecular model of the polypeptide and the regions of the amino acid sequence identified as β structure and α helix (Figure 12–26) had already been locked into these secondary structures, the model would snap into a conformation that resembles the native folded conformation of the polypeptide.

It has been possible in many instances to compare nuclear magnetic resonance molecular models with crystallographic molecular models. It is usually observed that the two molecular models resemble each other, occasionally quite closely.²⁷⁹ The resemblance is strongest in the assignment of α helices and β struc-

ture.²⁷⁹ The arrangement of these regular secondary structures in the tertiary structure, however, often differs significantly, but not dramatically, between the two molecular models.^{303–306} Some of these differences are real and informative.³⁰⁷ They often result from the fact that the protein in question is small and flexible or has flexible domains and the fact that contacts between the molecules of protein in the crystal are able to shift secondary structures relative to each other.³⁰⁶ If a protein is constructed so that in solution it assumes two or more conformations because shifts among these conformations are required for its function, nuclear magnetic resonance can be used to determine which crystallographic molecular models of these various conformations represent the species actually present in solution.³⁰⁸

In **superpositions of nuclear magnetic resonance and crystallographic molecular models** of the same protein, the root mean square deviations between heavy atoms (oxygen, nitrogen, and carbon) are usually the least within the polypeptide backbone of the regular secondary structure in the core, greater for side chains buried between these secondary structures in the core, and greatest for random meander at the periphery.^{300,303,309,310} In the comparison of the two molecular models for α -amylase inhibitor HOE-467A ($n_{\text{aa}} = 74$), the value of the root mean square deviation for the heavy atoms of the polypeptide backbone was 0.105 nm; that for the heavy atoms of the side chains buried in the core was 0.125 nm; and that for all heavy atoms was 0.184 nm.³⁰⁰ This protein, however, is almost entirely β structure with little random meander. In the comparison of the two molecular models of human granulocyte colony-stimulating factor ($n_{\text{aa}} = 174$ aa), a much larger protein with significant amounts of random meander, the root mean square deviation for the heavy atoms of the polypeptide backbone in its four α helices was 0.286 nm; that for all of the heavy atoms in these α helices was 0.333 nm; that for all of the heavy atoms in the entire polypeptide backbone was 0.315 nm; and that for all heavy atoms was 0.370 nm.³⁰³

It is in the **details of the atomic structure** that nuclear magnetic resonance and crystallographic molecular models differ most significantly. For example, the dispositions of the aromatic rings of Tyrosine 3, Tyrosine 45, and Phenylalanine 52 were different in two nuclear magnetic resonance molecular models of the immunoglobulin-binding domain of immunoglobulin G binding protein G from *Streptococcus* ($n_{\text{aa}} = 56$), and those dispositions in turn were both different from the dispositions in the crystallographic molecular model.³¹¹ In nuclear magnetic resonance molecular models it is the conformations of the side chains that are always more uncertain than those of the polypeptide backbone;³⁰⁰ but, unfortunately, it is the conformations of the side chains that usually accomplish the function of the protein. There are, however, some instances in which the conformation of a particular side chain in a nuclear mag-

netic resonance molecular model is more compatible with its known chemical properties than its conformation in the crystallographic molecular model of the same protein³¹² and other instances in which the atomic details of the crystallographic molecular model could be adjusted by nuclear magnetic resonance.³¹³

A nuclear magnetic resonance molecular model is a significantly less accurate²⁰⁵ representation of the actual structure of a molecule of protein than is a crystallographic molecular model for the following reasons. First, a crystallographic data set contains significantly more information than even the most extensive list of nuclear Overhauser effects and coupling constants³¹⁰ because the number of observable nuclear Overhauser effects is always less than the number of observable reflections and because each reflection comes with an amplitude. Second, the heavy reliance on energy minimization in building the nuclear magnetic resonance molecular model assures that unusual local conformations that are excluded by the procedure used for the minimization either intentionally or unintentionally will be missed. Third, it has been demonstrated by calculation that even with an average of 19 nuclear Overhauser effects for each amino acid, a value in excess of the number usually available, the root mean square deviation of the atoms in a nuclear magnetic resonance molecular model from their actual positions in the structure of the protein has to be at least 0.1 nm.²⁰⁵ Even this is an overestimate of the accuracy because the paucity of nuclear Overhauser effects from random meander was not considered when the pairs of hydrogens incorporated into the calculations were chosen. Fourth, because the crystallographic data constrains the crystallographic molecular model much more than the nuclear magnetic resonance data constrains the nuclear magnetic resonance molecular model, upon refinement with a combination of both the crystallographic data set and the observed nuclear Overhauser effects, the crystallographic molecular model of a protein quickly converges with only small changes in its structure to accommodate both sets of data while the nuclear magnetic resonance molecular model undergoes far more extensive changes to reach accommodation.³¹⁰ Fifth, the fact that the number of nuclear Overhauser effects observed between ¹hydrogens in the same amino acid that are inescapably greater than 0.5 nm apart in the final nuclear magnetic resonance molecular model is much greater than the number of nuclear Overhauser effects observed between ¹hydrogens in different amino acids that are greater than 0.5 nm apart in the final nuclear magnetic resonance molecular model indicates that in bringing as many ¹hydrogens connected by nuclear Overhauser effects as possible to within 0.5 nm of each other, the construction of the molecular model has produced a structure significantly different from the actual structure of the molecule of protein.³¹⁴ Sixth, it is usually observed that increasing the number of constraints in the construction of the nuclear

magnetic molecular model causes it to become closer to the crystallographic molecular model of the same protein rather than to assume its own distinct structure.²⁹⁰

There are, however, informative exceptions to this rule and in these instances, nuclear magnetic resonance does reveal differences in the **structure of a protein when it is in solution** and when it is in a crystal.^{307,308,315} As with solution scattering of X-rays, these differences permit the crystallographic molecular model to be adjusted, often minutely,³¹³ to a conformation representing the molecule of protein in solution, which is the goal of all structural studies.

Perhaps the greatest drawback of nuclear magnetic resonance spectroscopy is that it is confined to small proteins. This confinement is due not only to the problem of overlapping cross-peaks on two-dimensional and three-dimensional spectra. Because the rate at which a molecule rotationally diffuses in the solution affects both the ratio of signal to noise in a nuclear magnetic resonance spectrum and the effectiveness of the pulse sequences used for multidimensional and multinuclear spectra, the **size of a molecule of the protein** determines whether or not it will even yield a spectrum. Although methods have been reported that can increase the rate at which a molecule of protein rotationally diffuses in a solution,³¹⁶ this problem has yet to be solved satisfactorily. From 1986 to 2001, the size of the largest asymmetric units and the size of the largest symmetric dimers^{317,318} for which nuclear magnetic resonance provided a molecular model increased from 120 to 220 aa and from 200 to 450 aa, respectively.* The average size of the proteins for which molecular models were reported, however, increased only modestly during the same period, from about 90 to about 125 aa. Unfortunately, most proteins are oligomers with asymmetric units larger than 300 aa, sizes that present no difficulty to crystallography.

Because of their poor definition of the structure of random meander and of the conformation of side chains, because of their inaccuracy, because of their indistinguishability from crystallographic molecular models, and because of their confinement to small proteins, nuclear magnetic resonance molecular models have provided far less structural information than have crystallographic molecular models. Although there are situations in which nuclear magnetic resonance can be applied when crystallography cannot, for example in defining the details of the conformational change that occurs upon the binding of porcine phospholipase A₂ to micelles of dodecyl phosphocholine,³²⁰ and situations in which nuclear magnetic resonance establishes clear and significant differences between a crystallographic molecular model and the structure of a protein in solution, for example in showing that the central unsupported α helix

* A preliminary nuclear magnetic molecular model of malate synthase from *E. coli*, which is a monomer of 723 amino acids, has been reported.³¹⁹

in the crystallographic molecular model of calmodulin does not form in solution,²⁸⁰ the dramatic advantages that nuclear magnetic resonance has over crystallography are that it readily observes hydrogens and it observes proteins while they are in solution. Both of these advantages are exploited when nuclear magnetic resonance is used to monitor acid–base titrations of individual side chains and when it is used to monitor the exchange of specific amido protons or deuterons in the polypeptide backbone with deuterons or protons, respectively, of the water in which the protein has been dissolved.

The first successful application of nuclear magnetic resonance spectroscopy in the study of proteins was the determination of the **acid dissociation constants** of their **histidines**. The π electrons of an aromatic ring (2–24) are induced to circulate in a ring current by an applied magnetic field. This ring current creates a toroidal magnetic field opposite in direction to the applied field in the center of the ring but reinforcing the applied field at the periphery of the ring. This additional local magnetic field at the periphery causes all of the ^1H hydrogens around aromatic rings to absorb at higher frequencies and hence greater chemical shift (Equations 12–53 and 12–54). The nitrogens on either side of carbon 2 of the imidazole of a histidine

are electronegative elements that withdraw electrons from carbon 2, decreasing the shielding provided by the σ electrons in the carbon–hydrogen bond and shifting the absorption of a ^1H hydrogen on carbon 2 further downfield and away from the absorptions of the other aromatic ^1H hydrogens on phenylalanines, tyrosines, and tryptophans. The absorption of the ^1H hydrogen on carbon 2 of the imidazole of a histidine is not divided by spin–spin coupling when the adjacent protons on the two nitrogens have been exchanged with deuterons from the $[\text{D}_2]\text{H}_2\text{O}$ in which the protein is dissolved. For all of these reasons, the absorption from this ^1H hydrogen on each histidine in a protein dissolved in $[\text{D}_2]\text{H}_2\text{O}$ appears as a sharp individual peak in the nuclear magnetic resonance spectrum. One of the first nuclear magnetic spectra displaying these absorptions in a native protein was the spectrum for ribonuclease (Figure 12–28).³²¹ Improvements have been made since these early experiments that sharpen the peaks of absorbance and eliminate peaks in this region of the spectrum from unexchanged amido ^1H hydrogens.³²²

As the imidazole of histidine gains a proton during its acid–base reaction, the nitrogens of the conjugate acid become even more electron-withdrawing than those of the conjugate base, and the absorption of the

Figure 12–28: Low-resolution (100 MHz) nuclear magnetic resonance spectra covering the region of the unresolved absorptions of the ^1H hydrogens of the six tyrosines and three phenylalanines (aromatic) and the four resolved absorptions of the ^1H hydrogens on the carbons 2 of the four histidines (numbered 1–4) of ribonuclease A.³²¹ Absorption is presented as a function of chemical shift (in hertz from the peak of absorption of an internal standard). As the excitation frequency is 100 MHz, 100 Hz of chemical shift is 1 ppm. The sample was a 12 mM solution of ribonuclease A ($n_{\text{aa}} = 124$) in deuterioacetate buffers in $[\text{D}_2]\text{H}_2\text{O}$ at various values of p^2H (noted on the drawing). Peak 5 is a proton on carbon 4 of one of the histidines. Reprinted with permission from ref 321. Copyright 1967 retained by authors.

^1H hydrogen on carbon 2 assumes an even larger chemical shift (notice the movement of the peaks in Figure 12–28 to higher chemical shift as the pH decreases). Because a specific fraction of the imidazoles in a population of identical histidines is the cationic conjugate acid at a particular pH and because the transfer of protons among the individuals in that population is much faster than the time resolution of nuclear magnetic resonance spectroscopy, the absorption of the population of ^1H hydrogens on carbon 2 of a given population of histidines in a protein assumes a chemical shift, $\delta_{\text{H,obs}}$, that is the weighted mean between that of the neutral conjugate base $\delta_{\text{H,A}}$ and that of the cationic conjugate acid $\delta_{\text{H,HA}}$:

$$\delta_{\text{H,obs}} = f_{\text{A}} \delta_{\text{H,A}} + f_{\text{HA}} \delta_{\text{H,HA}} \quad (12-57)$$

where f_{A} and f_{HA} are the fractions of conjugate base and conjugate acid, respectively, at a particular pH. Therefore, the chemical shift as a function of pH traces the **titration curve** of a particular histidine in a molecule of protein. The first application of this method was the measurement of the titration curves for the four histidines of ribonuclease.³²¹

In a number of proteins, such as ribonuclease,^{323,324} myoglobin,³²⁵ subtilisin,³²⁶ and carbonate dehydratase,^{327,328} the individual peaks of absorption from ^1H hydrogens on the carbons 2, and hence the titrations of

their imidazoles, could be assigned to specific histidines in the sequence of each protein. These assignments are now usually made by mutating each of the histidines consecutively to another amino acid and observing which of the absorptions disappears in each mutant.^{326,329} The acid dissociation constants for particular histidines in native proteins have been used to test computational methods^{324,330} for assessing the effect of electric field and relative permittivity on the acid dissociation constant of a particular histidine in a crystallographic molecular model.^{324,325,330}

The absorptions of the ^1H hydrogens on the carbons 2 of the histidines in a protein can be observed in its one-dimensional nuclear magnetic resonance spectrum. Although the absorptions of the individual ^1H hydrogens on the indole nitrogens of tryptophan³³¹ and the individual ^1H hydrogens on the methyl groups of threonines³³² can also often be observed in a one-dimensional spectrum, these ^1H hydrogens do not register acid dissociations.

The absorptions from nuclei in the side chains of a particular type of amino acid in a protein, however, can also be isolated on a one-dimensional spectrum by expressing that protein in bacteria that are grown on ^{13}C carbon or ^{15}N nitrogen versions of that particular type of amino acid. When this is done, a bacterium auxotrophic for that amino acid is chosen for the expression. For example, endo-1,4- β -xylanase from *Bacillus circulans* could be expressed in a strain of *E. coli* that was missing the three transaminases normally capable of producing glutamate.²⁴⁶ In such cells, only the $[\delta\text{-}^{13}\text{C}]$ glutamate added to the growth medium is incorporated into the expressed protein.³³³ When the xylanase was purified from this expression system, a peak of absorption from the carboxyl ^{13}C carbon of each of its two **glutamates** could be readily observed in a one-dimensional ^{13}C nuclear magnetic resonance spectrum, and the values of the chemical shifts for these two peaks as a function of the pH of the solution traced the acid-base titrations of their side chains (Figure 12–29).³³⁴ Using enrichments such as the one in this example permits acid-base titrations to be performed on fairly large proteins (the xylanase is a monomer of 185 aa) without the necessity of making a full set of assignments.

If the cross-peaks in two- and three-dimensional spectra and the chemical shifts of all of the nuclei in a protein have been assigned, it is possible to follow in those two- or three-dimensional spectra the chemical shift of a particular nucleus in a particular side chain as it changes with pH to produce a titration curve for an acid-base in that side chain. For example, the chemical shifts of the β ^1H hydrogens on the **aspartates** and the γ ^1H hydrogens on the glutamates in murine epidermal growth factor, which could be monitored with two-dimensional (^1H – ^1H) TOCSY spectra (Figure 12–19), decrease in magnitude as the respective adjacent carboxyl groups lose their protons as the pH is increased.³³⁵ The chemical shifts of the nuclei in ribonuclease H from *E. coli* ($n_{\text{aa}} = 155$) that had been enriched in ^{13}C carbon and

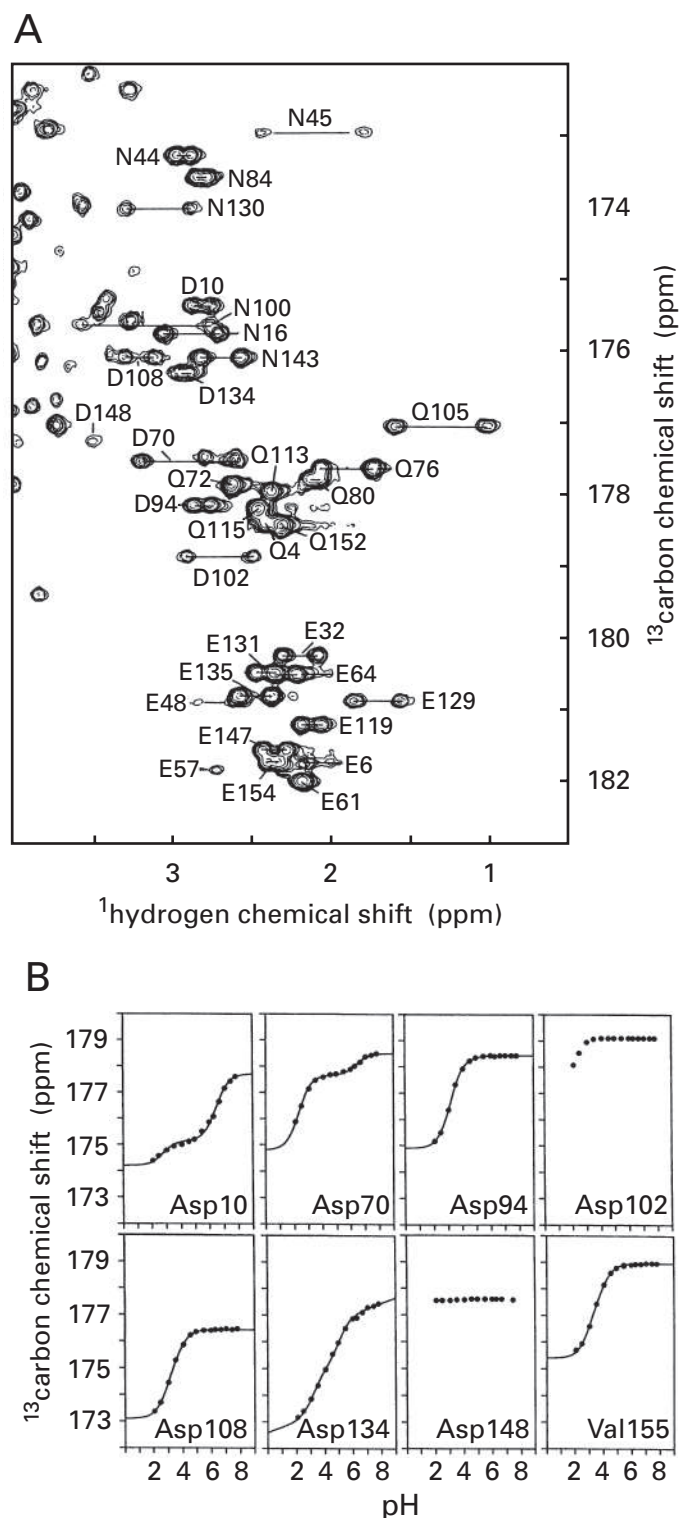

Figure 12–29: Acid–base titration of Glutamate 78 and Glutamate 172 in endo-1,4- β -xylanase ($n_{\text{aa}} = 185$) from *B. circulans*.³³⁴ A strain of *E. coli*, DL39, which is deficient in amino acid transaminases, was used to express the xylanase. It was grown on a medium containing $[\delta\text{-}^{13}\text{C}]$ glutamate as the sole source of this amino acid so that all of the glutamates in the resulting protein were enriched in ^{13}C carbon at the acyl position in their side chains. A series of one-dimensional ^{13}C nuclear magnetic resonance spectra were gathered at various values of pH. Every other value of the pH is noted on the vertical axis. The values for the pH of unlabeled traces are intermediate between those for the labeled traces. The region containing the peaks of absorption from the acyl ^{13}C carbons of glutamate and glutamine of the resulting spectra are presented, one above the other. The peaks assigned by site-directed mutation to Glutamate 78 and Glutamate 172, the only two glutamates in the protein, are highlighted. Peaks arising from the acyl ^{13}C carbons of several glutamines are labeled individually. Their chemical shifts respond to acid–base titrations of side chains in their vicinity. Reprinted with permission from ref 334. Copyright 2000 Elsevier B.V.

^{15}N nitrogen were assigned, and the acyl ^{13}C carbons of individual aspartates and glutamates could be distinguished on a two-dimensional ^{13}C – ^1H HSQC/HSQC correlated spectrum (Figure 12–30A).³³⁶ When the chemical shifts of the acyl ^{13}C carbons of the aspartyl side chains were plotted as a function of pH, titration curves for each aspartate were obtained (Figure 12–30B). Titration curves for the same aspartates could also be obtained by following the chemical shifts of the two ^1H hydrogens on the β carbons

on each aspartate (chemical shifts on the abscissa of Figure 12–30A). Aspartates 94, 108, and 134 had values of pK_a expected for carboxylates exposed on the surface of a protein (3.2, 3.2, and 4.1, respectively). Aspartates 102 and 194 had values of pK_a less than 2, which suggests that in the native structure of the protein they are in electropositive surroundings.

Aspartate 10 and Aspartate 70 are immediately

adjacent to each other in the crystallographic molecular model of ribonuclease H³³⁷, and their acid–base titrations are coupled tautomerically to each other (Figure 12–30B). The two **coupled titration curves** should be complex functions of the microscopic acid dissociation constants (Equation 2–24) and of the four values of the chemical shift of Aspartate 10 and the four values of the chemical shift for Aspartate 70 (the ones when Aspartate 10 and Aspartate 70 are both protonated, the ones when Aspartate 10 is protonated and Aspartate 70 is not, the ones when Aspartate 10 is not protonated and Aspartate 70 is, and the one when both are unprotonated).³³⁸ To obtain exact values for these 12 parameters, additional experiments in which each of the aspartates in turn is mutated to an asparagine would have to be performed. If, however, it is assumed that neither the chemical shift of protonated Aspartate 10 nor the chemical shift of unprotonated Aspartate 10 is perturbed by the ionization of Aspartate 70 and that neither the chemical shift of protonated Aspartate 70 nor the chemical shift of unprotonated Aspartate 70 is perturbed by the ionization of Aspartate 10, then the two respective titration curves register only the fraction of each aspartate that is ionized at a particular pH. If this is the case, as it seems to be, then the equilibrium constant between the concentrations of the two tautomers, the one in which Aspartate 10 is protonated and Aspartate 70 is unprotonated and the one in which Aspartate 10 is unprotonated and Aspartate 70 is protonated, is 3 and the two values for the macroscopic pK_a (Figure 2–7) are $pK_{a1} = 2.9$ and $pK_a = 6.4$.³³⁶ It follows that the microscopic pK_a for Aspartate 10 when Aspartate 70 is protonated is 3.5, that for Aspartate 70 when Aspartate 10 is protonated is 3.0, that for Aspartate 10 when Aspartate 70 is unprotonated is 6.3, and that for Aspartate 70 when Aspartate 10 is unprotonated is 5.8.

The titration curves of the two glutamates of the xylanase from *B. circulans* (Figure 12–29), which are also immediately adjacent to each other in the crystallographic molecular model,³³⁴ cannot be directly registering the macroscopic acid dissociations and the ratio of

Figure 12–30: Acid–base titration of aspartates in isoenzyme I of ribonuclease H from *E. coli*.³³⁶ (A) Two-dimensional (^{13}C - ^1H) HSQC/HSQC nuclear magnetic resonance spectrum of a 0.15 mM solution of the protein in $[\text{D}_2]\text{H}_2\text{O}$ at pH 5.5. The region of the two-dimensional spectrum displayed contains cross-peaks from the acyl ^{13}C carbons of the side chains of glutamate, glutamine, aspartate, and asparagine and the ^1H hydrogens on the adjacent methylene carbon. Each of the side chains produces a pair of cross-peaks because there are two ^1H hydrogens on each adjacent methylene carbon, and each of these ^1H hydrogens is positioned by the tertiary structure of the protein in a chemically different environment. The pairs of cross-peaks from each side chain are labeled with the position in the sequence of the amino acid producing them. (B) Titrations of individual aspartates in the protein. A series of two-dimensional spectra were gathered at different values of pH. The chemical shift of the acyl ^{13}C carbon of each side chain (ordinate of the pairs of cross-peaks in panel A) is plotted as a function of pH. Reprinted with permission from ref 336. the two tautomers, because in this example, the peak of absorption from the acyl ^{13}C carbon of Glutamate 78 drifts to a smaller value of the chemical shift rather than to a larger one upon the titration of Glutamate 172, and the peak of absorption from Glutamate 172 also drifts to a smaller value of the chemical shift rather than to a larger one upon the titration of Glutamate 78.

The carboxylates on the side chains of glutamates and aspartates sometimes form hydrogen bonds with amido nitrogen–hydrogens from the polypeptide backbone. These can be identified in nuclear magnetic resonance spectra because the chemical shift of the amido ^1H hydrogen participating in the hydrogen bond will increase in magnitude in concert with the decrease in the chemical shift of the ^1H hydrogens adjacent to the carboxyl group as it loses its proton, becomes a carboxylate, and forms the hydrogen bond with the amido nitrogen–hydrogen.³³⁹

Problem 12–13: This figure is a two-dimensional nuclear magnetic resonance spectrum of the cytochrome *c*-551 from *Pseudomonas aeruginosa*.³⁴⁰ Reprinted with permission from ref 340. Copyright 1990 American Chemical Society.

In the spectrum, the off-diagonal peaks arise from nuclear Overhauser enhancements ($t_m = 150$ ms). The symmetrically displayed peaks on the two sides across the diagonal result from the same nuclear Overhauser effects. You should convince yourself that the patterns are symmetric across the diagonal.

- What hydrogens in a protein produce off-diagonal peaks in this region of the spectrum?
- The peaks connected by the horizontal and vertical lines have been identified with a particular subset of these hydrogens. Each of the peaks connected by these lines is produced by a nuclear Overhauser enhancement between two hydrogens. Draw a polypeptide in the extended conformation as in 2–15. On your drawing show with double arrows only the connections that give rise to those peaks that are highlighted by the horizontal and vertical lines.
- What do the horizontal and vertical lines indicate about these peaks? Why are the peaks labeled with pairs of numbers that increase consecutively?
- What other information was used to assign the numbers to the particular peaks?

Problem 12–14: The figure is a portion of the two-dimensional nuclear Overhauser enhanced spectrum³⁴¹ of the lipoyl domain from the pyruvate dehydrogenase complex of *B. stearothermophilus*. Reprinted with permission from ref 341. Copyright 1991 Blackwell Publishing.

- What are the two functional groups in the polypeptide on which the hydrogens are located that produce the peaks in the spectrum?

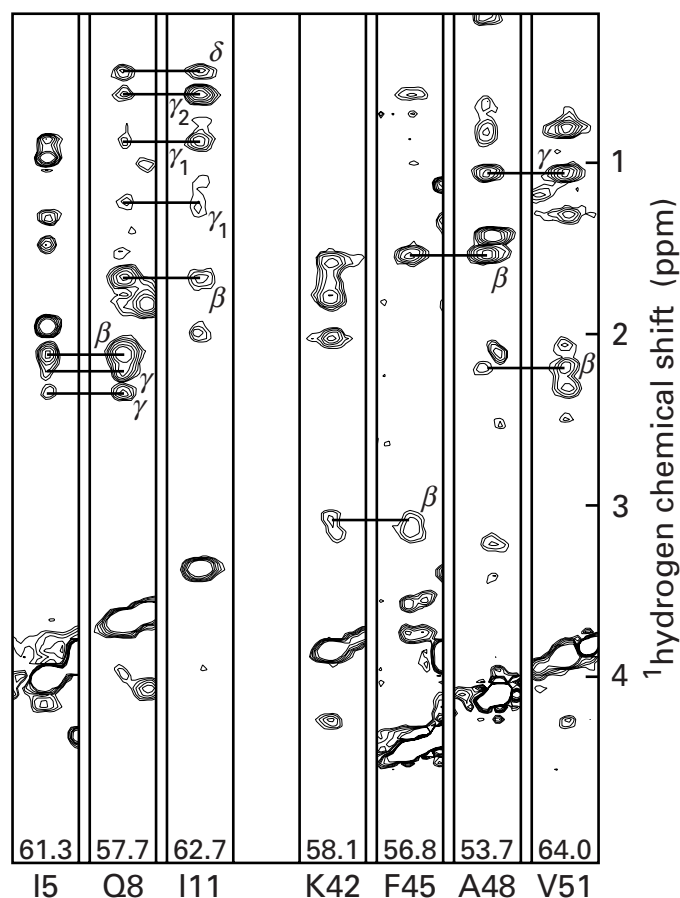

- (B) Draw the polypeptide from Cysteine 36 to Alanine 43, and draw double-headed arrows to indicate the connections between the pairs of hydrogens represented by the horizontal and vertical lines between the different peaks in the spectrum.
- (C) The squares in the spectrum represent the positions of peaks in another type of two-dimensional spectrum of the protein. What is this other type of spectrum, and what type of connections does it record?
- (D) Some of the squares coincide with peaks in the nuclear Overhauser enhanced spectrum and some do not. Why are there peaks in these positions in the other spectrum but not in the nuclear Overhauser enhanced spectrum?

Problem 12–15: Immunity protein Im9 is a folded polypeptide of 86 amino acids. It is responsible for inhibiting the action of colicin E9, an extracellular antibiotic protein produced by *E. coli*. Immunity protein Im9 uniformly labeled with ^{15}N was obtained by growing *E. coli* JM105 cells expressing high levels of the protein on minimal medium made with $[^{15}\text{N}]\text{NH}_4\text{Cl}$. The protein was purified, and the chemical shifts of most of the ^1H hydrogens and the ^{15}N nitrogens in the protein were assigned by the usual procedures. After the chemical shifts had been assigned, a three-dimensional spectrum was taken in which the three dimensions were the chemical shifts of ^1H hydrogen, ^1H hydrogen, and ^{15}N nitrogen.³⁴² The two hydrogen dimensions display nuclear Overhauser connections between pairs of hydrogens. Because the chemical shifts of each of the nitrogens in the polypeptide had been assigned, it was possible to select sections through the three-dimensional spectrum, each fixed at the chemical shift of a particular backbone nitrogen in the dimension of the chemical shifts of the ^{15}N nitrogens. Narrow strips from the resulting successive two-dimensional ^1H – ^1H nuclear Overhauser enhanced spectra are displayed in the figure. Each strip is centered on the horizontal axis at the chemical shift of the hydrogen on the amido nitrogen the chemical shift of which is fixed. The value of the chemical shift of each amido ^{15}N nitrogen at which the section was fixed and the identity of that amido nitrogen are indicated on each strip. Reprinted with permission from ref 342. Copyright 1994 American Chemical Society.

- (A) Peaks in the figure are labeled with pairs of numbers. Draw the polypeptide between Glutamate 30 and Valine 37 as the polypeptide is drawn in 2–15. Draw, however, the actual side chains along the polypeptide to identify each amino acid. Draw double-headed arrows labeled with the same pairs of numbers as the peaks in the strips are labeled and connecting every pair of hydrogens in your drawings that produce a labeled peak in the strips for Glutamate 30 to Valine 37.
- (B) What are the peaks in the spectra that are labeled with only a single number?
- (C) What are the peaks in the spectra that are not in the center of their strip?

Human interleukin-4 is a member of the family of hematopoietic cytokines that modulate cell proliferation and differentiation within the immune system. It is a folded polypeptide of 130 amino acids. A gene encoding human interleukin-4 was inserted into a pTR550 plasmid so that the protein could be expressed in *E. coli*. The human interleukin-4 expressed at high levels by these cells was uniformly labeled with ^{13}C by growing them on minimal medium made with $[^{13}\text{C}]\text{glycerol}$ (99 atom%). The protein was purified and the chemical shifts of most of the ^1H hydrogens and the ^{13}C carbons in the protein were assigned by the usual procedures. After the chemical shifts had been assigned, a three-dimensional spectrum was taken in which the three dimensions were the chemical shifts of ^1H hydrogen, ^1H hydrogen, and ^{13}C carbon.²⁷³ The two hydrogen dimensions display nuclear Overhauser connections between pairs of hydrogens. Because the chemical shifts of each of the carbons in the polypeptide had been assigned, it was possible to choose sections through the three-dimensional spectrum each fixed at the chemical shift of a particular α carbon in the protein in the dimension of the chemical shifts of the ^{13}C carbons. Strips from the resulting successive two-dimensional ^1H – ^1H nuclear Overhauser enhanced spectra are displayed in the figure. Reprinted with permission from ref 273. Copyright 1994 Elsevier B.V.

Each strip is centered on the horizontal axis at the chemical shift of the hydrogen on the α carbon the chemical shift of which is fixed. The value of the chemical shift of each $\alpha^{13}\text{C}$ carbon at which the section was fixed and the identity of that α carbon are indicated on each strip.

- (D) Peaks in the figure are labeled with the position of a hydrogen in an amino acid. The sequence of human interleukin-4 between Lysine 42 and Valine 51 is KETFCRAATV. Draw the polypeptide in this segment as the one is drawn in 2-15. Draw, however, the actual side chains along the polypeptide to identify each amino acid. Draw double-headed arrows labeled with the same numbers and Greek letters as the four peaks in the strips are labeled and connecting the pairs of hydrogens that produce the four labeled peaks in the strips for Phenylalanine 45, Alanine 48, and Valine 51. Peaks in adjacent strips are connected with horizontal lines. Draw double-headed arrows indicating the connections that are represented by each of the four horizontal lines connecting pairs of peaks from two different strips.
- (E) Into what type of secondary structure is the polypeptide between Isoleucine 5 and Isoleucine 11 and between Lysine 42 and Valine 51 folded in human interleukin-4?

Exchange of Protons

An acidic proton at any position in the covalent structure of a protein is subject to exchange with protons in the solution. Protons on the side chains of exposed polar amino acids such as asparagines, glutamines, aspartic acids, glutamic acids, serines, threonines, cysteines, arginines, lysines, and histidines usually exchange with protons in the solution so rapidly that the rates of their individual exchanges cannot be measured. The rate of exchange of a proton on the indole nitrogen of a **tryptophan**, when that proton is sterically hindered from exchanging because the side chain is buried, is, however, often slow enough to be measured.^{343,344} For example, when the constant fragment of human Bence-Jones protein Nag is dissolved in $[^2\text{H}]\text{H}_2\text{O}$, the proton on the indole nitrogen of Tryptophan 150, which is buried in its interior (Figure 6-39), exchanges with deuterons in the solvent at $1.2 \times 10^{-5} \text{ s}^{-1}$ at p^2H 7.1 and 25°C ,³⁴³ which is equal to the rate constant for the global unfolding of the protein at this pH and temperature. It was concluded that only upon the complete, transient unfolding of the protein does the proton on the indole nitrogen become sufficiently exposed to the solvent to exchange. A similar study of the rates of exchange of indole protons on the tryptophans in lysozyme from *G. gallus*, however, demonstrated that they exchanged more rapidly than the protein unfolds, presumably during local fluctuations in its structure that cause them to become exposed in turn to the aqueous phase.³⁴⁴

Almost all of the protons that are so sterically hindered from exchange by the structure of a molecule of protein that their rates of exchange are slow enough to be measured conveniently are **amido protons** in its peptide bonds. The rates of exchange of these amido protons can be monitored by following the rate at which protons are replaced by deuterons when the unmodified protein is transferred to a solution prepared with $[^2\text{H}]\text{H}_2\text{O}$ or the rate at which deuterons or tritons are replaced by protons when the protein that has been equilibrated in solutions made with $[^2\text{H}]\text{H}_2\text{O}$ or $[^3\text{H}]\text{H}_2\text{O}$, respectively, is transferred to a solution prepared with $[^1\text{H}]\text{H}_2\text{O}$. The exchange of a proton is registered when an acidic proton, deuteron, or triton dissociates from a lone pair of electrons on the protein and a deuteron, proton, or proton, respectively, then associates with that same lone pair of electrons. Because the concentrations of water, protons, and hydroxide ions are all constant at any particular pH, the exchange of a proton is a pseudo-first-order process with a pseudo-first-order rate constant.

The **exchange of an amido proton for a deuteron** when an undeuterated peptide is dissolved in $[^2\text{H}]\text{H}_2\text{O}$ can be followed by observing the decrease in the nuclear magnetic absorptions of its amido protons as a function of time.³⁴⁵ The observed pseudo-first-order rate constants, k_{ex} , display both **specific acid and specific base catalysis** (Figure 12-31):³⁴⁵

Figure 12-31: Magnitude of the observed first-order rate constants for the exchange of the amido proton on the amino-terminal side (solid symbols) or carboxy-terminal side (open symbols) in the *N*^α-acetyl-*N*-methyl amides of alanine (●, ○), serine (▲, △), and asparagine (◆, ◇).³⁴⁵ The structure of each compound is drawn and the protons that exchange are in boldface type. Solutions of each model compound were prepared in [²H]H₂O at the noted p²H and immediately introduced into a nuclear magnetic resonance spectrometer. The two amido protons in each compound produced the usual splitting into a doublet of the absorption of the spin-spin-coupled ¹hydrogen or ¹hydrogens on the respective, immediately adjacent carbons. As the proton on each nitrogen exchanged for a deuterium, the respective doublet was converted into a singlet. The areas of doublet and singlet were measured as a function of time, and it was observed that the doublet was converted to the singlet in a first-order process. The rate of this process was converted to an observed first-order rate constant, *k*_{obs} (minute⁻¹), and its value is plotted logarithmically as a function of p²H. The curves are fits of Equation 12-58 to the data. Reprinted with permission from ref 345. Copyright 1972 American Chemical Society.

$$k_{\text{ex}} = k_{\text{D}^+}[\text{D}^+] + k_{\text{OD}^-}[\text{OD}^-] \quad (12-58)$$

where D stands for deuterium. At the minimum rate (Figure 12-31), acid catalysis and base catalysis are of equal magnitude and the domination of one over the other inverts. The **catalytic mechanisms** are known to be

and

respectively.^{345,346} In both cases, the removal of the proton is the rate-limiting step in the reaction. The **second-order rate constants**, *k*_{D⁺} and *k*_{OD⁻}, have been tabulated for the amido protons on either side of specific side chains of amino acids in model compounds³⁴⁵ and small peptides.³⁴⁷ The second-order rate constants for acid catalysis, *k*_{D⁺}, vary between 6 and 5000 M⁻¹ min⁻¹ and those for base catalysis, *k*_{OD⁻}, vary between 2 × 10⁸ and 1 × 10¹¹ M⁻¹ min⁻¹.

When a protein such as myoglobin is incubated in tritiated water for an extended period of time at moderate temperature (37 °C), most of its amido protons reach equilibrium with the protons and tritons in the water. The tritiated water can then be replaced with untritiated water by molecular exclusion chromatography. During the chromatography all of the tritons on exposed polar side chains exchange with protons. When the tritium remaining on the protein is measured by liquid scintillation counting as a function of time at low temperature (0 °C), a population of tritiated amides that lose their tritons very slowly can be distinguished (Figure 12-32).³⁴⁸ The rates at which these amides exchange are far slower than the rates observed for small peptides in solution.³⁴⁷

The **amido hydrons on peptide bonds in a protein that exchange slowly** with other hydron isotopes in the solvent are the hydrons that participate in stable hydrogen bonds in the folded polypeptide.³⁴⁹ That the number of slowly exchanging tritons in myoglobin (Figure 12-32) is about equal to the number of amido protons participating in **buried hydrogen bonds** in the crystallographic molecular model (approximately 120) is consistent with this conclusion.³⁴⁸ In the case of lysozyme, the exchange

Figure 12-32: Exchange of tritons from myoglobin equilibrated with $[^3\text{H}]\text{H}_2\text{O}$ and then transferred to $[^1\text{H}]\text{H}_2\text{O}$ at pH 5, 0 °C.³⁴⁸ Myoglobin from *P. catodon* ($n_{\text{aa}} = 153$) was incubated at 37 °C and pH 9 with $[^3\text{H}]\text{H}_2\text{O}$ until equilibrium was reached (20 h) at all of its amides. The solution was cooled to 0 °C, and the protein was rapidly transferred by molecular exclusion chromatography to $[^1\text{H}]\text{H}_2\text{O}$. Over these intervals of preequilibrium, only protons on amides and more acidic acid-bases on the protein should exchange with tritons, and only the amides should retain any tritium through the chromatography. The amount of tritium associated with the protein [moles of tritium (mole of protein)⁻¹] was followed as a function of time (hours). Myoglobin contains 162 amido protons, and this number agrees favorably with the 155 tritons found on the protein at the earliest time after the chromatography. Reprinted with permission from ref 348. Copyright 1969 Academic Press.

of protons for deuterons at the amides of the polypeptide could be followed directly by observing the decrease in the absorbance of the amide II vibration in the infrared spectrum relative to the absorbance of the amide I vibration. The agreement between the number of slowly exchanging amido protons (44 moles for every mole of lysozyme) and the number of buried hydrogen bonds involving the amido protons of the polypeptide in the crystallographic molecular model is also quite close.³⁵⁰

It is also possible to follow such global exchange of the protons in a protein by **mass spectrometry**. The protein is diluted into $[^2\text{H}]\text{H}_2\text{O}$, and samples are removed at successive times and submitted to electrospray mass spectrometry to determine the number of deuterons that have been incorporated by exchange during each interval.³⁵¹⁻³⁵³ The samples are usually submitted to liquid chromatography in $[^1\text{H}]\text{H}_2\text{O}$ immediately prior to mass spectrometry to remove the $[^2\text{H}]\text{H}_2\text{O}$. This chromatography is performed at pH 3 and 0 °C to prevent exchange of the amido deuterons with protons but to permit exchange at carboxylic acids, amines, hydroxyls, thiols, and imidazoles, because the intention of such measurements is to monitor the global exchange of amido protons in peptide bonds. In some instances different populations of protons that exchange at different rates can be distinguished. In the case of fructose-bisphosphate aldolase from rabbit, these populations were

thought to represent protons from its different structural domains.³⁵³

A limitation of such global measurements of the exchange of amido protons is that the identity of those amides in the polypeptide that display slow exchange is not established. One way to increase the resolution is to digest quickly samples of the protein removed at different intervals over the time during which exchange is permitted to occur, separate the resulting peptides in each sample chromatographically, and use a mass spectrometer to assess the extent of incorporation of deuterium into each of the peptides.^{351,354} The exchange of protons is quenched at the end of each interval in $[^2\text{H}]\text{H}_2\text{O}$ by dropping the pH to 3 and the temperature to 0 °C to minimize further exchange. The protein, unfolded by the low pH, is digested with pepsin A, an endopeptidase that functions best at low pH; and the resulting peptides are separated by chromatography in $[^1\text{H}]\text{H}_2\text{O}$ at low pH and low temperature. Each peptic peptide is then identified by its mass and its pattern of fragmentation (Figure 3-8). In this way the amount of incorporation of deuterium into the amides of the peptide bonds within a particular segment of the folded polypeptide in the native protein, namely, that segment ending up in the peptic peptide, can be monitored.^{355,356} Still, the protons at the individual amides within that segment cannot be distinguished one from the other.

The advantage of such **endopeptidolytic analyses** is that they can be applied to large proteins³⁵⁵⁻³⁵⁸ such as rabbit fructose-bisphosphate aldolase ($n_{\text{aa}} = 4 \times 363$), the α -catalytic subunit of cyclic AMP-dependent protein kinase ($n_{\text{aa}} = 350$), human dual specificity mitogen-activated protein kinase kinase 1 ($n_{\text{aa}} = 393$), and dihydrodipicolinate reductase from *E. coli* ($n_{\text{aa}} = 4 \times 273$). Such large proteins cannot be analyzed by nuclear magnetic resonance. If, however, the protein is small enough, nuclear magnetic resonance spectroscopy can provide rates of exchange of most of the resolved amido protons along the polypeptide backbone in the native structure.

The cross-peaks in the fingerprint region of a two-dimensional (^1H - ^1H) **nuclear magnetic resonance correlated spectrum** (Figure 12-33)³⁵⁹ or a two-dimensional (^{15}N - ^1H) HSQC correlation spectrum³⁶⁰ arise from spin-spin coupling between an amido proton and its adjacent α ^1H hydrogen or amido ^{15}N nitrogen, respectively. When the protein is transferred from $[^1\text{H}]\text{H}_2\text{O}$ to $[^2\text{H}]\text{H}_2\text{O}$, each of these cross-peaks decreases in intensity as the amido proton exchanges for a deuteron (Figure 12-33).^{359,360} The rate of exchange of each proton is equal to the rate at which its cross-peak decreases in intensity.

It is generally assumed that a proton on a particular amide in the polypeptide backbone of a protein can exchange with a deuteron in the $[^2\text{H}]\text{H}_2\text{O}$ surrounding the protein only when that proton is exposed to the solution. An **unexposed position** in the polypeptide backbone becomes exposed as the result of a conformational change in the protein.^{361,362} Although the details of such conformational changes are unknown, they must differ

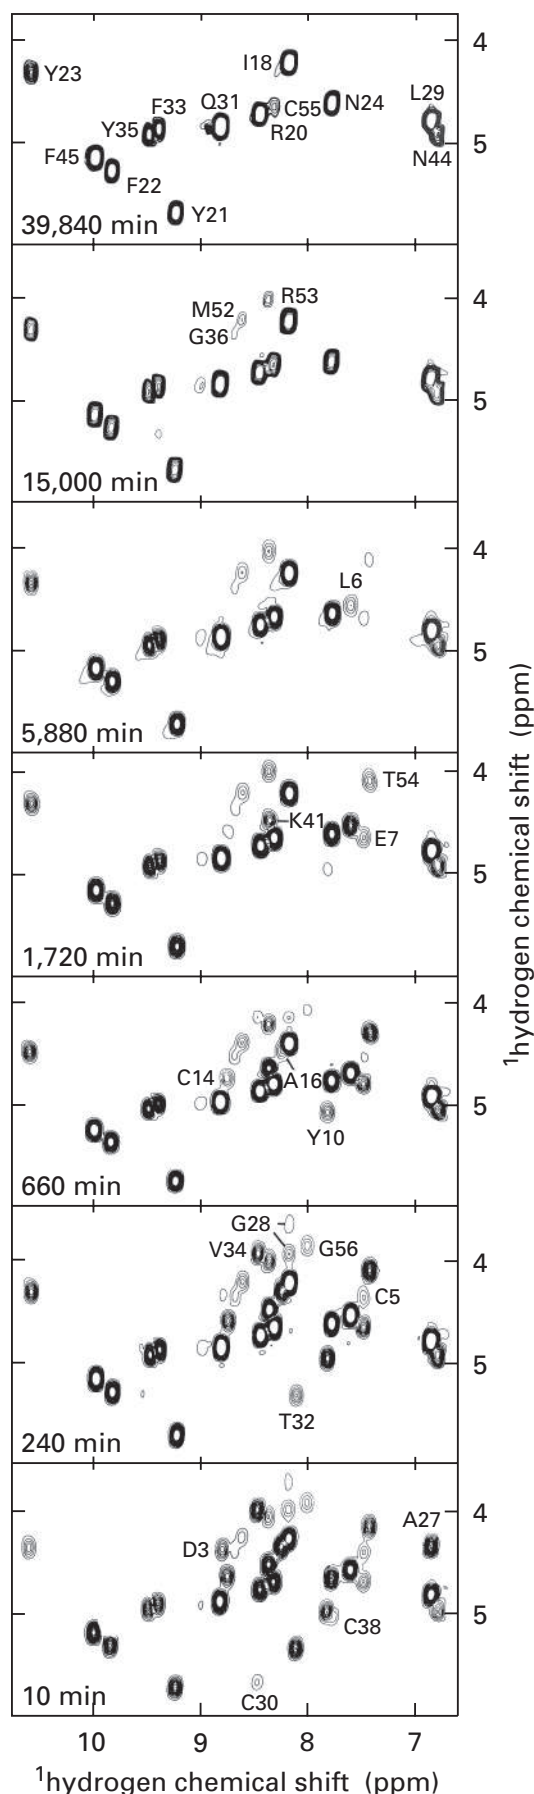

Figure 12-33: Exchange of amide protons in the polypeptide backbone of bovine basic trypsin inhibitor for deuterons in the solution.³⁵⁹ The protein was dissolved at a concentration of 0.02 M in $[^2\text{H}]\text{H}_2\text{O}$ and a p^2H of 3.5 and brought to 36 °C. After the noted times, samples were removed, the temperature was lowered to 25 °C, and a two-dimensional (^1H - ^1H) correlated spectrum was recorded. The fingerprint region containing cross-peaks resulting from spin-spin coupling between amide protons and α ^1H hydrogens (Figure 12-16) is presented. As amide protons in a given population exchange for deuterons, its cross-peak decreases in intensity. Each cross-peak is labeled in the last spectrum in which it can be observed with the position of its α ^1H hydrogen in the sequence of the protein. The cross-peaks from those amide protons remaining after 39,840 min are labeled with their positions in the sequence. Twenty of the original 32 cross-peaks disappear as a result of exchange of amide protons for deuterons in the solvent, and most of the cross-peaks remaining display sufficient decreases in intensity over this interval to give rate constants for the exchange of their amide protons. Reprinted with permission from ref 359. Copyright 1982 Academic Press.

from one location in the protein to another because protons exchange with a wide range of rate constants. **Conformational changes that expose protected protons** to the solution may be relatively rapid movements of loops on the surface, motions opening crevices in the surface of the protein more widely, fraying motions in α helices that unwind them from their ends,^{363,364} unzipping motions in β structure,^{365,366} or the complete, transient unfolding of individual elements of secondary structure,³⁶⁴ domains,³⁵³ or even the entire molecule of the protein.^{343,350,367} Almost all of the amide protons in the polypeptide backbone that exchange slowly enough that their rates can be measured are involved in hydrogen bonds in the native structure of the protein. Those hydrogen bonds must be broken during the conformational change to permit the unretarded³⁶⁸ exchange of the protons to occur.³⁴⁹

Associated with whatever conformational change is responsible for the exchange of a particular proton in a protein is a rate of opening k_{op} and a rate of closing k_{cl} . The **kinetic mechanism** for the process is³⁶⁹

where unexchangeable is the proton in a location where exchange is sterically prohibited, exchangeable is the proton in a location where it is exposed to the solution and exchange is unobstructed, exchanged is the site at which exchange has occurred and a deuteron is occupying the location that was occupied by the original proton, and k_{ex} is the pseudo-first-order rate constant for the exchange of the original proton by the deuteron.

There are two limits to the rate equation for this mechanism. If $k_{\text{ex}} \gg k_{\text{cl}}$ then

$$k_{\text{obs}} = k_{\text{op}} \quad (12-62)$$

where k_{obs} is the observed rate constant of exchange. This condition is the **EX₁ limit**. If $k_{\text{cl}} \gg k_{\text{ex}}$ then

$$k_{\text{obs}} = \frac{k_{\text{op}}}{k_{\text{cl}}} k_{\text{ex}} = K_{\text{conf}} k_{\text{ex}} \quad (12-63)$$

where K_{conf} is the equilibrium constant for the conformational change producing the exchangeable conformation, $[\text{exchangeable}]/[\text{unexchangeable}]$. This condition is the **EX₂ limit**.

It is customary to present the rate of exchange of a particular amido proton i in the polypeptide backbone of a protein in terms of its **protection factor**³⁴⁷ $k_{\text{ex},i}/k_{\text{obs},i}$. The rate constant $k_{\text{ex},i}$ is the reference rate constant for the exchange of that proton in the fully exposed, unfolded polypeptide, and $k_{\text{obs},i}$ is the observed rate constant under a given set of conditions. The rate constant for exchange in the fully exposed conformation, $k_{\text{ex},i}$, is assumed to be equal to the measured rate constant for exchange of an equivalent amido proton in a derivative of the amino acid (Figure 12-31)³⁴⁵ or short peptide³⁴⁷ as a function of pH. It has been shown by measuring the rates of exchange of particular amido protons in an unfolded polypeptide that such estimates are reliable.³⁷⁰

A protection factor for a particular proton is meaningful only when the exchange of the proton occurs at the EX₂ limit, where the protection factor is equal to the inverse of the equilibrium constant for the conformational change, K_{conf}^{-1} (Equation 12-63). When exchange occurs at the EX₁ limit, the observed rate constant is equal to $k_{\text{op},i}$, the rate constant for the opening of the structure that protects proton i (Equation 12-62). Dividing the observed rate constant by $k_{\text{ex},i}$ would be meaningless. Consequently, it is necessary to demonstrate that the exchange process is at the EX₂ limit for the protection factor to be meaningful. Presentations of protection factors in the absence of such a demonstration³⁷¹ are equivocal.

It is possible to make a **distinction between an EX₁ limit and an EX₂ limit** for exchange by evaluating whether the exchange at adjacent amido positions is **concerted** or not.³⁷² When exchange of a proton at a particular location occurs at the EX₁ limit, the open conformation persists long enough ($k_{\text{ex}} \gg k_{\text{cl}}$) that all of the protons at adjacent positions are exchanged before the protein snaps shut. Consequently, only two populations of protons at that location exist, one in which the proton and its neighbors have not yet exchanged and one in which both the proton and its neighbors have exchanged. When exchange of a proton at a particular location occurs at the EX₂ limit, the open conformation has such a short lifetime ($k_{\text{ex}} \ll k_{\text{cl}}$) that at most only one proton in a neighborhood can exchange at each opening. Consequently, in addition to the two populations already described, there are populations in which the proton has exchanged but its neighbors have not and populations in which the proton has not exchanged but its neighbors have. All of these populations can be distinguished by the

ratios of the intensities of cross-peaks arising from nuclear Overhauser effects. In the cases of both bovine basic pancreatic trypsin inhibitor ($n_{\text{aa}} = 58$) and α -amylase inhibitor HOE-467A from *S. tendae* ($n_{\text{aa}} = 74$), it was observed that, below 55 °C, the exchanges of all of the amido protons that could be monitored in the polypeptide backbone of each of these native proteins were unconcerted, consistent with exchange at the EX₂ limit.^{366,373}

Whether the exchange of a particular proton is at the EX₂ limit or the EX₁ limit can also be assessed by following the **effect of pH** on the observed rate of exchange. Above pH 5, $k_{\text{ex},i}$ for an amido proton in a peptide bond is directly proportional to the concentration of OH⁻ (Equation 12-58).^{345,347} If the exchange is at the EX₂ limit (Equation 12-63), it must display the expected increase in rate as the pH of the solution is increased. The observed rates of proton exchange at several of the peptide bonds in bovine basic pancreatic trypsin inhibitor at 68 °C increased by a factor of 10 for each increase of one unit in pH from pH 5 to 7³⁷³ as expected of exchange at the EX₂ limit. Above pH 7, however, the rates no longer increased as the pH was increased, perhaps because k_{ex} for these protons at this high temperature had become so rapid (Figure 12-31) that k_{ex} became greater than k_{cl} . These results suggest that the balance between exchange governed by the EX₂ limit and that governed by the EX₁ limit under certain conditions may lie in the range of physiological pH. In such instances, by following the exchange of a particular proton as a function of pH, the range of pH in which the EX₂ limit governs the exchange and the range of pH in which the EX₁ limit governs the exchange can be distinguished. In the former range, the exchange increases by a factor of 10 for every increase of one unit in pH; in the latter range, the exchange is invariant with pH. From such observations, values of k_{cl} , k_{op} , and K_{conf} for each member of a set of specific peptide bonds can be measured (Equations 12-62 and 12-63).³⁷⁴

It is difficult to make measurements of the exchange of protons at several values of pH. Often an analysis is made of rates of exchange at only two values of pH. In this instance, the logarithms of the observed rate constants of exchange of the amido protons in the polypeptide backbone at one pH are plotted as a function of their logarithms at a different pH.^{360,375} If they fall on a line of slope 1, then the individual conformational changes producing each exchange are not significantly dependent on pH, and if the line has an intercept at the ordinate axis equal to the difference in pH between the two solutions,³⁷⁵ then the process of exchange for each proton has the pH dependence expected of $k_{\text{ex},i}$ and is judged to be at the EX₂ limit. If, however, the intercept of the line is not equal to the difference in pH of the two solutions, the exchanges are not at the EX₂ limit.³⁶⁰ If the intercept of the line is zero, the exchange is probably at the EX₁ limit and the observed rate constants of exchange are equal to the

rate constants k_{op} for the various conformational changes permitting exchange.

In lysozyme from *G. gallus*, there is a group of amido protons in the core of the protein that all exchange their protons 10^6 times more slowly than the same amides in a small peptide.³⁵⁰ This group of amides in the center of the protein may be exposed to the solvent only during **large cooperative unfoldings** of a considerable fraction of the protein that expose many amido protons simultaneously for a short time before the polypeptide snaps shut again. If this is the case, these deeply buried regions of lysozyme spend 10^{-6} of their life in an unfolded state. The individual amido protons in the polypeptide backbone of bovine basic pancreatic trypsin inhibitor, however, have a rather heterogeneous set of rate constants of exchange (Figure 12–33).³⁷⁶ This suggests that **local vibrational modes** producing local unfoldings are responsible, at least in this protein, for performing the disconnections of a particular structure required to expose the amide to the solvent so that its proton can exchange. Whether the motions responsible for the exchange of a particular proton are local, regional, or global, the recurring observation that all or almost all of the amido protons, at least of small proteins, eventually exchange means that a molecule of protein is **continuously breathing** or unfolding throughout its lifetime.

It is also possible to observe the exchange of protons by **neutron diffraction**. Crystals of protein are routinely prepared for neutron diffraction by soaking them in $[^2\text{H}]\text{H}_2\text{O}$ to replace as many protons as possible with deuterons, which scatter neutrons more strongly. Molecules of trypsin³⁷⁷ and ribonuclease³⁷⁸ that had been soaking within crystals in $[^2\text{H}]\text{H}_2\text{O}$ for periods of 1 year retained protons on 54 and 28 of their amides, respectively. All of the sites that remained unexchanged were in the interior of the folded polypeptide. These were mainly on the central strands of β sheets and at the centers of α helices. Most of the sites retaining protons after 1 year were not even partially exchanged with deuterons, while those sites that had deuteriums were almost fully exchanged. The location of these sites and their occurrence in regions with very little thermal motion suggest that, in a crystal, only local motions are responsible for what exchange takes place. Because large regional unfolding or the complete unfolding of the polypeptide cannot occur in a crystal, these observations provide further evidence that the exchange of protons at deep locations in a protein observed in free solution result from such types of extensive unfolding.

Observations of the exchange of protons can be used to examine **heterologous associations**. For example, the rates of exchange of 11 amido protons in the polypeptide backbone of equine cytochrome *c*, which are at unrelated positions in its amino acid sequence but form a continuous region on the surface of the tertiary structure of the protein, decrease significantly when

it is bound by a monoclonal immunoglobulin.³⁷⁹ It was concluded that this region formed the epitope on the surface of the cytochrome *c*. When a synthetic peptide with the amino acid sequence from Alanine 1730 to Leucine 1747 in smooth muscle [myosin-light-chain] kinase from *G. gallus*, which was known to be the site to which calmodulin binds in the intact protein, associates with calmodulin, the rates of exchange of 12 of its amido protons decrease by factors between 10^3 and 10^6 as it forms the α helix embraced by the calmodulin in the complex.³⁶³

Results of such experiments, however, should be evaluated with caution. Effects on the exchange of amido protons can be felt at **locations distant from the site of interaction** because the association of a protein with a ligand always increases its global stability and consequently decreases the time its entire structure spends in open conformations. For example, the binding of thymidine 3',5'-diphosphate to micrococcal nuclease, causes the rate of exchange of at least 34 of its amido protons to decrease dramatically³⁸⁰ even though the site at which the ligand binds encompasses far fewer amino acids. In this instance, the binding of the ligand stabilizes the protein globally and decreases its conformational fluctuations. Likewise, when NADH is bound to dihydrodipicolinate reductase, the rates of exchange of amido protons in widely different locations showed significant decreases.³⁵⁵

Electron Paramagnetic Resonance

If an atomic orbital or a molecular orbital contains a pair of electrons, the magnetic moments of their spins cancel because of the Pauli principle, and that orbital is diamagnetic. If an orbital contains a single unpaired electron, that electron has an uncanceled magnetic moment and that orbital is **paramagnetic**. There are several ways in which a molecule of protein can contain an orbital with an unpaired electron. A **paramagnetic ion** of a transition metal such as Mn^{2+} , Fe^{3+} , Co^{2+} , Ni^{3+} , or Cu^{2+} can be bound to the protein either on its own or within a coenzyme like the heme in ferrimyoglobin (Figure 4–18). A **stable organic radical** like the glycyl radical in formate C-acetyltransferase or the tyrosyl radical in ribonucleoside-diphosphate reductase can be formed by posttranslational modification of the protein (Table 3–1). A coenzyme bound to the protein can contain an organic radical.³⁸¹ The protein can be modified with a reagent in which there is a stable organic radical, such as the one in a 1-oxyl-2,2,5,5-tetramethylpyrrolin-3-yl group:

12-11

Such a functional group can be coupled covalently either by incorporating an unnatural amino acid containing it into the protein in a cell-free translation¹⁵⁷ or by modifying the protein with an electrophilic reagent containing it.^{382,383}

An unpaired electron can have a **spin quantum number** of $+\frac{1}{2}$ or $-\frac{1}{2}$, and these two quantum numbers dictate two respective spin states with two respective angular velocities of the same magnitude but opposite polarity. When an unpaired electron is placed in an external homogeneous magnetic field, the axis of its spin tends to align with the direction of the applied field. The two degenerate energy levels of the spinning electron are split into two distinct energy levels, one for the spin aligned in the direction of the magnetic field and one for the spin aligned in the direction opposed to the magnetic field. The difference in energy between these two spin states for a given population i of identical unpaired electrons, ΔE_i , is directly proportional to the magnetic flux density B_i (tesla) at the location of unpaired electron i . The frequency ν_i (hertz) of electromagnetic energy that is absorbed by the population of electrons i during its transition between these spin states is

$$\Delta E_i = g_e \mu_B B_i = h\nu_i \quad (12-64)$$

where g_e is the g factor of a free electron (2.0023) and μ_B is the Bohr magneton ($9.27 \times 10^{-24} \text{ J T}^{-1}$). At magnetic flux densities normally used for electron paramagnetic resonance ($<2 \text{ T}$) the difference in energy is less than 20 J mol^{-1} , the energy contained in a photon of frequency less than 40 GHz , which is the microwave range of electromagnetic energy.

As with continuous-wave nuclear magnetic resonance spectrometers, an **electron paramagnetic resonance spectrometer** has a microwave generator of a fixed frequency, for example, 35 or 9 GHz , and the magnetic flux density is varied while the absorption of energy is monitored (Figure 12-34).³⁸⁴ Peaks of absorption are observed when Equation 12-64 is satisfied for a given population of identical electrons of unpaired spin. As with nuclear magnetic resonance, saturation of the absorption occurs readily in electron paramagnetic resonance owing to the small difference in the occupancy of the two spin states ($1 < K_{\text{sp}} < 1.008$) and the slow rate of relaxation between them. There are, however, several features of an electron paramagnetic resonance spec-

Figure 12-34: Electron paramagnetic resonance spectra of a 0.5 mM solution of CDP-6-deoxy-L-threo-D-glycero-4-hexulose-3-dehydrase in the presence of 10 mM CDP-6-deoxy-L-glycero-4-hexulose and 1 mM NADH frozen at 77 K .³⁸⁴ The bottom trace is the absorption as a function of the flux density of the magnetic field (tesla) at a carrier frequency of 9.05 GHz . The spectrum was obtained by varying the magnetic field while the microwave frequency remained fixed. The top trace is the first derivative (change in absorption/change in magnetic flux density) of the bottom trace; the dotted line sits on a value of zero for the first derivative. The $[2\text{Fe}-2\text{S}]$ cluster in the protein contains an unpaired electron that absorbs at g factors of 2.012 , 1.950 , and 1.932 , producing the three peaks of absorption in the two spectra at 0.321 , 0.331 , and 0.334 T , respectively. trum that distinguish it from a nuclear magnetic resonance spectrum.

For unpaired electrons on ions of transition metals, the intensity of the electron paramagnetic absorption increases and the width of the peak of absorption decreases dramatically as the **temperature of the sample** is lowered. For unpaired electrons on carbon, nitrogen, or oxygen, the intensity of the absorption also increases as the temperature is lowered. Consequently, electron paramagnetic resonance is often monitored while a sample of the protein containing the unpaired electron is in the frozen state at low temperature. For example, the electron paramagnetic resonance spectrum of aminocyclopropane carboxylate oxidase, the iron in whose heme had been complexed with nitrous oxide, was observed at 8 K ,³⁸⁵ and that of the molybdenum-iron protein of nitrogenase, the metal cluster of which had been complexed with ethene, was observed at 2 K .³⁸⁶ At such low temperatures, molecular motions and chemical reactions are severely limited. The most convenient low temperature is 77 K , the boiling point of liquid nitrogen, but the spectra of many types of organic radicals can be observed at room temperature even though the amplitudes of the peaks of absorption are less than they would be at lower temperatures.

The absorption of microwave energy is usually monitored as its **first derivative with respect to the flux density** of the magnetic field. Consequently, peaks of absorbance appear as pairs of positive and negative deflections representing the positive slope of the rising phase and the negative slope of the declining phase of the absorption itself, and the differential passes through zero at the maximum of each absorption (Figures 12–34 and 12–35).³⁸³

The absorption from a particular population of identical unpaired electrons is often split into two or more separate peaks by **spin–spin coupling**, either between the electron and magnetic nuclei connected to it by covalent bonds or between the electron and a magnetic nucleus on which it happens to reside. As in nuclear magnetic resonance, this spin–spin coupling results from local perturbations to the applied magnetic field. These perturbations are caused by differences in the orientations of the spins of the coupled nuclei, the magnetic fields of which are transmitted through the diamagnetic electrons in the covalent bonds surrounding the unpaired electron. As a result, the magnetic flux density sensed by a given electron i , B_i , is the sum of the flux density of the applied magnetic field, B_{app} , and the flux densities of any local magnetic fields, B_{loc} , created by these coupled magnetic nuclei. The spin–spin splitting in electron paramagnetic resonance is referred to as **hyperfine splitting**; the resulting pattern of peaks, as hyperfine structure; and the spin–spin coupling, as hyperfine coupling.

The 1-oxyl-2,2,5,5-tetramethylpyrrolin-3-yl group (12–11) serves as a simple example of hyperfine splitting (Figure 12–35). In this stable free radical, the nucleus that dominates the local magnetic field is that of the ¹⁴**nitrogen**, which has a spin quantum number of 1. The ¹⁴nitrogen nucleus is quadrupolar and can assume spins of +1, 0, and –1 with equal probability, because the distribution among its energy levels is insignificantly affected by the applied magnetic field. As a result, the local magnetic flux

density, B_{loc} , created by the nitrogen nucleus assumes three values, one of which is zero. The spectrum consists of a central absorption, arising from unpaired electrons coupled to nitrogen nuclei of spin quantum number 0 and from unpaired electrons not coupled to any magnetic nucleus, and two peaks of hyperfine absorption on either side of the central peak, arising from unpaired electrons coupled to nitrogen nuclei of spin quantum number +1 and –1. The hyperfine absorptions are of variable magnitude and are split different distances from the central absorption depending on the quality of the coupling between the nitrogen and the electron, but the central absorption will always be fixed because it is at the position where the contribution of the ¹⁴nitrogen to the local magnetic flux density is zero. Information about environment, rotational diffusion, and anisotropy is contained in the hyperfine absorptions.

The full coupling of the electron to the ¹⁴nitrogen is expressed in aqueous solution (Figure 12–35) because the electronic structure in which the radical occupies a **p orbital over nitrogen**, a distribution which requires a separation of charge, can be readily solvated by the water. In nonpolar environments such as within a molecule of protein, the nitroxyl radical can shift its hybridization to form an ethenyl molecular orbital system

12–12

composed from one of the lone pairs on oxygen and the radical. The unpaired electron occupies the **antibonding molecular orbital** and spends more of its time over oxygen, which is diamagnetic. This delocalization decreases the effect of the quadrupolar nucleus of the ¹⁴nitrogen, and the two hyperfine components decrease accordingly in intensity.

Hyperfine coupling can be used to draw conclusions about the **properties and location of the unpaired electron**. The unpaired electron on the glycy radical in formate C-acetyltransferase is unaffected by the diamagnetic ¹²carbon on which it resides but is split into two peaks by the single ¹hydrogen on that carbon (Figure 12–36).³⁸⁷ When formate C-acetyltransferase is transferred to [²H]H₂O, the ¹hydrogen exchanges with ²hydrogen in the solution in a reaction catalyzed by a nearby cysteine, and the spin–spin splitting disappears. Tryptophan tryptophylquinone is present in amine dehydrogenase as a posttranslational modification (Table 3–1, Figure 3–18). A model compound for tryptophan tryptophylquinone in which the two ⁺H₃N(COO[–])CH– groups of the bis(amino acid) are replaced with hydrogens can be reduced with one electron to produce the semiquinone with an unpaired elec-

Figure 12–35: Electron paramagnetic spectrum of 3-carbamoyl-1-oxyl-2,2,5,5-tetramethylpyrroline (see 12–11) in water at room temperature.³⁸³ The scale indicates the dimension of the horizontal axis in units of magnetic flux density (tesla). Figure 12-36: Electron paramagnetic resonance spectra of the glycy radical (Table 3-1) in formate C-acetyltransferase.³⁸⁷ The spectra were gathered from solutions of the protein at pH 7.6. (A) A solution (20 mg mL⁻¹) of the protein in $[^1\text{H}]\text{H}_2\text{O}$ was frozen in liquid nitrogen, and the spectrum was recorded at 77 K. (B) The solution was then thawed, mixed with three volumes of $[^2\text{H}]\text{H}_2\text{O}$, allowed to sit for 2 min, and refrozen, and another spectrum was recorded. The carrier frequency of the spectrometer was 9.23 GHz. The vertical axis is the first derivative of the absorption (change in absorption/change in magnetic flux density). The dimension of the magnetic flux density (tesla) along the horizontal axis is indicated by the scale, and the g factor of the absorption (2.0037) is indicated in panel A. Reprinted with permission from ref 387. Copyright 1995 American Chemical Society.

tron. The absorption from the unpaired electron in the semiquinone was split into at least 22 peaks. This splitting was thought to result from four nonequivalent ^1H hydrogens, one set of methyl ^{14}H hydrogens, and two nonequivalent ^{14}N nitrogens. It follows that, in the semiquinone, the electron must be delocalized over both indole rings.³⁸⁸ There is an unpaired electron in formate C-acetyltransferase that has been inactivated by covalent modification with fluoropyruvate. It could be shown to be located on carbon 3 of a defluorinated pyruvyl group because its absorption was split into three peaks when $[^1\text{H}]\text{fluoropyruvate}$ was used for the modification but was unsplit when $[^2\text{H}]\text{fluoropyruvate}$ was used.³⁸⁹

Just as in nuclear magnetic resonance, the set of peaks arising from the hyperfine splitting of the absorption from a particular population of identical unpaired electrons is distributed more or less symmetrically about a central point, which is the point in the spectrum at which that electron would have absorbed were its absorption not split by hyperfine coupling. This central point gives the g factor for that electron. The peak of the

absorption from a population of identical unpaired electrons that is unsplit by hyperfine coupling has its lone peak at its g factor (Figure 12-37).³⁹⁰ The flux density of the applied magnetic field, B_{app} , which is varied to produce the spectrum, can be converted into units of **g factor** (Figure 12-37) with the relationship

$$g = \frac{h\nu_0}{B_{\text{app}}\mu_B} \quad (12-65)$$

where h is Planck's constant (6.626×10^{-34} J s), ν_0 is the carrier frequency of the spectrometer, and μ_B is the Bohr magneton (9.274×10^{-24} J T⁻¹). When the unpaired electrons in a particular population are located on a carbon, a nitrogen, or an oxygen, the g factor of the absorption lies close to **2.0023**, which is that for a **free electron**. For example, the g factor for the absorption of the unpaired electron in a pheophytin radical in photosystem II from spinach is 2.0034;³⁸¹ that for the glycy radical in formate C-acetyltransferase from *E. coli* is 2.0037 (Figure 12-36);³⁸⁷ and that for the unpaired electron localized on ^{14}N nitrogen in **12-11** when it is covalently attached to Cysteine 76 of T4 lysozyme is 2.0066.³⁸²

If the unpaired spins of a particular population of identical electrons are on a paramagnetic transition metal ion such as Mn^{2+} , Fe^{3+} , Co^{2+} , Ni^{3+} , or Cu^{2+} , which affects the local magnetic field significantly, the g factor can vary dramatically depending on the **orientation of the orbital** it occupies relative to the direction of the applied magnetic field. For example, the orbital in which the unpaired electron resides on the ferric ion in a molecule of ferrimyoglobin (Figure 4-18) in a crystal of this protein is held in a specific orientation by the ligand field of the heme, which in turn is held in position by the crystal. In the unit cell of a crystal, there are two molecules of myoglobin, each with a different orientation. In the electron paramagnetic resonance spectrum of a crystal of myoglobin, there are two peaks of absorption, one for each of these orientations (Figure 12-37). When the crystal is rotated in the magnetic field, the g factors of the populations of electrons producing these peaks vary sinusoidally between a maximum of 6.0 and a minimum of 2.4.³⁹⁰ When the molecules of myoglobin are oriented randomly in a frozen solution, the absorption observed is the sum of all of the absorptions from the individual random orientations. As with the g factor of the absorption from an unpaired electron on a paramagnetic ion, the coupling constant for a particular hyperfine splitting from a magnetic nucleus can vary dramatically as the orientation of the orbital of the unpaired electron relative to the applied magnetic field is varied.³⁹¹ Such variations in g factor or coupling constant can be used to draw conclusions about the orientation in a particular sample of molecules in which the unpaired electron resides.

Just as energy transfer between two chromophores can be used to estimate the distance between them

Figure 12-37: Electron paramagnetic spectra of a crystal of myoglobin in the ferric oxidation state.³⁹⁰ A single crystal of ferrimyoglobin from *P. catodon* (1×10^{-8} mol) was oriented in the applied magnetic field so that its *ab* plane was parallel to the direction of the field and its *a* axis was at an angle of about 40° to the direction of the field. After the spectrum (A) of the crystal in this orientation was recorded, it was dissolved in 10 μ L of distilled water, the solution was frozen, and a second spectrum (B) was recorded. Both spectra were recorded at 77 K. The vertical axis, dA/dB , is the first derivative of the absorption with respect to magnetic flux density. The horizontal axis is calibrated in *g* factor, which is inversely proportional to magnetic flux density (Equation 12-65), hence the inverse calibration. Reprinted with permission from ref 390. (Equation 12-49), so can the magnitude of the **magnetic dipolar interactions** between two unpaired electrons. These dipolar interactions can be between an unpaired electron on a transition metal cation and an unpaired electron on a 1-oxyl-2,2,5,5-tetramethylpyrrolin-3-yl group³⁸² or between two 1-oxyl-2,2,5,5-tetramethylpyrrolin-3-yl groups.³⁹² The magnetic dipolar interactions decrease the intensity of the absorptions from the two unpaired electrons, and under appropriate circumstances an estimate of the distance between them can be made.³⁹² As with transfer of fluorescent energy, however, there are significant and usually uncontrolled **orientation factors** affecting the calculation. Changes in the magnitude of magnetic dipolar interactions between two 1-oxyl-2,2,5,5-tetramethylpyrrolin-3-yl groups inserted at specific positions in the amino acid sequence of T4 lysozyme have been used to monitor a change in its conformation upon binding of a ligand and estimate the change in distance between those positions during that conformational change.³⁹³

In simple situations it is often possible to infer the

identities of the magnetic nuclei producing a particular set of hyperfine splittings from a knowledge of the chemical structure of the radical bearing the unpaired electron. The identities of these inferred magnetic nuclei are usually confirmed by replacing them with one of their **isotopes** and observing the expected change in the hyperfine splitting. For example, the identity of the ^1H producing the hyperfine splitting of the absorption from the unpaired electron in the glycy radical in formate C-acetyltransferase (Figure 12-36) and the identities of the ^1H s around the phenyl ring producing the hyperfine splitting of the absorption from the unpaired electron in the tyrosyl radical of ribonucleoside-diphosphate reductase from *E. coli*³⁹⁴ were confirmed by replacing them with ^2H s.

If the pattern of hyperfine splitting cannot be explained because several unknown magnetic nuclei contribute to it, further information about their identity can be obtained from an **electron nuclear double resonance (ENDOR) spectrum**.^{395,396} The magnetic field of the spectrometer is adjusted so that the population of unpaired electrons is absorbing at the center of one of its hyperfine peaks. That absorption is then saturated by increasing the power of the microwave transmitter. The sample is then irradiated with a radiofrequency transmitter, the frequency of which is varied progressively. When the transmitter reaches the Larmor frequency of a population of magnetic nuclei participating in the particular hyperfine coupling that produced the peak on which the spectrophotometer is poised, the rate of relaxation of the electron increases and its absorption at saturation increases. The output of the spectrophotometer shows peaks of increases in absorption at radio frequencies equal to the Larmor frequencies of the population of nuclei producing the hyperfine splitting. There are a pair of Larmor frequencies for each population of coupled nuclei because the unpaired electron splits their absorption by the same coupling constant with which they split the absorption of the electron. These two peaks are centered on the Larmor frequency the population of coupled magnetic nuclei would have in the absence of the population of unpaired electrons.

Because the resolution of an electron nuclear double resonance spectrum is low and the splitting is large, usually all that can be learned is the **element of the population of coupled nuclei** and the coupling constant between that population of nuclei and the population of unpaired electrons. When $[8-^{15}\text{N}]N^8$ -hydroxyarginine is bound by rat neuronal nitric-oxide synthase, the hyperfine splitting of the absorption from the Fe^{3+} in the heme of the enzyme at a *g* factor of 4.03 could be shown to arise from the ^{15}N of the ligand because in the electron nuclear double resonance spectrum (Figure 12-38) there were a pair of peaks with the proper coupling constant centered on the Larmor frequency of the nucleus of a ^{15}N .³⁹⁷ Likewise, it could be shown that the hyperfine peak at a *g* factor of 1.96 in the electron paramag-

Figure 12-38: Electron nuclear double resonance (ENDOR) spectrum of a solution of 0.5 mM neuronal nitric-oxide synthase from *Rattus norvegicus* and 5 mM $[8-^{15}\text{N}]N^6$ -hydroxyarginine.³⁹⁷ The electron paramagnetic resonance spectrum of the frozen solution at 2 K had three peaks of absorption from the unpaired electron in the heme of the protein with g factors of 7.65, 4.03, and 1.8. The spectrometer was poised on the peak of absorption at the g factor of 4.03 at a microwave carrier frequency of 34.7 GHz, the absorption of microwave energy was saturated by increasing the output of the transmitter, and the absorption of microwave energy was recorded as a function of the applied radiofrequency energy. The absorption is presented as a function of radio frequency (megahertz) centered on the Larmor frequency (2.65 MHz) for ^{15}N at the applied magnetic field. The width of each peak exceeds by many fold the span of the full range of chemical shifts observed for ^{15}N in a protein (200 ppm). Reprinted with permission from ref 397. netic spectrum of the complex between $[^{13}\text{C}]$ ethene and the molybdenum-iron protein from nitrogenase was caused by the spin-spin coupling between the unpaired electron in the metal cluster and a ^{13}C in the bound ethene³⁸⁶ and that the hyperfine peak at a g factor of 4.23 in the complex between $[^{15}\text{N}]$ alanine, nitrous oxide, and aminocyclopropane carboxylate oxidase was caused in part by the spin-spin coupling between the ^{15}N of the alanine and the unpaired electron in the nitroxyl heme.³⁸⁵ In situations where electron nuclear double resonance spectra have several peaks because the peak of absorption on which the spectrophotometer is poised has several components, isotopic substitution, for example ^2H for ^1H , can sort out the origin of particular peaks.^{398,399} In complicated electron paramagnetic spectra in which it is unclear on which g factor a particular pattern of hyperfine peaks are centered, the coupling constants obtained from the electron nuclear double resonance spectra can often resolve the problem.

The similarity between electron nuclear double resonance spectra or electron paramagnetic spectra from two different molecules can be used as evidence that the radicals present in each are chemically identical. For example, the similarity between the electron nuclear double resonance spectrum of the radical in bovine cata-

lase to that of the tyrosyl radical in ribonucleoside-diphosphate reductase from *E. coli* confirmed that the former also was a tyrosyl radical.⁴⁰⁰ Likewise, the coincidence of the g factor for synthetic bacteriochlorophyll radical cation with the g factor of the initial photooxidized donor in the photosynthetic reaction center of photosynthetic bacteria and the fact that the absorptions from both of these radicals decreased by exactly the same factor when the bacteriochlorophyll and the bacteria, respectively, were perdeuterated identified the donor in the reaction center as a bacteriochlorophyll. The fact that under all circumstances the width of the absorption in the electron paramagnetic spectrum of the radical formed from the donor in the reaction center was $\sqrt{2}$ that of a monomeric bacteriochlorophyll radical cation demonstrated that the radical cation in the reaction center was actually an electronically coupled dimer of bacteriochlorophyll.⁴⁰¹ These conclusions were validated by the crystallographic molecular model of the protein.⁴⁰²

Chapter 13

Folding and Assembly

Each polypeptide begins its existence by emerging, amino terminus foremost, from a ribosome. Its initial amino acid sequence is the complete translation of the sequence in which the codons are arranged between the start codon and the stop codon on the messenger RNA. At some point in its early history, the polypeptide folds to assume its native state. The **native state** of a polypeptide is the limited set of equilibrating conformations in which it will spend the remainder of its lifetime and in which it is capable of performing its role within or on behalf of the living organism in which it was synthesized. The native state is the set of conformations of the polypeptide represented by the crystallographic molecular models of the protein. It is also referred to as the **folded state**. On the basis of the easily verified existence and identity of the native state, a denatured state of a polypeptide can be defined as its antonym. A **denatured state** of a polypeptide is any set of equilibrating conformations of that polypeptide that is not or does not contain the set of conformations of the native state. As it emerges from the ribosome, the nascent polypeptide is in a denatured state.

The initial folded state of the polypeptide can undergo posttranslational modification, it can combine with several other identically folded polypeptides of the same sequence or several other folded polypeptides of a different sequence and structure, or it can enter a helical polymeric protein as one of the protomers. The product of these steps is the mature native state of the protein encountered in the living tissue. The order in which these later processes occurs cannot be predicted, but all of them usually follow the folding of the unadorned polypeptide because it is usually only the folded polypeptide that contains the information controlling them.

Accordingly, the steps in the maturation of a protein can be divided into folding, posttranslational modification, and assembly. **Folding** is any process by which the polypeptide initially in a denatured state, for example, its set of conformations as it emerges from the ribosome, assumes the folded native state. **Assembly** is the process by which individual folded polypeptides associate to form their ultimate oligomeric or polymeric protein.

Thermodynamics of Folding

A polypeptide is a polymer of amino acids (2–15). It is known from studies of polymers in general that their

conformational behavior depends critically on the solvent in which they are dissolved.¹ If the functional groups of its repeating units are miscible with the solvent, the polymer is free to expand and expose all of those functional groups to that solvent without penalty. Such a solvent is a **good solvent**. When a polypeptide is dissolved in a good solvent, rotation about each bond between amide nitrogen and α carbon and between α carbon and acyl carbon is permitted, within the confines of the clashes represented in the Ramachandran plot (Figure 6–4) and within the requirement that no two atoms anywhere in the polypeptide can occupy the same space at the same time. As with any other unconfined organic molecule in solution, the conformation of a polypeptide in a good solvent is continuously changing as these rotations occur at random. Such a protean polymer in a good solvent is a **random coil**. This term incorporates unavoidably the uncontrolled and continuous motion of this process. A random coil is a special type of unfolded state. The **unfolded state** of a polypeptide is a state in which the polypeptide is significantly expanded relative to the native state so that most its structure is exposed to the solution even though it may not be a fully random coil.

Unfortunately, there are few good solvents for naturally occurring polypeptides. This is due to the fact that almost all^{2,3} natural polypeptides are created to fold. To fold, they must be composed of a mixture of hydrophobic and hydrophilic amino acids, placed in a particular sequence. There is almost no solvent in which the resulting mixture of side chains is miscible. In particular, water, although it is a good solvent for the hydrophilic side chains, is a bad solvent for the hydrophobic side chains.

A **bad solvent** is a solvent in which functional groups of the repeating units of a polymer are only sparingly soluble. In a bad solvent, a polymer contracts to decrease the exposure of those sparingly soluble functional groups to the solution. The hydrophobic effect is a force that seeks to minimize the exposure of a hydrophobic solute to water. Because of the hydrophobic effect that is exerted on the hydrophobic side chains in a natural polypeptide, water is a bad solvent for such a polypeptide at neutral pH and at an ionic strength of 0.2 M, which are the conditions under which most proteins are found. If water were not a bad solvent, natural polypeptides would not fold. Natural polypeptides, because they have evolved in water, fold in

water. Within a cell, each polypeptide begins its life emerging from a ribosome into the cytoplasm. Even though water is a bad solvent for the emerging polypeptide, it probably remains in an unfolded state until it reaches a length at which there are a large enough number of hydrophobic side chains to accomplish its contraction. Consequently, beyond a certain length, the polypeptide has the potential to contract to form a state other than a random coil, yet there are experimental observations suggesting that at least some incomplete polypeptides adopt expanded unfolded states when they are dissolved in aqueous solution.

Only glycerol, another cohesive, hydroxylic solvent, is also able to promote folding.⁴ Other pure solvents, because they dissolve hydrophobic functional groups rather than exclude them (Figure 5-22) cannot promote the folding of a polypeptide, but they are nevertheless bad solvents because they cannot solvate the polar side chains adequately. Consequently, if a polypeptide is not in its native state in a particular solvent, it will usually also not be a random coil. When an organic solvent that is miscible with water, such as ethanol, is added to a solution of protein, it causes the protein to denature because it solvates its nonpolar groups, but it also diminishes the solvation of the polar groups, preventing the formation of a random coil. **Denaturants** are solutes that, when added to an aqueous solution of a protein, promote the formation of a denatured state of that protein. Most denaturants do not turn water into a good solvent.

If one is studying its folding, both the native state and the denatured state of a polypeptide must be well-defined. The only denatured state of a polypeptide that can be defined with sufficient accuracy is a random coil. Therefore, the folding of a polypeptide is most informatively studied if the process that is monitored is the **isomerization between the random coil and the native state**, even though this may not be what occurs in a cell. For this study to be accomplished, a good solvent is required. One of the few ways to create a good solvent is to add either guanidinium chloride or urea to an aqueous solution of the protein. Both of these solutes are denaturants, but they are denaturants that create a good solvent. Regardless of whether or not a polypeptide in a cell is a random coil at its birth, experimentally an examination of the thermodynamics of protein folding usually begins with the polypeptide as a random coil in a concentrated solution of guanidinium chloride or urea.

When almost all natural proteins, the cystines of which have been reduced to cysteines, are dissolved in solutions of **guanidinium chloride** (13-1) or **urea** (13-2)

at concentrations of 6 or 8 M, respectively, they become completely unfolded, and their constituent polypeptides become random coils.

There are several ways to demonstrate this fact.⁵ The **molar masses** of the proteins determined from the colligative properties of these solutions are those of the constitutive polypeptides rather than the oligomers. The **intrinsic viscosities** of proteins dissolved in these solutions range from 15 to 100 cm³ g⁻¹ even though the intrinsic viscosities of the native proteins are between 3 and 5 cm³ g⁻¹. Furthermore, within a set of proteins, the intrinsic viscosities of their polypeptides dissolved in those solutions are correlated to the length of the constituent polypeptides by a relationship that agrees with theoretical expectation for the behavior of random coils. The optical rotatory dispersion spectra and **circular dichroic spectra** of proteins in such solutions are those theoretically expected from a polypeptide lacking any regular secondary structure, even if the spectra of the native proteins indicate that they are predominantly α helix and β structure. The **acid-base titration curves** of proteins dissolved in these solutions lose the normally observed shifts in intrinsic pK_a brought about by the electrostatic features of the native state and become simple sums of the constituent intrinsic acid-base titrations of the constituent amino acids (Table 2-2). All of the tyrosines in the protein display ultraviolet spectrophotometric acid-base titrations with expected intrinsic values of pK_a. The rates of **amido proton exchange** become very rapid when proteins are dissolved in these solutions, and no evidence for a class of slowly exchanging amido protons is usually found. The **ultraviolet spectra** between 270 and 300 nm of proteins dissolved in these solutions are simple summations of the spectra of phenylalanine, tyrosine, and tryptophan and display none of the spectral shifts characteristic of the native states.⁶

Solutions of either guanidinium chloride or urea promote the unfolding of a polypeptide by **increasing the stability of the random coil**. This increase in stability is due to favorable changes in the solvation both of the side chains of the amino acids and of the polypeptide backbone brought about by these solutes. From measurements of the solubility of various amino acids, as well as diglycine and triglycine, in solutions of either urea⁷ or guanidinium chloride,⁸ the standard free energies of transfer of both the side chains of the amino acids and the peptide bond between water and solutions of urea or guanidinium chloride have been estimated (Table 13-1). These **standard free energies of transfer** were derived from the differences between the solubilities of each of the amino acids and peptides and the solubilities of glycine in water, 7 M urea, or 5 M guanidinium chloride. To arrive at these estimates, it was assumed that the differences between the standard free energies of solution of glycine and each of the other amino acids in the various solutions of denaturants would give the standard

free energies of transfer of each of the side chains or the peptide bond, respectively.

The values obtained for leucine, phenylalanine, and tryptophan agree quite closely with direct measurements of the standard free energies of transfer for isobutane, toluene, and skatole as models of the respective side chains (Table 13–1).⁹ The *N*-acetyl ethyl esters of leucine and phenylalanine, however, were found to have standard free energies of transfer, relative to ethyl *N*-acetylglucinate, that were much less negative (Table 13–1).¹⁰ It may be premature to attach any significance to the absolute numerical values of these various estimates.

It has been uniformly observed that the free energies of transfer of both hydrophobic solutes and neutral hydrophilic solutes such as peptides between water and either 7 M urea or 5 M guanidinium chloride have negative values. Unlike the hydrophobic effect, which is imposed only on hydrogen–carbon bonds, the increase in solvation performed by urea and guanidinium ion is linearly related to the **accessible surface area** of the side chain, regardless of its polarity,¹¹ so that both hydrophobic and hydrophilic functional groups that are exposed to the solution upon formation of the random coil are more favorably solvated in solutions of urea or guanidinium chloride than they would be in water. This stabilization of the random coil increases monotonically, but not linearly¹² with the concentration of denaturant.^{7,8,10} At some concentration of the denaturant, which differs for each protein, the unfolded polypeptide becomes more stable than the folded polypeptide. This point is reached not only because of the increase in favorable solvation but also because the unfolded polypeptide is more disordered.

The favorable solvation of both polar and nonpolar functional groups in a polypeptide by urea or guanidinium ion quantified in the free energies of transfer in

Table 13–1 has been explained as the result of preferential binding of the denaturant to the random coil.^{5,13,14}

There is no evidence, however, for the existence of particular binding sites for either of these denaturants, which if they existed would have to be distributed rather uniformly over the dramatically heterogeneous surface of the random coil. A more realistic explanation would be that these denaturants partition favorably into the peculiar layer of water solvating the random coil, relative to the water in the bulk of the solution.¹⁵ Regardless of the molecular explanation, the experimental observation that accounts for the increase in the stability of the random coil relative to that of the native state is that both urea and guanidinium ion preferentially solvate those portions of a polypeptide exposed to the solution,^{15,16} and a random coil simply exposes more of the polypeptide than does the native state. The **preferential solvation** (Equation 1–57) of bovine serum albumin in its native state¹⁵ by urea is +0.10 g mL^{–1}; and by guanidinium ion, +0.14 g mL^{–1}. The increase in preferential solvation that occurs during the unfolding of lysozyme from *Gallus gallus* by urea¹⁶ is +0.25 g mL^{–1}. These positive experimentally measured preferential solvations demonstrate that both of these denaturants are significant salting-in solutes. They do not exert their effects by decreasing the cohesion of the water and producing in turn a decrease in the hydrophobic effect because both urea and guanidinium ion increase the surface tension of an aqueous solution.¹⁷

The favorable solvation of the hydrophobic side chains by urea and guanidinium chloride does make a major contribution to the stabilization of the random coil (Table 13–1). This observation suggests that urea and guanidinium chloride cause the solution to become more like a usual organic solvent in its properties (Figure 5–22). This effect may result from the stable introduction

Table 13–1: Estimates of the Standard Free Energy of Transfer of Various Side Chains of the Amino Acids between Water and Solutions of Urea or Guanidinium Chloride

amino acid side chain	$\Delta G^{\circ}_{\text{transfer, H}_2\text{O} \rightarrow 7 \text{ M urea}}$ (kJ mol ^{–1})			$\Delta G^{\circ}_{\text{transfer, H}_2\text{O} \rightarrow 5 \text{ M GdmCl}}$ (kJ mol ^{–1})

^aCalculated from the difference between solubility of glycine and the appropriate amino acid.^{7,8} ^bFree energy of transfer of isobutane, toluene, or skatole.⁹ ^cDifference in free energy of transfer of ethyl *N*-acetylglucinate and *N*-acetyl ethyl ester of the amino acid.¹⁰

of the nonpolar π clouds of the denaturants (2–26) into the solution. *N*-Alkyl-, *N,N'*-dialkyl-, and *N,N,N',N'*-tetraalkylureas are even more effective at increasing the solubility of naphthalene, indole, and ethyl *N*-acetyltryptophanate in water than is urea itself.^{18,19} This observation also suggests that it is nonpolar noncovalent interactions between urea and the hydrophobic amino acids that explain its ability to solvate them favorably.¹⁸ The fact that methylurea, dimethylurea, and tetramethylurea are each in turn increasingly better denaturants of proteins than urea itself¹⁹ and the fact that some alkylureas are better denaturants than even guanidinium chloride²⁰ suggest that the favorable solvation by urea of the hydrophobic functionalities revealed during the formation of the random coil, in addition to its ability as a donor or acceptor of hydrogen bonds,¹⁴ is the major feature of its ability to promote unfolding.

A polypeptide will fold only if the free energy of the native state is less than the free energy of all accessible denatured states. Because of this requirement, for example, a nascent polypeptide cannot fold until it is long enough for the native state to contain a large enough collection of noncovalent interactions to overcome the significant unfavorable loss of standard entropy that must always accompany folding. It is also the case that a polypeptide which has undergone extensive covalent **posttranslational modification** after it originally folded may not be able to fold again after it has been returned to a denatured state. For example, proinsulin can be unfolded and its cystines reduced to cysteine. The protein will then refold spontaneously to its native state, and the proper cystines will reform under oxidizing conditions.²¹ Insulin, however, which is a posttranslationally modified fragment of proinsulin, missing 25 amino acids from the middle of the polypeptide, does not refold spontaneously after it has been unfolded and its cysteines reduced, and it can be refolded only with subterfuge. The only fact that seems to be inescapable is that, at some point in its lifetime, a polypeptide has a covalent structure capable of folding to produce either the mature native state directly or an initial native state, which is modified subsequently but retains its basic folded state.

A polypeptide that has not been modified so extensively as to cause the mature native state to be higher in free energy than the random coil or higher in free energy than any other accessible denatured state will, under the proper circumstances, **spontaneously refold** to its mature native state after it has been purposely turned into a random coil by dissolving it in 6 M guanidinium chloride or 8 M urea. Most of our understanding of the folding of polypeptides has been derived from the study of such conformational isomerizations. Their existence states that all of the information necessary to achieve the proper native state resides in the amino acid sequence of the polypeptide.

The conformational isomerization that encom-

passes the process of protein folding can be presented as the equilibrium

where F is the polypeptide folded in its native state and U is the unfolded state. The rate constants k_F and k_U are composite rate constants including any kinetic steps between the two extremes, and the **equilibrium constant for folding**, K_{Fd} , is defined by

$$K_{Fd} = \frac{[F]_{eq}}{[U]_{eq}} = \frac{k_F}{k_U} \quad (13-2)$$

Because polypeptides folded in their native state are by design reasonably stable in aqueous solution at physiological temperatures and ranges of pH, the molar concentration of the unfolded state under normal circumstances is immeasurably low, and in such a situation, neither the equilibrium constant nor the thermodynamic changes associated with folding can be measured directly by following the concentrations of the two forms of the protein. One solution to this problem is to shift the equilibrium by introducing an unnatural perturbation. Because the unfolded states produced by adding guanidinium ion or urea are random coils, the least controversial perturbation that can be used to shift the equilibrium is to add increasing concentrations of one or the other of these solutes to a series of solutions of the protein. As the concentrations of these perturbants are increased, the unfolded form of the protein becomes more and more stable until the equilibrium constant for Equation 13–1 is small enough for measurable amounts of the unfolded form of the protein to exist.

Raising the temperature or lowering the pH of the solution or a combination of these perturbations also stabilizes unfolded states of the protein relative to the native state. The decrease in the magnitude of the equilibrium constant for Equation 13–1 brought about by **raising the temperature** is presumably due to increases in thermal motion that always shift reactions in favor of more disordered states. The decrease in the magnitude of the equilibrium constant brought about by **lowering the pH** is due to the fact that, because an unfolded state is expanded relative to the folded state, it can support a greater net charge and thus can take up more protons than the folded state as the pH is lowered. The relationship between the equilibrium constant for folding and the pH of the solution is governed by the differential equation⁵

$$\frac{\partial \ln K_{Fd}}{\partial \ln a_{H^+}} = \bar{Z}_{H,F} - \bar{Z}_{H,U} \quad (13-3)$$

where a_{H}^+ is the activity of protons in the solution and $\bar{Z}_{\text{H,U}}$ and $\bar{Z}_{\text{H,F}}$ are the mean net proton charge numbers of the unfolded and the folded states of the protein, respectively.

The unfolded state of the protein can support a greater mean net proton charge number because the values of $\text{p}K_{\text{a}}$ for its functional groups are higher. Consequently, it takes up more protons as the pH is lowered than does the folded state. This fact is verified by measuring the **acid–base titration curves** of the protein (Figure 1–11) in the absence and the presence of 6 M guanidinium chloride.^{22–24} The two titration curves are then related to each other in absolute terms by measuring the moles of protons that must be added to a solution to maintain a constant pH as the protein is unfolded by adding guanidinium chloride.²⁴ In the acid region of the titration curves, the mean net proton charge number of the unfolded state is usually greater than that of the folded state, so the equilibrium constant for folding decreases as the pH is lowered (Equation 13–3). The decrease in K_{Fd} becomes more pronounced the more the pH is lowered so that a larger and larger fraction of the carboxylates in the protein become involved in the titration.²³ At low ionic strength, there also may be a small increase in the repulsion between the positively charged side chains in the compact native state, which destabilizes it relative to the denatured state.²⁵

Because a side chain that is an acid–base often titrates anomalously when it becomes incorporated into the native structure of a protein, its incorporation will affect the equilibrium constant for folding. If the side chain is a carboxylic acid, the effect of its incorporation is most readily understood by considering the folding–unfolding at a pH low enough that it is fully protonated in both the unfolded and the folded states. If it is buried in the folded state so that its $\text{p}K_{\text{a}}$ is elevated,²⁶ the carboxylic acid will lose its proton at a higher pH in the folded state than in the unfolded state. Consequently, as the pH is raised, $\bar{Z}_{\text{H,F}}$ will be greater than it would have been if the carboxylic acid had not been buried, and the equilibrium constant for folding will be smaller than it would have been.^{27,28} If the carboxylic acid has its $\text{p}K_{\text{a}}$ lowered by participating as the acceptor in one or more hydrogen bonds in the folded state,^{29,30} it will lose its proton at a lower pH in the folded state than in the unfolded state, and the equilibrium constant for folding will be larger than it would have been.³¹ For example, Aspartate 76 in ribonuclease T₁ from *Aspergillus oryzae* participates in several hydrogen bonds in the native state that lower its $\text{p}K_{\text{a}}$ to 0.5, coincident with an increase in the equilibrium constant for its folding of a factor of 400.³⁰ A buried lysine, the $\text{p}K_{\text{a}}$ of which is lowered because it remains unprotonated in the folded state of a protein,²⁶ also decreases the stability of the folded state relative to the unfolded state³² for the same reasons that a buried carboxylic acid does, but the argument begins with a pH high enough that the lysine is unprotonated in

the unfolded state and the pH is decreased. Similarly a histidine with an elevated $\text{p}K_{\text{a}}$ stabilizes the folded state.²⁹ All of these shifts can be explained quantitatively by considering the effects of the respective values of $\text{p}K_{\text{a}}$ for a particular side chain on the magnitudes of $\bar{Z}_{\text{H,F}}$ and $\bar{Z}_{\text{H,U}}$ ⁵ in the integrated form of Equation 13–3.^{31–33}

A solution of **guanidinium chloride at 6 M** seems to produce the most complete unfolding to the random coil.⁵ The values of the various physical parameters for the same protein dissolved in 8 M urea rather than 6 M guanidinium chloride are slightly but significantly displaced in the direction of a folded state. Proteins dissolved in solutions of low pH the temperatures of which have been raised until no further change in optical rotation occurs will still display further changes when guanidinium chloride is added,^{5,34} even when no intramolecular hydrogen bonds seem to remain in the denatured protein,³⁴ and this observation suggests that reversible thermal denaturation does not produce a random coil. Lowering the pH of a solution of a protein without applying heat often leads to its denaturation, but the denatured state produced by acid alone usually also retains residual structure.^{35,36} When either the temperature is increased or the pH is lowered, hydrophobic clusters (Figure 6–21) in otherwise unfolded polypeptides should remain associated. This would account for the incomplete unfolding observed in these situations.

In any meaningful measurement of the properties of folding, the conditions must be such that the reaction remains reversible. When a concentrated solution of ovalbumin and lysozyme, otherwise known as the white of an egg, is heated, the polypeptides unfold but then rapidly coagulate among themselves to form a white, intractable, gelatinous precipitate. In the unfolded state produced initially by raising the temperature, otherwise buried hydrophobic amino acids on these polypeptides all become simultaneously exposed to the solution and noncovalent intermolecular polymerization takes place. There is little doubt that, in this example, a significant portion if not the majority of the changes in standard enthalpy and standard entropy proceeding during this process are those of the coagulation, which is of only marginal interest.

In all studies of protein folding, the first result presented should demonstrate the complete **reversibility of the reaction**. Foldings perturbed by the addition of urea or guanidinium chloride usually are reversible. With larger proteins, the rates of renaturation from a concentrated solution of urea or guanidinium chloride, however, can be slow; and if the concentration of denaturant is abruptly decreased by dilution, an otherwise reversible folding can become irreversible.³⁷ Denaturation produced by acid is usually reversible because the denatured polypeptides are so positively charged that they will not coagulate.³⁶

Although a few foldings perturbed solely by increases in temperature are reversible at neutral pH,^{38,39}

most proceed irreversibly, usually with coagulation.⁴⁰ When thermal unfolding is performed in a **scanning calorimeter**, however, the solution is heated continuously while the absorption of excess heat is monitored. It is possible that, under these conditions, the transition from folded protein to unfolded protein takes place in a short enough period that little coagulated protein accumulates, and the reaction remains reversible during that interval and only becomes irreversible upon coagulation at the higher temperatures experienced beyond the range of temperatures encompassing the transition to the denatured state. It has been argued that the behavior of many foldings in a scanning calorimeter—namely, the shapes of the curves, the effects of ligands, and the molecularities of the apparent reactions—is that expected of a simple reversible isomerization.^{41,42} At low pH (pH 2–3), however, most thermally perturbed foldings, even though they would proceed with coagulation at higher pH, often become reversible.^{43,44} Presumably, this is due to the fact that coagulation is prevented by charge repulsion among the denatured polypeptides. It is usually observed that a polypeptide denatured thermally and reversibly at low pH will coagulate visibly and irreversibly as the pH is increased, and often the onset of this coagulation is found to occur abruptly within a very narrow range of pH.⁴⁵

When a physical property of a protein such as its intrinsic viscosity, its sedimentation velocity, its optical rotation, its molar ellipticity, its intrinsic fluorescence, its

absorption of ultraviolet light, its capacity to take up protons from the solution at constant pH,²⁴ its absorption of heat at constant temperature,⁴⁶ its elution volume on chromatography by molecular exclusion,⁴⁷ its electrophoretic mobility,¹¹ or its nuclear magnetic resonance absorptions^{48,49} is measured as a function of temperature, pH, or the concentration of urea or guanidinium chloride, changes indicative of a **shift in the value of the equilibrium constant** K_{Fd} for folding (Equation 13–1) are observed (Figure 13–1A).⁵⁰

Each pair of experimental points (a square and a circle) in Figure 13–1A represents a solution of cold shock-like protein from *Thermotoga maritima* at a particular temperature, pH, and concentration of guanidinium chloride. Two different initial solutions of protein were used. Either a solution of the native protein in the absence of denaturant was diluted by mixing into a solution of guanidinium chloride (open symbols) or a solution of the unfolded protein in 5.5 M guanidinium chloride was diluted by mixing into a solution of guanidinium chloride (solid symbols). In each case, the mixture was formulated to produce the noted final concentration of denaturant. One member of each pair of points is the initial fluorescence of the solution immediately after mixing (squares). For each final concentration of guanidinium chloride, the solution was allowed to reach equilibrium (circles), which was assumed to be the state after all changes in fluorescence had ceased.

Figure 13–1: Shift of the equilibrium constant for the folding of the cold shock-like protein from *Thermotoga maritima* ($n_{aa} = 66$) in solutions of guanidinium chloride.⁵⁰ Solutions of cold shock-like protein and solutions of guanidinium chloride, both at 25 °C, were mixed in a rapid mixing chamber that then introduced the mixture immediately into the cuvette of a fluorometer so that the fluorescence of the solution (expressed as the voltage from the photomultiplier) could be monitored continuously. The emission at wavelengths greater than 300 nm upon excitation at 280 nm (intrinsic fluorescence of tryptophan) was monitored as a function of time. (A) Initial and equilibrium levels of fluorescence. A solution of protein (15 μ M) was diluted 11-fold by mixing into solutions of guanidinium chloride prepared so that the final concentration (molar) of guanidinium chloride (GdmCl) after mixing would be that noted on the horizontal axis. The initial solution of protein was prepared either in an aqueous buffer at pH 7.0 (open symbols) or in the same aqueous buffer 5.5 M in guanidinium chloride (solid symbols). The latter solution unfolded the protein completely. The initial fluorescence of each sample immediately after mixing was estimated by extrapolating the traces back to zero time (squares) to correct for the short interval between mixing and the start of the monitoring. Each isomerization was allowed to progress until the lack of further changes in fluorescence indicated that equilibrium had been reached. The fluorescence of the solution at equilibrium (circles) is plotted as a function of the final concentration of guanidinium chloride for protein that was refolded (\bullet) from 5.5 M guanidinium chloride or that was unfolded (\circ). (B) Rate constants for folding. For each sample, the fluorescence was monitored continuously as a function of time at 25 °C after mixing. The fluorescence in each sample either decreased or increased, respectively, as unfolding or folding progressed with first-order kinetics. Plots of these changes in fluorescence were fit by nonlinear least-squares to single-exponential functions to obtain first-order rate constants, $k_U + k_F$ (second⁻¹), which are plotted as a function of the final concentration (molar) of guanidinium chloride (GdmCl). Reprinted with permission from ref 50. Copyright 1998 Nature Publishing Group.

Below a certain concentration of guanidinium chloride (about 2 M), there is, at equilibrium, a linear increase in the intrinsic fluorescence with decreasing concentration of guanidinium chloride. Even in samples of native protein that eventually will unfold (\square), the immediate magnitude of the fluorescence upon addition of guanidinium chloride, before unfolding commences, falls upon this baseline. This **baseline** traces the perturbation in the intrinsic fluorescence of the fully folded state due only to addition of the denaturant in the absence of any unfolding or after complete folding has been achieved.

Above a certain concentration of guanidinium chloride (about 4 M) there is, at equilibrium, a linear increase in intrinsic fluorescence with increasing concentration of guanidinium chloride, presumed to reflect the effect of increasing the concentration of denaturant on the intrinsic fluorescence of the unfolded polypeptide. When fully unfolded protein is diluted into the range of concentrations of guanidinium chloride where it will fold (\blacksquare), the immediate fluorescence of the solution before folding commences also falls upon this other baseline.

At intermediate concentrations of guanidinium chloride, in the region of transition, the observed magnitudes of the intrinsic fluorescence at equilibrium fall between the extremes of fluorescence of the fully folded protein and the fluorescence of the fully unfolded protein. The **region of transition** is that range of denaturant concentration, pH, temperature, or pressure in which measurable concentrations of both denatured and native states are present in the solution in equilibrium with each other. It is flanked on its two sides by the ranges in which the polypeptide is almost completely folded and almost completely unfolded, respectively. It is in the region of transition that the equilibrium constant between the native state and the denatured state can be measured because sufficient concentrations of both states are present in the solution so that both are registered by the physical property being monitored.

Within the region of transition, the same equilibrium value is reached whether the folded protein (\square) or the unfolded protein (\blacksquare) is the initial state, and this demonstrates that a reversible process is being monitored. If an equilibrium between folded state and unfolded state has not been established over the interval of observation, such a coincidence between the curve for folding and the curve for unfolding is not observed.⁵¹ That the changes in the measured parameter within the region of transition cease at **intermediate values** between the extremes is also consistent with the conclusion that equilibrium has been achieved.

Assume for the moment that at all concentrations of guanidinium chloride the solution contains an equilibrium mixture of only the fully native protein and its random coil. This is the **two-state assumption**.⁵² At high enough concentrations of guanidinium chloride, the

concentration of random coil becomes sufficiently large that it contributes significantly to the intrinsic fluorescence. At this point, the isomerization of the folding (Equation 13-1) continuously interconverts measurable quantities of native state and measurable quantities of unfolded state in equilibrium with each other. As the concentration of guanidinium chloride is increased further, a greater fraction of the protein is in the unfolded state until, finally, immeasurably small amounts of the native state are present at equilibrium.

A similar monotonic transition between the native state and a denatured state, the two in equilibrium with each other, is observed when a series of solutions of a protein are each brought to a different temperature, as long as the thermal denaturation is reversible (Figure 13-2).⁵³ In the example presented in the figure, the increase in the stability of the denatured state relative to that of the native state with decreasing pH, as defined by Equation 13-3, is apparent in the shifts of the regions of transition to lower temperatures as the pH of the solution is lowered. Similar shifts of the region of transition caused by either pH⁵⁴ or temperature⁴⁶ are observed when the equilibrium between folded and unfolded states is being shifted with guanidinium chloride or urea. A monotonic transition reflecting the shift in equilibrium

Figure 13-2: Shift of the equilibrium constant for the folding of bovine ribonuclease A produced by increases in temperature at different values of pH: 1.13 (\bullet), 2.10 (\bullet), 2.50 (\circ), 2.77 ($+$), and 3.15 (∇).⁵³ The difference in extinction coefficient ($\Delta\epsilon$; liters gram⁻¹ centimeter⁻¹) is the difference between the extinction coefficient at 287 nm for ribonuclease at pH 7, 25 °C, and the samples at the noted pH and temperature. The changes in extinction coefficient over the ranges monitored were fully reversible. The samples were buffered with 40 mM glycine (pH 2.77 and 3.15) or by the protein itself (pH < 2.7). For each point on the curves, the solution was brought to the noted temperature (degrees Celsius), and the absorbance was tabulated after it no longer changed. The change in extinction coefficient is plotted as a function of the final temperature. Reprinted with permission from ref 53. Copyright 1967 American Chemical Society.

between the native state and a denatured state can also be observed by differential scanning calorimetry,³⁹ provided the rate of temperature increase is slow enough that equilibrium is reached at each temperature and the process remains reversible over the interval in which the region of transition is traversed.^{55,56}

If the two-state assumption is made, the fluorescence of the solution (F_{obs}) observed at equilibrium at each concentration of guanidinium chloride in Figure 13-1A is

$$F_{\text{obs}} = f_F F_{0,F} + f_U F_{0,U} \quad (13-4)$$

where $F_{0,F}$ is the intrinsic fluorescence that would be observed if all of the protein were fully folded, $F_{0,U}$ is the intrinsic fluorescence that would be observed if all of the protein were fully unfolded, f_F is the fraction of the protein in the folded state, and f_U is the fraction of the protein in the unfolded state, all at the particular concentration of guanidinium chloride. Because $F_{0,U}$ and $F_{0,F}$ at each concentration of guanidinium chloride are known from the respective baselines and because $f_F + f_U = 1.0$ as a result of the two-state assumption, f_F and f_U at each concentration of guanidinium chloride can be calculated. From f_F and f_U , the equilibrium constant for folding ($K_{\text{Fd}} = f_F/f_U$) can be determined for that concentration of guanidinium chloride, temperature, and pH. The same analysis can be applied to the behavior of any other **physical property** that is directly proportional to the concentration of native protein and denatured protein, respectively, such as absorbance, optical rotation, circular dichroism, or specific viscosity.

If the two-state assumption is correct and significant concentrations of only the native state and the random coil are present at each concentration of guanidinium chloride, then the situation is dramatically simplified. It is, however, reasonable that this should be the case. When a polypeptide folds from a random coil to form the native state under physiological conditions, it must pass through intermediate states between the random coil and the native state. If, however, these intermediate states were as stable or more stable than the folded state, there would be significant, measurable concentrations of them at equilibrium, a possibility that has rarely been observed and that would be unfortunate for the protein in terms of both its function and its ability to avoid endopeptidolytic digestion. That these intermediate states remain less stable than the native state as guanidinium chloride is added to the solution is not surprising, so long as they are about as compact as the native state. There are several observations which suggest that, in many cases, the two-state assumption is valid.

In the region of transition, a point on the curve in Figure 13-1A should represent, if the two-state assumption is valid, an equilibrium mixture of only fully native protein and its random coil. The same equilibrium mixture forms when either the native state in the absence of

guanidinium chloride (□) or the random coil in a concentrated solution of guanidinium chloride (■) is transferred into a solution at that pH and final concentration of guanidinium chloride. Either of these reactions is a special case of a general kinetic category referred to as an **approach to equilibrium**.

The approach to equilibrium of either the unfolding or the folding polypeptide, respectively, should be governed only by the two composite first-order rate constants k_F and k_U (Equation 13-1) if the two-state assumption is valid. Either the unfolded state or the folded state, respectively, should be the exclusive product formed in the two reactions as the equilibrium is established. The rate at which the concentration of either species, U or F, in Equation 13-1 changes is

$$-\frac{d[U]}{dt} = \frac{d[F]}{dt} = k_F[U] - k_U[F] \quad (13-5)$$

Because the concentration of total protein, $[\text{protein}]_{\text{TOT}}$, remains constant, it follows that

$$[U] + [F] = [\text{protein}]_{\text{TOT}} = [U]_{\text{eq}} + [F]_{\text{eq}} \quad (13-6)$$

where $[U]_{\text{eq}}$ and $[F]_{\text{eq}}$ are the concentrations of native state and random coil at equilibrium. Combining Equations 13-5 and 13-6 and focusing on the concentration that is decreasing, arbitrarily chosen to be the unfolded form for the following derivation, then

$$-\frac{d[U]}{dt} = (k_F + k_U)([U] - [U]_{\text{eq}}) - k_U[F]_{\text{eq}} + k_F[U]_{\text{eq}} \quad (13-7)$$

At equilibrium no further changes occur in the concentrations of either the native state or the random coil so

$$k_U[F]_{\text{eq}} = k_F[U]_{\text{eq}} \quad (13-8)$$

at all times, and, because $[U]_{\text{eq}}$ is a constant

$$\begin{aligned} -\frac{d[U]}{dt} &= -\frac{d([U] - [U]_{\text{eq}})}{dt} = \\ &= (k_F + k_U)([U] - [U]_{\text{eq}}) = k_{\text{obs},F}([U] - [U]_{\text{eq}}) \end{aligned} \quad (13-9)$$

where $k_{\text{obs},F}$ is the observed rate constant for the approach to equilibrium during net folding.

Equation 13-9 is a simple first-order differential equation in the variable $([U] - [U]_{\text{eq}})$ and describes a first order-process in this variable. Upon integration

$$\frac{[U] - [U]_{\text{eq}}}{[U]_0 - [U]_{\text{eq}}} = \exp(-k_{\text{obs,F}} t) \quad (13-10)$$

where $[U]_0$ is the concentration of unfolded form at the beginning of the approach to equilibrium. Because the process is symmetric (Equation 13-5), if unfolding were being monitored rather than folding, the variable would have been $([F] - [F]_{\text{eq}})$ rather than $([U] - [U]_{\text{eq}})$ but the **observed rate constant for the approach to equilibrium**, $k_{\text{obs,U}}$, would still be $(k_{\text{F}} + k_{\text{U}})$.

Suppose one were to monitor any physical property Y , such as intrinsic fluorescence, absorbance, optical rotation, circular dichroism, or specific viscosity, that is directly proportional to the concentration of unfolded state and directly proportional to the concentration of folded state, respectively. The observed magnitude of that physical property for any solution containing a mixture of unfolded state and folded state at any time

$$Y_{\text{obs}} = \zeta_{\text{U}} [U] + \zeta_{\text{F}} [F] \quad (13-11)$$

where ζ_{U} and ζ_{F} are the constants of proportionality between the concentration of each species and its respective contribution to the overall magnitude of the physical property for the mixture. When Equation 13-11 is combined with Equation 13-6,

$$Y_{\text{obs}} - Y_{\text{obs,eq}} = (\zeta_{\text{U}} - \zeta_{\text{F}})[U] - (\zeta_{\text{U}} - \zeta_{\text{F}})[U]_{\text{eq}} \quad (13-12)$$

where $Y_{\text{obs,eq}}$ is the magnitude of that physical property at equilibrium. It follows from Equation 13-10 and 13-12 that

$$\frac{Y_{\text{obs}} - Y_{\text{obs,eq}}}{Y_{\text{obs,0}} - Y_{\text{obs,eq}}} = \exp(-k_{\text{obs,F}} t) \quad (13-13)$$

Equation 13-13 states that the fraction of the total change that occurs in the magnitude of a particular physical property monitoring the isomerization between unfolded state and folded state of a polypeptide should decrease exponentially as a function of time if during that isomerization only two states are significantly populated, namely, the unfolded state and the folded state. Again, because the process is **symmetric**, if the derivation just presented had been based on $[F]$ instead of $[U]$ because unfolding was being monitored rather than folding, the same outcome would have occurred, and because $k_{\text{obs,F}} = k_{\text{obs,U}} = k_{\text{U}} + k_{\text{F}}$, Equation 13-13 is the same whether net folding is progressing from an initially unfolded state or net unfolding is progressing from an initially folded state.

This derivation for the approach to equilibrium as monitored by a physical property is completely general and can be applied to any situation where the equilibrium can be described by two first-order rate constants, forward and reverse. In the case of cold shock-like protein (Figure 13-1A), clearly first-order, exponential approaches to equilibrium were observed whether unfolded protein (■) was folded (●) or folded protein (□) was unfolded (○).⁵⁰ An uncomplicated **first-order approach to equilibrium** is generally accepted as support for a two-state assumption.⁵⁴

The observed rate constants for these approaches to equilibrium for cold shock-like protein (Figure 13-1B)⁵⁰ have identical values at the same concentrations of guanidinium chloride whether the equilibrium was approached in the direction of folding (●) or in the direction of unfolding (○), another observation consistent with the two-state assumption. Furthermore, the observed rate constants for the approach to equilibrium decrease smoothly as the concentration of guanidinium chloride is increased until the region of transition is reached and increase smoothly with guanidinium chloride beyond the region of transition, as expected if only one rate constant, k_{F} , dominates in the former portion of the plot and another, k_{U} , dominates in the latter. Such uncomplicated behavior of these observed rate constants is also presented as evidence for two-state behavior. In the region of transition, both k_{F} and k_{U} contribute to the observed rate constant for the approach to equilibrium $k_{\text{F}} + k_{\text{U}}$.

It is the decrease in k_{F} and the increase in k_{U} (dashed lines in Figure 13-1B) with increasing concentrations of guanidinium chloride that together shift the equilibrium constant into the measurable range. As the guanidinium chloride has its greatest effect on the stability of the unfolded state, it is not surprising that k_{F} is affected more than k_{U} .

Often conditions are purposely chosen to ensure that the approaches to equilibrium of the folding reaction in the region of the transition between fully native and fully denatured protein are simple first-order processes. Under other conditions of temperature, pH, or concentration of denaturant, either folding or unfolding or both are not first-order processes and these conditions are avoided. For example, the equilibrium constant for folding of myoglobin at 25 °C is shifted into the measurable range at pH 4.2. At this pH both the folding and unfolding of the polypeptide are first-order processes.⁵⁷ They both proceed with clean isosbestic points in the Soret region of the visible spectrum, and this also indicates that both folding and unfolding at this pH are two-state processes. At higher or lower values of pH, however, the kinetics of both the folding and unfolding reactions become complex.

If a point in the region of transition in Figure 13-1A represents a mixture containing only the native state and the random coil, then Equation 13-4, with appropriate

substitutions, should describe the behavior of every physical parameter measured as long as it is directly proportional to the concentrations of folded state and unfolded state. In this equation, the values for the fraction of native state, f_F , and the fraction of random coil, f_U , must be the same at a particular pH and at a given concentration of guanidinium chloride regardless of the physical property used to follow folding.⁵⁴ A convincing demonstration of the **coincidence of physical measurements** was presented for the thermal denaturation of bovine ribonuclease A (Figure 13-2). When the fraction of denatured ribonuclease A, f_U , as a function of temperature at pH 2.1 was monitored by intrinsic viscosity, optical rotation, and ultraviolet absorption, all of these properties gave the same values for this quantity (Figure 13-3).⁵⁸ If even one intermediate were present, the values of all three of these physical properties for this intermediate would have to assume the same fractional deviation relative to the two extremes of each respective property. It seems unlikely that an intermediate could exist, for example, that had an intrinsic viscosity a third of the way between the intrinsic viscosities of the native protein and the random coil and an optical rotation also a third of the way between those of the native protein and the random coil and an ultraviolet absorption also a third of the way between those of the native protein and the random coil. In effect, this test is formally equivalent to the observation of an isosbestic point in a series of spectra, and this observation has always been accepted as evidence for a transition between only two states.

Intermediate states between the unfolded state and the native state of a polypeptide must be less stable than the native state at physiological temperature and pH and may remain so as the equilibrium is shifted towards the unfolded state. If, however, the perturbation does happen to destabilize these intermediate states less than it does the native state, they may become more stable than the native state before the denatured state dominates the equilibrium as the level of the perturbation is increased. If the criteria just discussed are routinely used to establish that such intermediate states are not present at significant concentrations and that the two-state assumption is valid, then these same criteria must also be able to detect the presence of such **stable intermediate states at equilibrium** when they are revealed by the perturbation. It has already been noted that, in the folding of myoglobin, the departure of the approach to equilibrium from simple first-order behavior indicated the presence of intermediate states.⁵⁷ In the case of phosphoribosylanthranilate isomerase from *Escherichia coli*, both the kinetics of folding and the kinetics of unfolding at all concentrations of guanidinium chloride proceeded in two well-resolved first-order exponential phases rather than a single phase, an observation indicating that an intermediate must be present.⁵⁹ Furthermore, plots of the transition between the folded state and the unfolded state of phosphoribosylanthranilate isomerase differed

Figure 13-3: Change in the fraction of unfolded bovine ribonuclease A, f_U , calculated by Equation 13-4, for a solution of the protein at pH 2.10 (Figure 13-2) as a function of temperature.⁵⁸ The variation in three physical properties of a solution of ribonuclease A at pH 2.10 and ionic strength of 20 mM were measured as a function of temperature. These three properties were the absorbance at 287 nm (Δ), the intrinsic viscosity (\square), and the optical rotation, $[\alpha]_{365}$, at 365 nm (\circ). In each case, the direct observations were first plotted as a function of temperature as in Figure 13-2. The behavior of the physical property for the native state and the fully denatured state as a function of temperature was estimated by linear extrapolation as in Figure 13-1. The fraction of the denatured state f_U was then calculated from each separate curve by Equation 13-4. The values of the calculated fraction of unfolded protein determined by each physical property are presented together as a function of temperature (degrees Celsius). To demonstrate that the process being followed was reversible, the absorbance at 287 nm was followed a second time (\blacktriangle) after a sample was heated to 40.8 °C for 16 h and then cooled. Reprinted with permission from ref 58. Copyright 1965 American Chemical Society.

significantly in their shape and their dependence on the concentration of guanidinium chloride depending on whether the transition was monitored by circular dichroism at 278 nm, circular dichroism at 222 nm, or intrinsic fluorescence. It was concluded that at least one intermediate state of this protein was present in the region of transition.

A clear example of the existence of a stable intermediate state during the transition between the folded state and the unfolded state has been observed for bovine γ -crystallin B (Figure 13-4A).⁶⁰ When the transi-

tion was monitored by circular dichroism, sedimentation velocity, fluorescence emission at 320 nm, and fluorescence emission at 360 nm, the changes observed differed dramatically. Each curve, however, showed an obvious plateau at intermediate concentrations of urea, consistent with an almost completely populated intermediate state in this range. The kinetics of both folding and unfolding over the entire range of concentrations of urea displayed two distinct exponential phases with different rate constants during the approach to equilibrium, and these two sets of observed rate constants when plotted against the concentration of urea gave two separate, overlapping curves, each resembling the one in Figure 13-1B. The plot for the observed rate constants of the isomerization between the unfolded state and the intermediate was displaced to higher concentrations of urea than the one for the isomerization between intermediate and the native state. Consequently, it was concluded that this unfolding promoted by urea is a **three-state process** with a discrete intermediate state that is almost completely populated at concentrations of urea between 3 and 4 M.

In situations such as the one described, in which a discrete intermediate is thought to exist, the curves plotting the transition from native state to fully unfolded state as a function of the concentration of denaturant often show an obvious **plateau** or inflection,^{59,61} and these curves can be fit by equations similar to Equation 13-4 based on a three-state assumption to obtain the fraction of native state, intermediate state, and unfolded state at each concentration of denaturant. From these fractions, equilibrium constants for the isomerizations between these three states as a function of the concentration of denaturant can be calculated. In some situations, four states—the native state, the unfolded state, and two discrete intermediates—can be detected in the inflections within the plots of the magnitude of physical properties as a function of the concentration of a denaturant.^{62,63}

Often, however, the curve for a particular physical property is a smooth function with no inflections, and the only indication that an intermediate is present is the

lack of coincidence of the curves for different physical properties.^{64,65} For example, when the shift in the equilibrium between the native state and the unfolded state of bovine α -lactalbumin (Figure 13-4B)⁶⁶ was followed

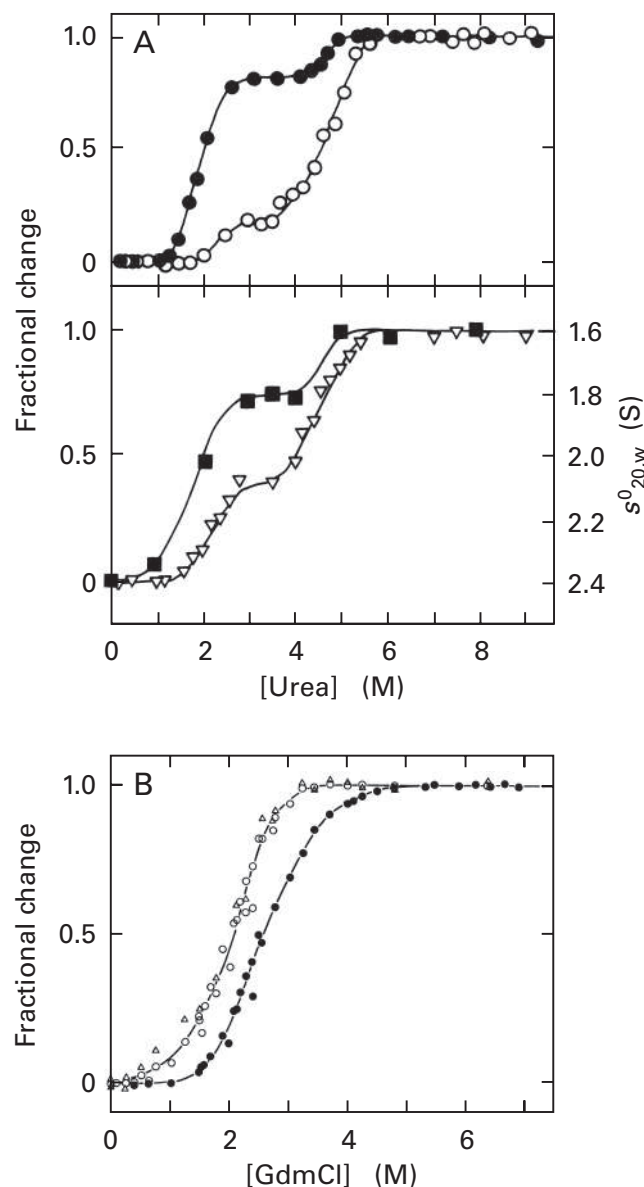

Figure 13-4: Evidence for the existence of stable intermediate states appearing during transitions between the native state and the random coil produced by increasing concentrations of urea or guanidinium chloride. (A) Shift of the equilibrium constant for the folding of bovine γ -crystallin B.⁶⁰ Solutions of the protein ($n_{aa} = 174$) in 0.1 M NaCl at pH 2.0 and 20 °C were diluted into solutions of urea at pH 2.0 and 20 °C so that the final concentration of urea (molar) would be as noted. Either the intrinsic fluorescence emission of the tryptophans of the protein at 360 nm (●; excitation at 280 nm, final concentration = 0.04 mg mL⁻¹), the intrinsic fluorescence of its tryptophans at 320 nm (○; excitation at 280 nm, final concentration = 0.04 mg mL⁻¹), its sedimentation velocity ($s_{20,w}^0$ ■; final concentration = 0.2 mg mL⁻¹), or its circular dichroism at 222 nm (▽; final concentration of protein = 0.1 mg mL⁻¹) were recorded as a function of the concentration of urea after each of the solutions was brought to equilibrium (24 h). Reprinted with permission from ref 60. Copyright 1990 held by authors. (B) Shift of the equilibrium constant for the folding of bovine α -lactalbumin.⁶⁶ Solutions of the protein ($n_{aa} = 123$) at pH 6.7 and 25 °C were diluted into solutions of guanidinium chloride at pH 6.7 and 25 °C so that the final concentration of guanidinium chloride (molar) would be as noted. The molar ellipticities of these solutions of protein were measured at 296 nm (△), 270 nm (○), and 222 nm (●) after each was brought to equilibrium. Reprinted with permission from ref 66. Copyright 1976 Academic Press. For the measurements presented in both panels, the direct results at equilibrium were plotted as in Figure 13-1 for each set of observations. Lines were drawn for the behavior of each physical property for fully native and fully unfolded protein as a function of the concentration of urea or guanidinium chloride, respectively, and the apparent fractional change of each measurement from the behavior of that physical property for the fully folded state were estimated from the positions of each data point relative to these lines. These estimated values of the fractional change are plotted in each panel as a function of the concentration (molar) of urea or guanidinium chloride (GdmCl).

by circular dichroism at 222 nm (●), the transition observed did not coincide with the one measured by circular dichroism at 270 and 296 nm (○, Δ).

The shift in the equilibrium constant for the folding of bovine carbonate dehydratase has been followed by changes in circular dichroism at 269 nm, ultraviolet absorption at 290 nm, and optical rotation at 400 nm as a function of the concentration of guanidinium chloride at pH 7.0.⁶⁷ The circular dichroism smoothly traced one transition and the optical rotation smoothly traced another transition proceeding at a higher concentration of guanidinium chloride. The change in absorbance traced a curve between the other two that displayed an inflection, suggesting that it was able to monitor both transitions. Furthermore, the kinetics of the refolding of the random coil was not a homogeneous, first-order process. It was concluded that one or more stable conformers of the polypeptide of carbonate dehydratase, other than the fully folded state and the random coil, are present in solutions of guanidinium chloride between 2 and 3 M in concentration. The properties of these other states are distinct from those of either the native state or the random coil. From observations of different transitions with different physical properties, the fractions of native, intermediate, and unfolded states as a function of the concentration of denaturant can also be estimated,⁶⁸ even in situations where very little intermediate forms,⁶⁹ and equilibrium constants among the states can be calculated.

If the protein being unfolded or refolded is an **oligomer** of two or more subunits, the respective dissociation or association of those subunits causes the transition between folded state and unfolded state to depend on the concentration of protein in the solution. Suppose that the native protein is an α_2 dimer. The equilibrium between the unfolded state α_U and the native state $(\alpha_F)_2$ is

and because

$$[\text{polypeptide}]_{\text{TOT}} = 2[(\alpha_F)_2] + [\alpha_U] \quad (13-15)$$

if there are only two states present, native dimer and unfolded monomer, at equilibrium

$$K_{\text{Fd}} = \frac{[(\alpha_F)_2]}{[\alpha_U]^2} = \frac{1 - f_U}{2f_U^2 [\text{polypeptide}]_{\text{TOT}}} \quad (13-16)$$

As the magnitude of the perturbation is increased, the equilibrium constant between folded and unfolded state is shifted in the direction of the unfolded state. At the midpoint of the transition between fully folded and

fully unfolded states that is being monitored by a particular physical property, $f_F = f_U$ (Equation 13-4); $f_U = 1/2$; and, instead of K_{Fd} being equal to 1 at this point, as with a monomer, K_{Fd} for a dimer is equal to $[\text{polypeptide}]_{\text{TOT}}^{-1}$. Consequently, as the total concentration of protein is increased, the equilibrium constant between unfolded and folded states must be shifted more and more before the midpoint is reached, which requires a greater and greater perturbation. If there are only the two states, as the total concentration of protein is increased, the midpoints of the curves describing the transition between folded dimer and unfolded monomer move systematically to higher and higher concentrations of guanidinium chloride^{63,70-72} or urea⁷³ or to higher temperatures.^{38,74} Because it is only the **molecularity of the reaction** that causes these shifts in the curves with the concentration of protein, they are no longer observed when the dimer is artificially converted to a monomer by joining the carboxy terminus of one of its subunits with the amino terminus of the other.^{74,75} Even greater shifts with the concentration of protein are observed in the curves following folding of higher oligomers⁷⁶ as a function of the perturbation.

Often when the equilibrium between folded oligomer and unfolded monomer is shifted by a perturbation, stable intermediate states are formed. For example, during the increase in the perturbation, a dimer may dissociate to monomers before the polypeptides unfold, and if the physical property detects only unfolding, the curves following the transition between the folded state and the unfolded state will not shift as the concentration of protein is increased³⁸ because the formation of the monomeric intermediate goes undetected. Similarly, a tetramer can dissociate into dimers before the dimers unfold to monomers.⁷² In some cases, the intermediate state is detected. In one such instance, the curves showed a plateau as in Figure 13-4A, but because both the native protein and the intermediate were dimers, it was only the portion of the curve monitoring the transition from the dimeric intermediate to the unfolded monomer that shifted with concentration of protein.⁷³

When the protein binds a **ligand**, the addition of the ligand also causes the curves following the transition between the native state and the unfolded state to shift to higher levels of perturbation. Because only the folded protein can bind the ligand, L, if the ligand is present at saturation so that only liganded native protein is present at all concentrations of denaturant

and

$$K'_{\text{Fd}} = \frac{[F \cdot L]}{[U][L]} = \frac{f_F}{f_U [L]} \quad (13-18)$$

Consequently, as the concentration of ligand is increased beyond its level of saturation, a greater perturbation is required to shift the equilibrium to a point at which $f_F = f_U$, and the curves move toward greater perturbation, for example to higher concentrations of guanidinium chloride, as the concentration of ligand is increased. It is also the case that, at the same concentrations, a ligand with a smaller dissociation constant will shift the curve a greater distance than one with a larger dissociation constant.⁷⁷

The change in **standard enthalpy of folding**, ΔH°_{Fd} , can be measured directly in a differential scanning calorimeter^{39,41} or it can be calculated from the dependence of the equilibrium constant of folding, K_{Fd} , on temperature. From the van't Hoff relationship

$$\left[\frac{\partial \ln K_{Fd}}{\partial \left(\frac{1}{T} \right)} \right]_P = - \frac{\Delta H^\circ_{Fd}}{R} \quad (13-19)$$

If a folding is followed as the temperature is varied and the value of the logarithm of the equilibrium constant for folding is plotted as a function of T^{-1} , the slope of the plot will be directly proportional to the change in standard enthalpy. When the folding of β -lactoglobulin was made reversible and kinetically first-order in both directions by adding appropriate concentrations of urea and adjusting the pH to 3, the equilibrium constant for folding, K_{Fd} , could be measured at each concentration of urea for temperatures between 10 and 50 °C. The behavior of $\log K_{Fd}$ as a function of T^{-1} (Figure 13-5A)⁷⁸ demonstrates that the change in standard enthalpy for the reaction, ΔH°_{Fd} , is not constant but varies considerably with temperature.

In fact, the values of the change in standard enthalpy for folding, ΔH°_{Fd} (Figure 13-5B),⁷⁸ calculated from the slopes of this first plot, vary from **exothermic to endothermic** over the range of temperatures sampled, a fact suggesting that the change in standard enthalpy for folding is by itself uninformative. Furthermore, the change in standard enthalpy for folding of a series of mutants of the same protein is usually linearly related to the change in standard entropy (Equation 5-63) with a slope T_c of about 350 K.^{79,80} Although the slope is somewhat greater than most other noncovalent processes, the compensation observed suggests that as with the hydrophobic effect both standard enthalpy and standard entropy are registering mainly compensatory changes in the water.

When the change in standard enthalpy, ΔH°_{Fd} , is plotted against the temperature (Figure 13-5B), the slope of the relationship observed at each point is the **standard heat capacity change of folding**, $\Delta C^\circ_{p,Fd}$, for that temperature

$$\left(\frac{\partial \Delta H^\circ_{Fd}}{\partial T} \right)_P = \Delta C^\circ_{p,Fd} \quad (13-20)$$

The change in standard heat capacity can also be measured directly in a calorimeter⁸¹ or by combining measurements of unfolding in solutions of urea and with temperature in a different manner.⁸²

From the observations presented in Figure 13-5B, it could be calculated that the change in standard heat capacity⁷⁸ for the folding of the polypeptide of β -lactoglobulin ($n_{aa} = 162$) between 5.5 and 4.4 M urea, pH 2.5 and 3.2, and 15 and 50 °C is $-8700 \pm 700 \text{ J K}^{-1} \text{ mol}^{-1}$, or $-54 \text{ J K}^{-1} (\text{mol of amino acid})^{-1}$. The measured values for the changes in standard heat capacity for the folding of proteins composed of a single polypeptide and lacking cystines are $-60 \pm 10 \text{ J K}^{-1} (\text{mol of amino acid})^{-1}$, regardless of the perturbation used to shift the equilibrium.^{78,79,82-87}

Unlike the changes in standard entropy and standard enthalpy that vary considerably from situation to situation, this uniform decrease in standard heat capacity seems to be a fundamental property of folding. It must arise from a combination of the decrease in heat capacity that occurs when **hydrophobic amino acids** are transferred from the aqueous phase into the interior of the molecule of protein,⁸⁸ the increase in heat capacity that arises from the **desolvation of polar amino acids** when they are transferred into the interior,⁸⁹ and the decrease in **conformational heat capacity** that occurs when vibrations and rotations along the polypeptide become more hindered after it is folded.⁸³ Of the three contributors, however, the difference in conformational heat capacity between the native state and the random coil may not be very significant because the observed heat capacity of an unfolded polypeptide is quite close to the heat capacity calculated only from the individual side chains and the individual peptide bonds composing that polypeptide.^{85,90,91}

The value for the change in standard heat capacity of folding is consistent with the decrease in standard heat capacity (-200 to $-400 \text{ J K}^{-1} \text{ mol}^{-1}$) observed for the transfer of alkanes and arenes from water into an organic phase (Table 5-8) if it is recalled that hydrophobic amino acids make up only a fraction (30%) of the amino acids in a polypeptide and that many of them remain accessible to water in the native state after the protein has folded. These considerations suggest that the uniform decrease in standard heat capacity [$-60 \text{ J K}^{-1} (\text{mol of amino acid})^{-1}$] associated with the folding of a polypeptide is one of the few signatures of the hydrophobic effect arising from the removal of hydrophobic amino acids from the solvent during their burial in the interior of the native state upon folding. The **hydrophobic effect** is the only noncovalent force that can provide a significant favorable contribution to the standard free energy of folding.

Although not always the case,⁷⁹ it has been pointed

Figure 13-5: Determination of ΔH°_{Fd} and $\Delta C^\circ_{p,Fd}$ for the folding of β -lactoglobulin in solutions of urea between pH 2.5 and 3.5.⁷⁸ A series of measurements of the optical rotation at 365 nm of solutions of β -lactoglobulin as a function of the concentration of urea were made at various temperatures. From the lines extrapolated from the pre-transition and posttransition regions of these smooth curves, the optical rotation of the fully native state and the fully unfolded state, respectively, of β -lactoglobulin at any particular temperature and at any concentration of urea were estimated. Solutions were then prepared at 4.48, 5.09, and 5.53 M urea, concentrations at which equilibrium constants could be measured over the temperature range of 10–50 °C. For each of these solutions, from the optical rotation at a given temperature and the estimated optical rotations of the native state and the unfolded state at that temperature and concentration of urea, the equilibrium constant for folding, K_{Fd} , could be calculated (Equation 13-2 and 13-4). (A) Logarithms to the base 10 of K_{Fd} ($\log K_{Fd}$) plotted as a function of the inverse of the temperatures [$1/T$ (Kelvin⁻¹ $\times 10^3$)]. The plots are curves, from the slopes of which the standard enthalpies of folding, ΔH°_{Fd} , can be calculated (Equation 13-19) at any particular temperature. (B) Standard enthalpy of folding, ΔH°_{Fd} (kilojoules mole⁻¹), plotted as a function of the temperature (degrees Celsius). The slope of the line is the change in standard heat capacity, $\Delta C^\circ_{p,Fd}$, for folding. Reprinted with permission from ref 78. Copyright 1968 American Chemical Society.

out that there is a tendency for the characteristic change in standard heat capacity of folding to decrease in magnitude as the frequency of disulfides in the polypeptide increases.^{84,87} This effect is thought to arise from a reduction in the otherwise complete exposure of hydrophobic side chains to the water upon unfolding because of the inability of the cross-linked unfolded state to expand fully,⁹² but the presence of cystines in the unfolded state must also decrease its conformational heat capacity. This decrease in the magnitude of the change in standard heat capacity may also result from an evolutionary compensation because the unfolded state, losing standard configurational entropy by the introduction of the disulfides, requires less of a contribution from the hydrophobic effect to achieve the proper standard free energy of folding.

The fact that the changes in standard heat capacity of folding for all proteins are significant negative numbers dictates that the change in standard enthalpy of folding, ΔH°_{Fd} , must decrease significantly as the temperature is raised (Figure 13-5B) and must pass through a value of zero at some temperature. This causes the equilibrium constant for folding to pass through a maximum at that same temperature (Figure 13-5A). From these considerations it follows that if the negative change in standard heat capacity is an intrinsic property of folding, each protein must have a **characteristic temperature of maximum stability**.^{78,93,94} These temperatures of maximum stability vary from less than 0 °C to more than 35 °C. In the presence of moderate concentrations of urea⁹⁵ or guanidinium chloride⁹⁴ or at high pressure,⁹⁶ a protein that is fully folded at room temperature will often unfold as the temperature is decreased to 0 °C or below.

It is also possible to shift the equilibrium constant for folding in the direction of denaturation by applying pressure to a solution of protein.⁹⁶⁻⁹⁹ This observation

requires that the solvated denatured state have a smaller volume than the solvated native state because

$$\left(\frac{\partial \Delta G_{\text{Fd}}^{\circ}}{\partial P} \right)_T = \Delta V_{\text{Fd}}^{\circ} = V_{\text{F}} - V_{\text{U}} \quad (13-21)$$

where $\Delta G_{\text{Fd}}^{\circ}$ is the standard free energy of folding ($-RT \ln K_{\text{Fd}}$), $\Delta V_{\text{Fd}}^{\circ}$ is the **standard volume change of folding**, V_{F} is the molar volume of the folded state, and V_{U} is the molar volume of the unfolded state. The volume changes for folding calculated from these results are positive as expected. At pH 2.0 and 0 °C the volume change for folding of bovine ribonuclease A⁹⁷ is +48 cm³ mol⁻¹ and that for bovine chymotrypsinogen⁹⁸ is +14 cm³ mol⁻¹, while that for myoglobin⁹⁹ from pH 4 to 6 at 20 °C is +92 ± 5 cm³ mol⁻¹.

The changes in **isoentropic compressibility of folding**

$$\Delta \kappa_{\text{S,Fd}} = - \left[\frac{1}{V_{\text{F}}} \left(\frac{\partial V_{\text{F}}}{\partial P} \right)_S - \frac{1}{V_{\text{U}}} \left(\frac{\partial V_{\text{U}}}{\partial P} \right)_S \right] \quad (13-22)$$

are more informative. The isoentropic changes in compressibility of folding for ribonuclease A and chymotrypsinogen^{97,98} are both about -0.015 GPa⁻¹. The negative values for these isoentropic compressibilities indicate that the solvated denatured state is more compressible than the native state. This is not a surprising result because the isoentropic compressibilities of native proteins are very small, 10-fold smaller than those of organic liquids and 2-fold smaller than those of amorphous organic solids.¹⁰⁰ The greater compressibility of the denatured state is probably due in part to its more fluid structure, but it is also possible that the hydrophobic functional groups revealed in the denatured state increase the structure of the water surrounding them and thereby increase its compressibility. This increase in the structure of water, if it is significant, would resemble the increase in its structure caused by decreasing the temperature, and decreasing the temperature of liquid water increases its compressibility (Figure 5-5).

High pressures also are able to dissociate multimeric proteins into monomers, reversibly, without causing denaturation, even at neutral pH. The volume change is small; in the case of enolase at 10 °C and pH 7.4, $\Delta V^{\circ} = 0.025 \text{ cm}^3 (\text{mol of amino acid})^{-1}$. Presumably the individual volume changes occur only at the faces of the subunits that are exposed during the dissociation.¹⁰¹

To be able to calculate the equilibrium constant K_{Fd} for folding from the measured concentrations of the two states of the protein, it must be decreased significantly by one or a combination of rather unphysiological perturbations such as increasing the temperature or pressure, lowering the pH, or adding guanidinium chloride or urea to the solution. It would be of interest to be able to esti-

mate the value at pH 7 and 25 °C of this **equilibrium constant in the absence of any perturbation**. This is generally accomplished by extrapolation¹⁰² from realms of pH, temperature, pressure, and concentrations of urea and guanidinium chloride where measurements can be made.

Various equations have been derived for extrapolating values of the equilibrium constant K_{Fd} to small or zero concentrations of urea and guanidinium chloride^{103,104} and from acidic to neutral pH.¹⁰⁴ Most of these equations plot the observed **standard free energies of folding**, $\Delta G_{\text{Fd}}^{\circ}$, as functions of the magnitude of the perturbation to perform the extrapolations. It is also possible to perform nonlinear least-squares fits of empirical equations to plots of the directly observed changes of a physical property as a function of denaturant.¹⁰⁵ Unfortunately, each theoretical curve, although it is successful at reproducing the behavior in the measurable regions, deviates from the other theoretical curves beyond the measurable regions. The values for the standard free energy of folding measured both at elevated temperatures and in the presence of urea can be extrapolated simultaneously to obtain an estimate of the value for standard free energy of folding at 25 °C in the absence of urea.⁸⁶ Extrapolation both from high concentrations of guanidinium chloride and from low pH can also be performed simultaneously.¹⁰⁶ It is also possible to measure the thermal unfolding of a protein in a differential scanning calorimeter at a series of concentrations of urea below the range of concentrations at which the transition is observed at 25 °C.

The **extrapolation** that has become most widely accepted is one for values of standard free energies of folding, $\Delta G_{\text{Fd}}^{\circ}$, observed in solutions of guanidinium chloride or urea, and the equation for performing this extrapolation that has emerged as the most popular is¹⁰⁷

$$\Delta G_{\text{Fd,[D]}}^{\circ} = \Delta G_{\text{Fd,H}_2\text{O}}^{\circ} - m [\text{D}] \quad (13-23)$$

where $\Delta G_{\text{Fd,[D]}}^{\circ}$ is the standard free energy of folding calculated (Equation 5-14) from the observed equilibrium constant at a given concentration of the denaturant; $\Delta G_{\text{Fd,H}_2\text{O}}^{\circ}$ is the standard free energy of folding for the protein in aqueous solution at the same pH, ionic strength, and temperature; and m is the slope of a line that is fit to the observations. This equation states that the standard free energy of folding is a simple linear function of the concentration of denaturant, which seems to ignore the observation that the changes in solvation brought about by guanidinium chloride and urea (Table 13-1) are not directly proportional to their molar concentrations.^{8,12,25,103,108}

Nevertheless, there are many observations supporting the **validity** of this relationship. In situations where there are **wide ranges of the concentration** of denaturant over which the equilibrium constant for folding can be

measured accurately (Figure 13–6),^{109,110} the standard free energies of folding do in fact vary linearly with the concentration of denaturant over the entire range of measurements.* Most of the time, however, the range of concentrations of denaturant over which measurements of the equilibrium constants for folding can be made is much narrower (Figure 13–7).¹⁰⁵ Extrapolations of standard free energies of folding perturbed by **different denaturants** give the same value for $\Delta G^\circ_{\text{Fd,H}_2\text{O}}$, in spite of the long distances over which those extrapolations must be made.^{105,107,111} Standard free energies of folding beyond the range of denaturant concentrations in which they can be directly measured can be estimated from measurements of unfolding induced by raising the temperature in a differential scanning calorimeter, and these estimates usually fall close to the line of extrapolation.¹¹¹ Measurements of the first-order **rate constants** for the approach to equilibrium can be made for the entire range of concentrations of denaturant, and from a plot of these observed rate con-

Figure 13–6: Estimation of the standard free energy of folding in the absence of denaturant by extrapolation. Cold shock protein CspB ($n_{\text{aa}} = 67$) from *Bacillus subtilis*¹⁰⁹ was dissolved in a series of solutions of increasing molar concentrations of urea at pH 7 and 25 °C. Two final concentrations of protein, 1.35 μM and 13.5 μM , were used. The emission of fluorescence of each solution, F_{342} , was monitored at 342 nm upon excitation at 280 nm (inset). After equilibrium was reached, the equilibrium constant for folding was estimated for each concentration of urea, and from these equilibrium constants, the respective standard free energies of folding (kilojoules mole⁻¹) were calculated. These standard free energies of folding (kilojoules mole⁻¹) are plotted as a function of the concentration of urea (molar). A line was fit to the data by linear least-squares analysis. The dashed line at zero (equilibrium constant of 1) emphasizes that direct measurements of the equilibrium constant can usually be made only over a limited range. Reprinted with permission from ref 109. Copyright 1995 Nature Publishing Group.

* The ionic strength of the solution must be maintained as the concentration of guanidinium chloride is decreased to retain linear behavior of $\Delta G^\circ_{\text{Fd,[GdmCl]}}$.¹¹¹

stants, values for k_{F} and k_{U} in the absence of denaturant can be estimated by extrapolation (dashed lines in Figure 13–1B). If the folding is a two-state process, the equilibrium constant for folding calculated from the estimates of these two rate constants (Equation 13–2) gives a value for the standard free energy of folding that agrees^{50,112} with that obtained by use of Equation 13–23.

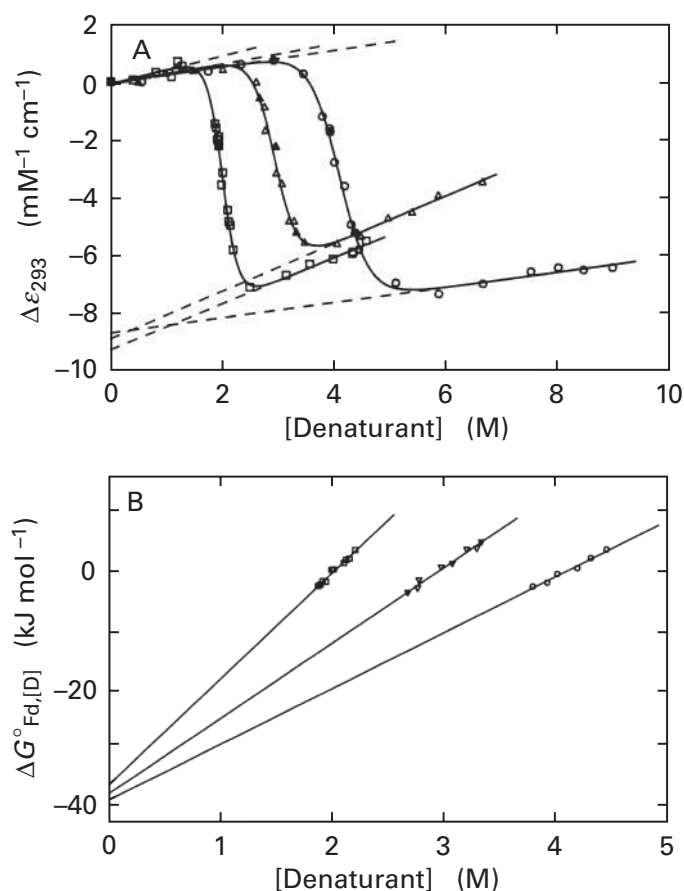

Figure 13–7: Estimation of the standard free energy of folding by extrapolating standard free energies of folding observed in solutions of different denaturants.¹⁰⁵ (A) Shifts of the equilibrium constants of folding. Bovine chymotrypsin ($n_{\text{aa}} = 241$), which had been sulfonated with phenylmethanesulfonyl fluoride to inactivate the endopeptidase, was dissolved in solutions of different concentrations of urea (\circ), 1,3-dimethylurea (Δ), and guanidinium chloride (\square) at pH 4.0 and 25 °C. The several folding isomerizations were monitored by the change in extinction coefficient at 293 nm ($\Delta \epsilon_{293}$; millimolar⁻¹ centimeter⁻¹), which is plotted as a function of the concentration (molar) of urea. In the respective regions of transition, the fraction of the protein in the folded state and the fraction in the unfolded state were calculated from the distance of each data point from the values of the change in absorbance for the fully folded (upper dashed lines) and the fully unfolded (lower dashed lines) states. Equilibrium constants for folding were calculated from these fractions for each concentration of denaturant, and from each of these equilibrium constants, standard free energies of folding $\Delta G^\circ_{\text{Fd,[D]}}$ were calculated at the respective concentrations of denaturant. (B) Standard free energies of folding (kilojoules mole⁻¹) plotted against the respective concentrations (molar) of each denaturant. Each of the lines was fit to the respective set of data by linear least-squares analysis. Reprinted with permission from ref 105. Copyright 1988 American Chemical Society.

That the numerical value for $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$, obtained by use of Equation 13–23 is a reasonable estimate of its actual value can also be demonstrated by evaluating the **effect of pH** on its magnitude. Acid–base titration curves for the folded state of the protein and its unfolded state in 8 M urea or 6 M guanidinium chloride can be measured directly^{23,24} or calculated from its composition of amino acids,²⁵ and an integrated form of Equation 13–3³³ can be used to calculate the variation expected in $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ caused by changes in pH. These calculated variations reproduced the observed variations with pH of estimates of $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ obtained by the extrapolation defined by Equation 13–23 for bovine ribonuclease A^{23,25} and bovine chymotrypsin²⁴ when they were unfolded in solutions of urea and guanidinium chloride.

The observed changes in the dependence of $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ on pH caused by **site-directed mutation** of a particular amino acid in the protein also agree quantitatively with those calculated with integrated forms of Equation 13–3. The observed values of $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ between pH 5 and 8 for the carboxy-terminal domain of protein L9 from the 50S subunit of the ribosome of *E. coli* fell on the curve calculated with an integrated form of Equation 13–3 by use of the values of $\text{p}K_a$ for its four histidines in the native state as determined directly by nuclear magnetic resonance.¹¹³ When each of these histidines was mutated in turn, the observed changes in the behavior of $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ were again those predicted from their individual values of $\text{p}K_a$. In particular, the mutation of Histidine 134, which is buried in the interior and has the lowest $\text{p}K_a$ of the histidines in the native protein, caused the greatest change in the observed pH dependence of $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$. Aspartate 26 is buried in the native state of thioredoxin from *E. coli*, which causes its $\text{p}K_a$ to be 7.5, a fact that destabilizes the folded state relative to the unfolded (Equation 13–3). The destabilization calculated from the difference in the values of $\text{p}K_a$ for just Aspartate 26 is equal to the difference in the values of $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ estimated by Equation 13–23 for the wild-type protein and a mutant in which Aspartate 26 is replaced by alanine.²⁷ Differences in $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ calculated from observed shifts in the values of $\text{p}K_a$ for histidines in ribonuclease T₁ from *A. oryzae* caused by mutation of Glutamate 58 to alanine also agreed with differences in values of $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$ estimated with the extrapolation of Equation 13–23.¹¹⁴

The constant fragment C_L of the light chain of immunoglobulin G (Figure 11–1) is a small protein, the folding of which as a function of the concentration of guanidinium chloride has been measured.¹¹⁵ The protein contains a deeply buried cystine that is readily reduced by dithiothreitol when it is unfolded in solutions of guanidinium chloride. The rate of its reduction in the random coil in the absence of guanidinium chloride can be estimated by extrapolation of its rate of reduction at higher concentrations of guanidinium chloride. The actual rate of its reduction in the absence of guanidinium chloride when the protein is folded is much slower than

the extrapolated value. If it is assumed that the reduction of this cystine in the absence of guanidinium chloride occurs only when the native protein is briefly and reversibly a random coil, the difference between the rate of reduction for the native state and that estimated for the random coil is consistent with a value for the standard free energy of folding of -26 kJ mol^{-1} . This is close to the value (-30 kJ mol^{-1}) obtained by extrapolation from ranges of guanidinium chloride concentrations in which the equilibrium constant can be measured.

Measurements of **proton exchange** also support an extrapolation of standard free energy of folding that is linear in the concentration of denaturant. The amide protons of peptide bonds buried deeply in the interior of a protein, when they exchange at the EX₂ limit (Equation 12–63), often register a conformational change that is the global unfolding and folding of the protein.¹¹⁶ Consequently, in these situations, K_{conf} (Equation 12–63)* is actually K_{Fd}^{-1} . When the standard free energy of this conformational change revealed by proton exchange, $\Delta G_{\text{HX}}^\circ$, is monitored, it is found to be a linear function of the concentration of the denaturant (Figure 13–8).^{116,117} In the case of cysteineless type I ribonuclease H from *E. coli*, only Methionine 47 is buried deeply enough to respond only to the global unfolding and folding over the range of rates that could be measured, but the change in standard free energy of the conformational change that it monitors remains a linear function of the concentration of guanidinium chloride to concentrations well below those at which global folding can be monitored directly (inset in Figure 13–8). The range of values for proton exchange that can be measured for deeply buried amide hydrogens can be extended by raising the temperature, and at higher temperature, they remain linear functions of the concentration of guanidinium chloride until none is left in the solution.¹¹⁶ Furthermore, the standard free energies of folding in water, $\Delta G_{\text{Fd,H}_2\text{O}}^\circ$, estimated from these plots of $\Delta G_{\text{HX}}^\circ$ as a function of the concentration of denaturant, agree satisfactorily with values of standard free energies of folding in water estimated from linear extrapolations of standard free energies of folding calculated from direct measurements of the equilibrium constant for folding at higher concentrations of denaturants (inset to Figure 13–8).¹¹⁸

There are several observations, however, suggesting that the standard free energy of folding of at least some proteins that fold in a two-state process may not be a linear function of the concentration of denaturant all

* By convention, the equilibrium constant for the conformational change producing exchange is defined for the opening of the structure, while the equilibrium constant for folding is defined reciprocally, namely, for the closing of the structure. Consequently, $K_{\text{Fd}}^{-1} = K_{\text{conf}}$ and $\Delta G_{\text{Fd}}^\circ = -\Delta G_{\text{HX}}^\circ$ when the conformational change being monitored by the exchange is the global unfolding and folding of the protein.

Figure 13-8: Standard free energies of unfolding estimated from the rates of exchange for particular amido protons in cysteineless type 1 ribonuclease H from *Escherichia coli*.¹¹⁷ All three of the cysteines in ribonuclease H were mutated to alanines. The resulting cysteineless protein was dissolved at a concentration of 1 mM in a series of solutions of deuterated guanidinium chloride prepared in deuterium oxide at p²H 5.1 and 25 °C. The rates at which 53 of the amido protons in the polypeptide backbone of the protein exchanged with deuterons from the solvent were slow enough to be monitored by two-dimensional nuclear magnetic resonance spectroscopy (Figure 12-33). Observed rate constants were calculated by fitting the amplitudes of the peaks as a function of time to single exponential decays by nonlinear least-squares analysis. Each proton exchanged in the EX₂ limit, and from the observed rate constant of its exchange, an equilibrium constant K_{conf} for the conformational change that exposed it to solvent was calculated (Equation 12-63). It was assumed that for the most deeply buried positions showing the smallest values of K_{conf} , the value of K_{conf} would actually be the equilibrium constant for global unfolding (the reciprocal of the equilibrium constant for folding). It was concluded that the exchange rates of Methionine 47 (■), Glutamine 105 (▲), and Alanine 110 (◆) were monitoring this global unfolding equilibrium of the protein. From the values of K_{conf} for each of these three exchanges, the respective free energies for the conformational change exposing the protons for exchange, $\Delta G^{\circ}_{\text{HX}}$, were calculated. These standard free energies of exposure (kilojoules mole⁻¹) are plotted as a function of the concentration (molar) of guanidinium chloride (GdmCl). The inset presents the fraction of the protein that is folded (f_F) as a function of the concentration of guanidinium chloride (molar), as monitored by circular dichroism at 220 nm. Reprinted with permission from ref 117. Copyright 1996 Nature Publishing Group.

the way to the point at which none remains. Values for the changes in standard heat capacity of folding ($\Delta C^{\circ}_{p,\text{Fd}}$), the standard enthalpies of folding ($\Delta H^{\circ}_{\text{Fd}}$), and the temperatures at which the concentrations of folded and unfolded states are equal (the melting temperatures, T_m) were measured for ribonuclease from *Bacillus amyloliquifaciens*⁸⁶ at concentrations of urea below those at which the equilibrium constant for folding could be measured at 25 °C. From these thermodynamic parameters, the standard free energy of folding at 25 °C and at

each of these concentrations of urea could be calculated with the relationship

$$\Delta G^{\circ}_{\text{Fd}} = \Delta H^{\circ}_{\text{Fd},m} + \Delta C^{\circ}_{p,\text{Fd}} (T - T_m) - \Delta H^{\circ}_{\text{Fd},m} \left(\frac{T}{T_m} \right) - T \Delta C^{\circ}_{p,\text{Fd}} \ln \left[\left(\frac{T}{T_m} \right) \right] \quad (13-24)$$

where T is the temperature (kelvins) for which these calculations are to be made (in this case, 298 K) and $\Delta H^{\circ}_{\text{Fd},m}$ is the standard enthalpy of folding at T_m , which can be measured in the calorimeter. The change in standard heat capacity of folding $\Delta C^{\circ}_{p,\text{Fd}}$ was estimated from the temperature dependence of $\Delta H^{\circ}_{\text{Fd}}$ (Equation 13-20). When these calculated values of $\Delta G^{\circ}_{\text{Fd,[urea]}}$ for concentrations of urea below those for the region of transition at 25 °C were plotted, they deviated from the line fit to the values of $\Delta G^{\circ}_{\text{Fd,[urea]}}$ measured directly within the region of transition at 25 °C.

The deviation was a gradual curvature sending the plot of the actual standard free energy of folding below the linear extrapolation. A similar downward curvature has been directly observed for the standard free energy of folding for helical peptides as a function of the molar concentration of urea in the range from 4 M down to 0 M.¹¹⁹ If these thermodynamic calculations and direct observations are correct and applicable to folding in general, then the linear extrapolations normally performed consistently **underestimate the magnitudes of the standard free energy** of folding at 25 °C in the absence of denaturant. In the case of ribonuclease from *B. amyloliquifaciens*, the actual value for the standard free energy of folding would be about 15% more negative than that obtained by extrapolation,⁸⁶ but a somewhat larger underestimate has been reported for the magnitude of the standard free energy of folding for lysozyme from *G. gallus* by a similar approach.¹²⁰ A drawback of the heavy reliance on measurements of thermal unfolding in these experiments, however, is that the thermally denatured state of a protein is not a random coil.

Another approach, which is somewhat simpler to accomplish than extrapolating a set of measurements at different concentrations of denaturant, is widely used when the standard free energies of folding for mutants are compared to the standard free energy of folding of the unmutated protein.^{121,122} The equilibrium constant for folding is measured over the region of transition at higher temperatures in which the concentration of denatured state becomes significant (Figure 13-2). With the van't Hoff relationship (Equation 13-19), the standard enthalpies of folding are estimated for both wild type and the mutants within this range of temperatures. The melting temperatures T_m for wild type and mutants are the temperatures at the midpoint of the thermal transition; the change in standard heat capacity of folding $\Delta C^{\circ}_{p,\text{Fd}}$ is

assumed to be the same for wild type and mutants, a value that has been either directly measured or estimated from $60 \text{ J K}^{-1} (\text{mol aa})^{-1}$; and the differences in standard free energy of folding, $\Delta\Delta G^\circ_{\text{Fd}}$, between mutants and wild type at a particular temperature within the range of the measurements are calculated with Equation 13–24.

One might assume that the relative stabilities of a series of mutants of a protein could be estimated from the concentrations of guanidinium chloride required to shift the equilibrium constants for their folding to a value of 1. This is not the case, however, because mutants requiring greater concentrations of guanidinium chloride to shift their equilibrium constants can have less negative standard free energies of folding in the absence of guanidinium chloride.¹²³

Representative values for extrapolated standard free energy changes of folding* under physiologically relevant conditions in the absence of denaturants at 25 °C have been assembled in Table 13–2. Each of the several values for a particular protein is the result of a different extrapolation, often from the same experimental data. The remarkable feature of this tabulation is that the standard free energies of folding for at least these 12 proteins are similar and fall between -20 and -60 kJ mol^{-1} . These are not large changes of standard free energy when the magnitude and the number of the individual noncovalent interactions involved in the process are considered. They are clearly the **sums of a large number of positive and negative terms** that cancel each other to produce small negative numbers. That they are all negative is merely the result of evolution by natural selection and consequently uninformative. The small magnitudes of these values may also be a consequence of evolution by natural selection. It is possible, if one is lucky, to increase the stability of proteins by site-directed mutation,¹²⁹ and proteins from hyperthermophilic organisms are generally more stable than those from organisms adapted to normally encountered temperatures¹³⁰ so the opportunity to evolve more stable proteins must exist, but it is usually not exploited.

With these values for the standard free energy changes (Table 13–2), the values for the equilibrium constants for the folding of these native proteins at 25 °C should be between 10^4 and 10^{10} . If this is the case, 10^{-4} to 10^{-10} of the lifetime of each of these proteins is spent in the fully unfolded state under normal circumstances.

* The standard state for free energy of folding has not been well defined. Because most foldings that have been studied are intramolecular isomerizations, their equilibrium constants should be independent of their concentration; and either infinite dilution or a corrected volume fraction of 1 (Equations 5–13 and 5–14) could be chosen as the standard state with little effect on the values for the standard free energies. The foldings of oligomers, however, are concentration-dependent and require that a finite concentration be chosen for standard state.

Table 13–2: Standard Free Energies of Folding in the Absence of Guanidinium Chloride or Urea, $\Delta G^\circ_{\text{Fd,H}_2\text{O}}$, at 25 °C

protein	pH	perturbation extrapolated	$\Delta G^\circ_{\text{Fd,H}_2\text{O}}$ (kJ mol ⁻¹)
ribonuclease A	6.0	GdmCl ¹²⁴	-50
<i>Bos taurus</i>	6.0	GdmCl ¹²⁴	-40
	6.6	urea ^{103,107}	-30
	6.6	GdmCl ^{103,107}	-40

<i>E. coli</i>			

The protection factors for the proton exchange of deeply buried amide hydrogens are usually 10^6 or greater, and these most deeply buried amide protons are probably exchanged only during the brief periods when the native state has become reversibly and completely unfolded. Natural selection has settled on an equilibrium constant large enough to limit the time the protein spends in the unfolded state in part to protect it from degradation by endopeptidolytic enzymes.¹²⁹

The requirement that a protein must **unfold and refold during its lifetime** may be viewed as a consequence of the need to fold in the first place (Equation 13–1) and the inescapable dictates of microscopic reversibility. If the observed rate constant k_F for the spontaneous refolding of a recently unfolded polypep-

time¹³¹ is on the order of 10 s^{-1} at $25\text{ }^{\circ}\text{C}$ and the equilibrium constant K_{Fd} for folding is on the order of 10^8 , then the observed rate constant for the unfolding of a native protein to the random coil ($k_{\text{U}} = k_{\text{F}}/K_{\text{Fd}}$) must be on the order of 10^{-7} s^{-1} . This would state that a protein has a 50% chance of unfolding to the random coil every 100 days at $25\text{ }^{\circ}\text{C}$. This is not a major problem in the life of a protein.

Measurements of the equilibrium constants K_{conf} for the conformational changes permitting the exchange of amide protons at the EX₂ limit (Equation 12-63) are consistent with the proposal that the most deeply buried positions in the polypeptide backbone exchange only upon its complete unfolding (Figure 13-8). The conformational equilibrium constants governing the exchange rates for the less deeply buried amide protons, however, are larger than the one for the most deeply buried positions and are spread over a range of values.¹³²⁻¹³⁵ The larger values for these other conformational equilibrium constants, which produce faster rates of exchange, are the result of conformational changes confined only to portions of structure of the protein, for example to individual α helices or loops of random meander,^{116,132,136,137} rather than the result of the fundamental unfolding encompassing the entire structure.

These **local conformational changes** appear to be of two types: those involving considerable exposure of nonpolar functional groups to the solvent, similar to the exposure experienced during global unfolding, and those involving exposure of the amide protons to be exchanged without any significant expansion of the local structure into the solvent.¹³⁸ The former are recognized by the increase in their equilibrium constants produced by adding guanidinium chloride or urea; the latter, by the insensitivity of their equilibrium constants to the addition of these denaturants.^{116,132,137} For example, above 0.8 M guanidinium chloride, the α amide protons on Glutamine 105 and Alanine 110 of cysteineless type I ribonuclease H (Figure 13-8) must exchange during a major unfolding of the protein because the standard free energy for the conformational change permitting their exchange decreases significantly as the concentration of guanidinium chloride increases. At lower concentrations of guanidinium chloride, however, their respective rates of exchange are governed by other conformational changes the equilibrium constants for which are unaffected by the concentration of guanidinium chloride. These other conformational changes, therefore, must not involve significant increases in the exposure of the polypeptide to the solvent. Because they are unaffected by the concentration of guanidinium chloride, the equilibrium constants for these other conformational changes become larger than the equilibrium constant for the major unfolding at low concentrations of the denaturant.

These observations indicate that in solution, in its native state, the structure of a protein is **constantly fluctuating** as a result of conformational changes of various

extents, occurring in different locations, some involving isomerizations retaining compact globular structure, others involving large, rapid expansions into the solvent followed by a collapse back into the native state.¹³⁹

Because a polypeptide can fold in the first place and because it must refold in part or in its entirety during the span of its life, the **information** dictating the final native state of the protein must be contained within its amino acid sequence. Because the standard free energy of folding of most proteins is not a large negative number (Table 13-2), perhaps for cause, if some of the information is lost or misinformation is added, the protein will not fold. For example, whenever the sequence of a protein is changed by site-directed mutation, the possibility exists that the mutant will not fold, for reasons that will never be learned. Many site-directed mutations, however, have little effect on the ability of the protein to fold, and in a few instances, a site-directed mutation has been found to increase the stability of a protein. For example, when the amino acids at positions 40-49 of lysozyme from bacteriophage T4 were all replaced with alanines,¹⁴⁰ its standard free energy of folding increased by only 10 kJ mol^{-1} , while the appropriate replacement of five of the amino acids in type I ribonuclease H from *E. coli*¹²⁹ decreased its standard free energy of folding by 20 kJ mol^{-1} .

Incomplete polypeptides often lack sufficient information to fold properly. A form of the polypeptide of bovine ribonuclease A ($n_{\text{aa}} = 124$) that is missing the last six amino acids is unable to produce a folded protein with enzymatic activity, and what structure it does have at $20\text{ }^{\circ}\text{C}$ is eliminated by heating to only $40\text{ }^{\circ}\text{C}$ at pH 7.5 in the absence of denaturants.¹⁴¹ This truncated polypeptide is also susceptible to endopeptidolytic degradation, unlike the intact native protein. When the last 23 amino acids, which form only a small number of contacts with the bulk of the folded polypeptide in its crystallographic molecular model, are removed from the polypeptide of micrococcal nuclease ($n_{\text{aa}} = 149$), the polypeptide produced is a random coil by the criteria of circular dichroism, optical rotation, and ultraviolet absorption.¹⁴² It is also readily digested by trypsin, unlike the native enzyme. Its residual enzymatic activity of 0.1%, which is an intrinsic property of the shortened polypeptide,¹⁴³ suggests that it can still fold properly to form an active enzyme but that the equilibrium constant for folding is displaced heavily ($K_{\text{Fd}} \leq 10^{-3}$) in the direction of the random coil. When the first 12 amino acids and the last 9 amino acids are removed from the protein, it folds partially to form a state in which some of its normal secondary structures are formed but in low yield.^{144,145}

Another set of examples of the fact that a polypeptide can fold only when all the necessary information is present is proteins that are posttranslationally modified during their natural maturation. In many instances, the polypeptide that folds to produce the native state is

longer than the final product because the initial folded form is clipped, and the smaller piece or pieces resulting from the **posttranslational clipping of the polypeptide** dissociate.¹⁴⁶ For example, subtilisin E from *Bacillus subtilis* folds naturally when it is a polypeptide 352 amino acids in length. After it folds, it is posttranslationally modified. During this process, the peptide bond after Tyrosine 77 is cleaved, and the first 77 amino acids of the polypeptide, the prosequence, are lost. If the mature, enzymatically active form of the protein ($n_{aa} = 275$) is unfolded, it will not refold; but if the full-length polypeptide ($n_{aa} = 352$) is unfolded in 6 M guanidinium chloride, it readily refolds to produce the native state.¹⁴⁷ If the prosequence ($n_{aa} = 77$) is included in the solution when the mature protein is being refolded, considerable native state is recovered.¹⁴⁸ The yield of enzymatic activity is low but increases as the concentration of prosequence is increased up to a molar excess of 4-fold.¹⁴⁹ Only when the complete amino acid sequence of the longer polypeptide is intact, however, is there sufficient information to produce a high yield of the mature form. Once folded and posttranslationally modified, the mature protein is stable and biologically competent, as long as it is not unfolded. In the case of carboxypeptidase C from *Saccharomyces cerevisiae*, however, the mature posttranslationally modified form of the protein ($n_{aa} = 421$) is considerably more resistant to the effects of guanidinium chloride than is its intact precursor ($n_{aa} = 512$), a result suggesting that the prosequence provides information rather than standard free energy for folding.¹⁵⁰

There are many other examples of proteins that lose portions of their polypeptide, usually from the amino terminus, after they have folded. This is so common that the term **proprotein** is used to designate the longer polypeptide that folds, with the implication that the cleaved, mature native state is designated as the protein. Familiar examples of this designation are proinsulin, proalbumin, and prothrombin.

Fragments of a polypeptide, each lacking sufficient information to fold separately, can sometimes cooperate to produce the proper native state. The first example of this was the ability of the amino-terminal fragment of ribonuclease (Lysine 1–Alanine 20), which is almost structureless in isolation,¹⁵¹ to reassume its native structure as an α helix when combined with the remainder of the polypeptide (Serine 21–Valine 124).¹⁵² Both the fragment Alanine 1–Arginine 126 and the fragment Glycine 49–Glutamine 149 of micrococcal nuclease ($n_{aa} = 149$) are structureless in isolation.^{142,153} When they are mixed together, however, they combine with each other to form two different forms of the native state that both appear to be properly folded but together have only 10% of the nuclease activity of the native enzyme.¹⁵³

Higher yields of enzymatic activity have been observed upon **combination of fragments** of ribonuclease from *B. amyloliquifaciens* (fragments of 36 and 74 aa; yield 30%),¹⁵⁴ fragments of phosphoribosylanthranilate

isomerase from *S. cerevisiae* (fragments of 174 and 59 aa; yield 50%),¹⁵⁵ fragments of penicillin amidase from *E. coli* (fragments of 209 and 557 aa; yield 60%),¹⁵⁶ and fragments of porcine 3-oxoacid CoA-transferase (fragments of 250 and 270 aa; yield 85%).¹⁵⁷ In the case of the ribonuclease, each fragment was a random coil in the absence of the other, but in the cases of the isomerase and the amidase, one of the two fragments refolded on its own to form a compact structure. The two fragments of the transferase that were chosen for expression are structural domains in its crystallographic molecular model, and both formed compact structures in the absence of the other, but neither formed the structure it has in the intact protein. None of the fragments from any of these proteins had enzymatic activity on its own, and it was only upon mixing the two respective fragments that activity was regained.

When a protein is split into two fragments and the separated, incompetent fragments are mixed together in the hope of regenerating the native state of the protein, the situation is complicated by the fact that the fragments must associate with each other. For example, the complex of the fragments of ribonuclease from *B. amyloliquifaciens* and the complex of the fragments of phosphoribosylanthranilate isomerase from *S. cerevisiae* had dissociation constants of 0.4 μ M and 0.2 μ M, respectively, so the fragments had to be present at concentrations in excess of these dissociation constants for the full yield of the native state to be regained.^{154,155}

One solution to this problem of the bimolecular association of the fragments is to perform a **circular permutation**¹⁵⁸ of the protein. By genetic manipulation, the coding sequence for the protein in the DNA is severed at a particular position, and the portion to the 5' side of the break is moved to the 3' end of the remainder of the coding sequence. The 3' end of the 3' fragment is joined in phase to the 5' end of the 5' fragment with a linking sequence of DNA encoding a segment of polypeptide long enough to connect comfortably the carboxy terminus of the original unpermuted protein to the amino terminus of the original unpermuted protein.¹⁵⁹ Consequently, a protein is eligible for circular permutation only if its amino terminus and its carboxy terminus are near each other in its crystallographic molecular model so that after the circular permutant has been expressed and has folded properly, its former carboxy terminus and former amino terminus can be joined by a continuous stretch of polypeptide.

Following circular permutation, there is a break in the polypeptide elsewhere in the native structure of the protein, formally equivalent to the break that would otherwise produce two fragments of the protein, but the polypeptide is continuous from the former carboxy terminus to the former amino terminus. If the break is placed at a position in its amino acid sequence known to be a **disordered loop**, the circularly permuted protein will usually fold, display almost normal enzymatic activ-

ity or biological function, assemble into the native oligomer, and have similar standard free energies of folding to that of the wild type.^{159–163} In such a situation, the disordered loop is broken by the new amino and carboxy termini, and the former carboxy and amino termini, which are usually disordered anyway, are now joined together, to prevent the two fragments of the original protein from dissociating when it is unfolded.

Circular permutation can be used to examine the **information necessary to fold**. The position at which the amino acid sequence of the wild-type protein is broken to produce the new amino terminus or carboxy terminus can be varied at random, and circular permutants that are still enzymatically active can be selected genetically. In almost all of the enzymatically active circular permutants of aspartate carbamoyltransferase from *E. coli*, the new carboxy and amino termini were found in segments of the polypeptide between α helices and β structure in the crystallographic molecular model of the wild-type protein.¹⁶⁴ This result seemed reasonable at the time because such elements of secondary structure probably could not form if there were a discontinuity within them. When a similar analysis, however, was made of random circular permutants of thiol:disulfide interchange protein dsbA from *E. coli*, the majority of the new amino and carboxy termini of the enzymatically active permutants were located at positions in the sequence of amino acids that in the wild-type protein are α helices or β structure. Four of the nine α helices and three of the five β strands could be interrupted, and the resulting circular permutants folded and were enzymatically active.¹⁶⁵

Another approach is to place systematically the new carboxy and amino termini at each position in the amino acid sequence of the protein and measure the enzymatic activity and standard free energy of folding for each of the resulting circular permutants. When such an analysis¹⁶⁶ was performed on dihydrofolate reductase from *E. coli* ($n_{aa} = 159$), a set of 10 segments varying in length from 2 to 14 aa could be identified, the interruption of which by introducing new amino and carboxy termini at any position led to a protein incapable of folding and enzymatically inactive. Placing the interruption at almost any one of the 87 positions outside these 10 forbidden regions gave a circular permutant that could fold to produce an enzymatically active protein. As with thiol:disulfide interchange protein dsbA, many of the permissive positions were within segments that are α helices or β strands in the crystallographic molecular model of the wild-type protein. The **forbidden regions**, however, also failed to correlate with elements of secondary structure. These results suggest that the information necessary to fold a polypeptide may be distributed over its sequence of amino acids by rules that are not immediately obvious.

The fact that many, if not most, of the circular permutants of a protein can fold to produce enzymatically and biologically active proteins and even the proper

oligomers clearly states that one piece of information that has nothing to do with the folding of a protein is the order in which its amino acids emerge from the ribosome. If there are portions of the protein that do fold before the complete protein emerges, those portions are not required to fold before the complete protein emerges. It has been suggested, however, that if a protein has domains, each domain might be required to fold as it emerged from the ribosome during biosynthesis before the next emerged. There is no evidence in favor of this conjecture, and proteins containing two or more **domains** undergo reversible folding as readily as proteins with only one domain.^{44,167–169}

If the reaction producing the unique native state of a folded polypeptide is an isomerization between the random coil and that native state, the individual contributions to the overall standard free energy change for this isomerization determine its outcome. Neither the formation of a hydrogen bond between a donor and an acceptor in the random coil nor the formation of an ionic interaction between a positively charged side chain and a negatively charged side chain in the random coil can provide any net favorable standard free energy for the folding of a protein in aqueous solution. In fact, their formation would be unfavorable. Nor can van der Waals forces make any contribution because the isomerization occurs in a condensed phase. Therefore, by exclusion and perhaps for the lack of a better candidate, the hydrophobic effect has attracted the most attention in discussions of the folding of a polypeptide.¹⁷⁰ The hydrophobic effect provides favorable standard free energy for the formation of the native state because hydrophobic side chains, which are exposed to water in the random coil, are removed to the interior of the protein during the folding.¹⁷¹

One of the major **deficits of standard free energy in the folding** of a protein results from the requirement to unsolvate those hydrophilic functional groups destined for the interior. This loss is due to the fact that water participates in strong interactions with donors and acceptors of hydrogen bonds and charged functional groups and to the fact that when **charged side chains** are withdrawn from water they are usually neutralized first. The removal of even neutral **hydrogen-bond donors** from water, even though they may always find an acceptor in the interior of the protein, is a significantly endothermic transfer.¹⁷² It has already been noted, however, that the formation of a hydrogen bond between an acceptor and a donor on a side chain, in the context of a folded polypeptide, is usually favorable with a standard free energy of formation of around -5 kJ mol^{-1} (Table 6–6). For example, in 52 instances in which a tyrosine was mutated to a phenylalanine, the standard free energy of folding increased by $6 \pm 4 \text{ kJ mol}^{-1}$ when the tyrosine was involved in a hydrogen bond in the crystallographic molecular model of the protein but showed no change when it was not. In 40 instances in which a threonine was

mutated to a valine, the standard free energy of folding increased by $4 \pm 4 \text{ kJ mol}^{-1}$ when that threonine was engaged in a hydrogen bond in the crystallographic molecular model but showed no change when it was not.¹⁷³

The reason that these hydrogen bonds between side chains in the native state have the modestly favorable free energies of formation that they do is **approximation**. The hydrophobic effect drives the condensation of the random coil that unavoidably withdraws donors and acceptors in the backbone of the polypeptide from contact with water. These donors and acceptors then combine to form the hydrogen bonds that define the **secondary structure**. These hydrogen bonds form because these donors and acceptors can no longer participate in hydrogen bonds with water and must do so among themselves. α Helices and β structure appear not because they are beautiful (Figures 6–6 and 6–9) but because they are an efficient way to provide an acceptor to most if not all of the donors pulled out of the water by the condensation driven by the hydrophobic effect. The proper **packing** of the secondary structure then can juxtapose the donor on a side chain with an acceptor. It is this approximation, brought about by the complete, cooperative process of folding, that is the only reason the resulting hydrogen bond has a favorable standard free energy of formation relative to the separated donor and acceptor in the random coil.

Because the realization of this favorable standard free energy of formation results from approximation, there are significant geometric requirements for its favorability. In addition, if too many of the hydrophobic groups on the side chains in the interior were replaced with properly aligned donors and acceptors to exploit these favorable increments in standard free energy of formation, the polypeptide could not fold in the first place.³ These are among the reasons that there are few such hydrogen bonds involving a donor on a side chain in the interiors of proteins.¹⁷¹ Those few hydrogen bonds between side chains that are found are the result of evolution by natural selection so it is not surprising that they have favorable free energies of formation.

In addition to the unfavorable standard free energy of transfer associated with the dehydration of hydrophilic functional groups as they are pulled into the interior of the folded polypeptide,¹⁷⁴ the other major deficit that must be overcome during the folding process is the **configurational entropy of the random coil**. This is the positive, intrinsic standard entropy that arises from the fact that the random coil can assume a large number of different configurations. It represents a deficit during the folding of the polypeptide because the native state, to a first approximation, assumes only a few conformations. Therefore, when the random coil becomes the native state its configurational entropy almost disappears.

At first glance, it seems that the configurational

entropy of the random coil, dictated by the sum over all of its states, should be very large because each amino acid has at least the two dihedral angles, ψ and ϕ (Figure 6–2), each of which can assume a number of values as dictated by the Ramachandran plot (Figure 6–4). This initial intuition, however, neglects excluded volume.¹⁷⁵

Excluded volume designates the qualification that every configuration of the random coil in which two or more atoms would occupy the same space at the same time is impossible and thus cannot contribute to the configurational entropy. This is the consequence of the steric effects that produce the Ramachandran plot itself operating over the whole polymer rather than just between neighboring amino acids. Excluded volume makes a large contribution to diminishing the configurational entropy of the random coil. For a polypeptide 100 amino acids in length, a set of configurations could be generated by randomly assigning values to the dihedral angles ψ and ϕ within their allowed ranges. The number of these configurations that do not superpose two or more atoms in the polypeptide has been estimated to be only 10^{-44} of the total number of randomly generated configurations.¹⁷⁶

Even though a consideration of excluded volume remarkably decreases the number of configurations available to the random coil, there are still a large number of configurations that are accessible. Only a small number of these configurations constitute the compact native state of the folded polypeptide. For the native state to be stable relative to the random coil, the configurational entropy resulting from the sum over all of the allowed unfolded configurations must be overcome by the hydrophobic effect realized upon the formation of the native state.

The presence of a **cystine** in a folded polypeptide makes a contribution to the change in configurational entropy for the isomerization between random coil and native protein. The polypeptide must first fold before the cysteines juxtaposed by the folding can be oxidized to cystines.¹⁷⁷ Because the folded native state is a prerequisite for the formation of a proper cystine and because the formation of a naturally occurring cystine usually has little effect on the structure or conformational freedom of the native protein,^{177–179} it necessarily follows that the cystine itself cannot significantly change the intrinsic configurational entropy of the properly folded protein and can change its intrinsic standard enthalpy only by the standard enthalpy of formation of the cystine. It has been demonstrated, however, that the standard enthalpy of formation for cystine in a random coil is about the same as that estimated for the standard enthalpy of formation of the same cystine in the native state.¹⁸⁰ Consequently, the incorporation of a cystine cannot affect the change in standard enthalpy of folding either. Rather, a cystine between two cysteines that are adjacent in the native structure increases the value of the equilibrium constant of the folding and decreases the change in

standard free energy of folding of a protein because it **decreases the configurational entropy of the random coil**.

The decrease in standard free energy of folding can be demonstrated experimentally by introducing a specific cross-link between two adjacent amino acids into the native structure of a protein and determining its effect on its folding. Glutamate 35 and the enol tautomer of the oxindole produced by the oxidation (Reaction 10–37) of Tryptophan 108 in lysozyme from *G. gallus* form an ester:

This ester introduces an intramolecular cross-link between these two amino acids¹⁸¹ that are adjacent to each other in the crystallographic molecular model of the protein. The cross-linked lysozyme has a standard free energy of folding at pH 2 in 2 M guanidinium chloride at 62 °C that is 22 kJ mol⁻¹ less than that of un-cross-linked lysozyme.¹⁸⁰ Lysine 7 and Lysine 41 in bovine ribonuclease A can be cross-linked specifically by 2-(*p*-nitrophenyl)-3-(3-carboxy-4-nitrophenyl)thio-1-propene (Figure 10–8).¹⁸² The difference in the standard free energy change of folding between the cross-linked and un-cross-linked ribonuclease at pH 2.0 and 40 °C¹⁸³ is –21 kJ mol⁻¹.

Many studies have incorporated single cystines by site-directed mutation between positions in the amino acid sequence of a protein that are adjacent to each other in its crystallographic molecular model. For example, cystines have been introduced into lysozyme from bacteriophage T4 ($n_{aa} = 164$). This protein has no cystines to begin with, so each mutant contained only one cross-link in its polypeptide.^{184,185} In one study, four different mutants were made containing cystines cross-linking positions 29, 34, 121, and 155 aa apart. In another, the same two site-directed mutants containing cystines cross-linking positions 121 and 155 aa apart were used and a third, cross-linking positions 94 aa apart, was made; and each of these mutants was submitted to the same circular permutation to produce permutants of T4 lysozyme with cystines cross-linking positions 49, 15, and 76 aa apart, respectively. Together, these manipulations gave eight mutants of the same protein, each with a cross-link producing a covalent loop in the denatured polypeptide of a different length. For each mutant, the difference in the standard free energy of folding ($\Delta\Delta G_{Fd,SS}^\circ$) between the protein with the cystine intact and the protein with the cystine cleaved by disulfide interchange (Figure 3–20) was estimated from its melting

temperature. The differences in standard free energies of folding varied from –3 to –14 kJ mol⁻¹, and the difference increased monotonically as the distance between the cysteines, and hence the **length of the loop**, increased.

A theoretical treatment of the expected decrease in configurational entropy caused by **cross-linking a random coil**, which accounts for excluded volume, predicts that the configurational entropy should decrease linearly with the natural logarithm of the distance between the cross-linked positions with a slope of 2.4.¹⁸⁶ When the experimental values of $(\Delta\Delta G_{Fd,SS}^\circ)/T$ are plotted against the natural logarithm of the distance, in number of amino acids, between the cystines in each of the mutants of T4 lysozyme, the expected relationship is observed. Furthermore, the difference in standard free energy of folding between native α -lactalbumin and α -lactalbumin in which the cystine between Cysteine 6 and Cysteine 120 has been reduced falls on the same line.¹⁸⁷

The effects of introducing cystines into other proteins, however, differ significantly from those measured in these observations. In some instances the magnitude of the difference in standard free energy of folding is much less than expected;¹⁸⁸ in others, much more.¹⁸⁹ The magnitudes of the differences in standard free energy of folding for lysozyme from *G. gallus* cross-linked through the oxindole ester (**13-3**) and bovine ribonuclease A cross-linked by 2-(*p*-nitrophenyl)-3-(3-carboxy-4-nitrophenyl)thio-1-propene are also greater than those observed with cystines introduced into lysozyme from bacteriophage T4.

The equilibrium constant for the folding of the constant fragment of the light chain of an immunoglobulin G, C_L (Figure 11–1), at pH 7.5 and 25 °C in solutions of guanidinium chloride is decreased when its single cystine is reduced. All of the change could be accounted for by the fact that the observed **rate constant for folding** (k_F in Equation 13–1) of the random coil with the cystine was 100-fold greater than the observed rate constant for the random coil without the cystine.¹⁹⁰ This is consistent with the conclusion that the intact, correct cystine decreases the configurational entropy of only the random coil, while retaining access to the properly folded structure, and permits the random coil to fold more rapidly. Whether or not the proper cystine was present had no effect on the observed rate constant of unfolding (k_U in Equation 13–1).

It has been shown that if the favorable noncovalent standard free energies of association between a subpopulation of the monomers along a polymer are significantly more negative than their individual standard free energies of solvation, the polymer should spontaneously collapse to a globular form.¹⁹¹ Because the constraints of excluded volume are even more extreme in this compact, globular form, the number of accessible configurations and hence its configurational entropy should be much smaller. Because the hydrophobic effect is the only inter-

action capable of producing significant net favorable standard free energies of association among the side chains of the amino acids in a random coil, it is generally assumed that the noncovalent force that would perform the condensation leading to a globular state of a polypeptide is the hydrophobic effect exerted upon the hydrogen-carbon bonds in those side chains in the polypeptide. This view of the folding of a polypeptide could be called the **condensation model**. Its central proposal is that the collapse of the random coil to a condensed state decreases the configurational entropy of the polypeptide dramatically and narrows the search for the native state to a much smaller number of accessible conformations.

On the basis of this model, folding can be treated theoretically as a process in which the unfavorable loss of the configurational entropy of the random coil is balanced only by the favorable removal of hydrophobic side chains from contact with the aqueous phase.^{176,192} The statistical treatment of the random coil developed by Flory,¹⁹³⁻¹⁹⁵ which takes account of excluded volume and the solvation of the monomeric units, can be expanded¹⁷⁶ to include the hydrophobic effect exerted during the sequestration of the monomers in the condensed state¹⁹⁵ and the fortuitous sequestration of the monomers in the random coil,¹⁷⁶ as well as the much smaller, but still significant, configurational entropy of the condensed polypeptide before it assumes the native state.

The process of folding is divided into two imaginary steps,¹⁷⁶ not necessarily related to the actual steps. These imaginary steps are the **condensation** of the random coil to a globular structure excluding water and the **reconfiguration** of the polymer in this condensed state to maximize the exposure of hydrophilic groups and minimize the exposure of the hydrophobic groups to the water. It is during this reconfiguration following the condensation that the donors and acceptors for hydrogen bonds that have been withdrawn away from the acceptors and donors of the water form hydrogen bonds among themselves to produce the α helices and β structure observed in the final native state of the protein. Before the condensation, water formed hydrogen bonds with those donors and acceptors.

With reasonable values both for the hydrophobic effect on the average hydrophobic amino acid (-8 kJ mol^{-1}) and for the fraction of the amino acids in the polypeptide that are hydrophobic (0.50), the formation of a unique globular state from a random coil should proceed with net negative standard free energy change for polypeptides greater than about 70 amino acids in length.¹⁹² Polypeptides less than about 70 amino acids in length should not fold because they should not be able to bury a large enough number of hydrophobic amino acids to overcome the configurational entropy of their random coils. It is the case that small, folded, cystineless, monomeric proteins of less than 70 amino acids are quite rare. Proteins composed of polypeptides shorter than 70

amino acids usually contain several cystines, are oligomeric,^{196,197} or have a relatively large hydrophobic core.¹⁹⁸ There are, however, a few small domains, for example the WW domains (35 aa)¹⁹⁹ or the peripheral subunit-binding domain from dihydrolipoyllysine-residue acetyltransferase (41 aa),²⁰⁰ that fold to form stable monomeric, well-defined native structures lacking cystines.

Although it was only for the sake of the computations that the folding of the polypeptide described in this condensation model was divided into the two steps of condensation and reconfiguration, there are stable, condensed but fluidly unstructured states of a polypeptide that seem to have the properties required of a condensed state on its way to the native state. These are the molten globules. A **molten globule** is a state of a polypeptide in which it has collapsed to a globular particle from the expanded random coil but remains fluid with a constantly changing conformation rather than achieving the limited set of conformations that is the native state. In such a fluid condensed state, the configurational entropy of the polypeptide should be significantly reduced relative to that of the random coil, and only a much smaller number of conformations that avoid the problems of excluded volume should be accessible.¹⁹¹ Many of these conformations should display α helices and β structure that form spontaneously.²⁰¹

Under conditions that differ significantly from those in the living system in which a particular polypeptide has evolved to fold, its native state may no longer be the most stable of the condensed conformations accessible to that polypeptide, and a number of other condensed, structured conformations may be as stable. Peculiar conditions such as low pH or the presence of denaturants, however, are necessary to prevent the polypeptide from assuming its native state, as it would do normally. It is argued that the intermediates detected in the folding of proteins under several such circumstances are examples of molten globular states and that all of these various intermediates represent a single configurational state assumed by a polypeptide that is at least as distinct as that of the random coil. This may be an overstatement. For example, two different molten globular states of apomyoglobin have been distinguished,²⁰² and there are intermediate states that do not have the properties assigned to a molten globule.²⁰³

Stable intermediates believed to be molten globules have been detected under many different circumstances. They have been observed for α -lactalbumin²⁰⁴ below pH 4.5 at concentrations of guanidinium chloride below 2.5 M; for α -lactalbumin,²⁰⁵ stripped of bound Ca^{2+} , at pH 8 and guanidinium chloride concentrations between 0.5 and 2.0 M; for cytochrome *c*^{206,207} below pH 3 either at chloride concentrations greater than 0.1 M or at concentrations of *O*- α -D-glucopyranosyl(1-3)- β -D-fructofuranosyl- α -D-glucopyranoside greater than 0.5 M; and for carbonate dehydratase⁶⁴ at temperatures

below 60 °C and values of pH less than 3.5. The mutation of Phenylalanine 173 to an alanine in murine interleukin 6 converts the protein into a molten globule.²⁰⁸ These are all unphysiological conditions, but proteins have evolved to be entirely in their native states under physiological conditions. Consequently, it would not be surprising that, to isolate intermediates in the normal process of folding, such peculiar conditions would be required. Molten globules often become stable relative to the native state at low pH. Presumably, their fluidity permits carboxy groups that are rigidly buried in the native state to reach the surface of the globule and be exposed to the solvent, thereby lowering the standard free energy of the molten globule relative to that of the native structure (Equation 13–3).

Various physical measurements have been made of these stable intermediates identified as molten globules. The **circular dichroic absorptions** of the native protein between 260 and 290 nm are largely lost in the molten globule, and this loss must result from the disappearance of the unique asymmetric environments around tryptophans, tyrosines, and phenylalanines.^{66,209} The complex **nuclear magnetic resonance spectrum** of the native state becomes much simpler and much more like that of the random coil upon formation of these molten globules,^{210,211} as would be expected if the unique environments around each amino acid had been lost and each side chain now sampled continuously a broad range of changing environments. When the internal dynamics of one of these molten globules are examined by **quasielastic neutron scattering**,²¹² it is observed that the potential barriers to bond rotations in the side chains are lower than those in the native state, while diffusive motions of side chains are greater, and significantly smaller units of structure diffuse cooperatively than those diffusing in the native state. Measurements of the **absorption of ultrasound** also indicate that such molten globules are more fluid than the native state,²¹³ and conformational relaxations in the interior that occur in the 2 MHz range are significantly enhanced.

The majority of the circular dichroic absorption between 200 and 240 nm seen in the native states is retained in the respective molten globules, and this suggests that they contain α helices and β structure.^{66,209} The slow **proton exchange** observed by nuclear magnetic resonance for buried peptide bonds in the native state increases by factors of 1000–100,000 upon the transition to one of these molten globules, even though the α amido protons of many of the same amino acids remain relatively less accessible.^{65,214} These observations suggest that some of the same elements of secondary structure but not all of them²¹⁵ remain at the same locations in the amino acid sequence of the polypeptide but open up 1000–100,000-fold more often. These accelerated rates of exchange are increased much more by adding denaturants¹³⁸ so the conformational changes within the molten globule leading to exchange of amido

protons do involve some expansion of the structure into the solvent, but the effect, and hence the expansion, is much less than when the native state unfolds to the random coil. Three of the eight α helices of the native state of apomyoglobin²¹⁶ are present in its molten globule,⁶⁵ but site-directed mutations at the interfaces in the native state between these α helices have little effect on the stability of the molten globule.²¹⁷ It was concluded that although these α helices had formed, they were not packed against each other in any stable arrangement.

The accessibility of tryptophans to the solvent, as judged by **quenching of fluorescence** (Equation 12–41), differs significantly in these molten globules, and tryptophans that are relatively more exposed in the native state become less exposed.²¹⁸ The fluorescence intensities of the tryptophans in cytochrome *c*, which are quenched by the nearby heme in the native state but are fully expressed in the random coil, remain quenched in its molten globule.²¹⁰ The **intrinsic viscosity**, **rotational relaxation times**, and **diffusion coefficients** of the molten globules are indistinguishable from those of the corresponding native states but are different from those of the random coil.^{209,210} All of these observations demonstrate that they are condensed, globular structures like the native state.

It is thought that these intermediates identified as molten globules represent the random coil that has collapsed to a **globular state** because of the hydrophobic effect, even though it is **fluid** and cannot assume the unique set of conformations that is the native state. In this regard, it is interesting that the majority (85%) of the change in standard heat capacity between the random coil and the native state of α -lactalbumin, which is a signature of the hydrophobic effect, is experienced in the transition between the random coil and the intermediate that has been characterized as a molten globule.²⁰⁵ The equilibrium constant for the formation from the random coil of an intermediate thought to be a molten globular state of apomyoglobin displays a significant temperature dependence, passing through a maximum between 0 and 20 °C. This observation is also consistent with a process accompanied by a large change in standard heat capacity,²⁰² but in this case, only about 50% of the overall change in standard heat capacity is realized in the transition from random coil to molten globule.

If these intermediate, molten globular states resemble intermediates on the normal kinetic pathway between the random coil and the native state, then the condensation model for the folding of a polypeptide may be an accurate rendition of the process. In this description of folding, the random coil spontaneously collapses under the influence of the hydrophobic force to form a condensed state that would be a molten globule. This molten globule would fluidly sample the limited number of conformations available to the condensed polymer until the native state, the set of conformations of lowest standard free energy, was encountered.

The alternative to the condensation model for the

folding of a polypeptide could be referred to as the **nucleation model**. In this view of the process, a short segment of the polypeptide or several short segments would spontaneously assume a metastable conformation similar to the conformation of that short segment or those short segments in the complete native state. This nucleus for folding would resemble the conformation of the native state in both its secondary and tertiary interactions in this restricted region, and it would represent the most independently stable region of the native state. From this nucleus, folding would rapidly spread to produce the entire native structure. Evidence for this proposal comes from the study of short segments of polypeptide that can assume structured states other than the random coil and from stable expanded states of some polypeptides.

Although almost all short segments of polypeptide have proven to be structureless, a few have been found that assume a structured state. For example, two peptides from bovine pancreatic trypsin inhibitor ($n_{aa} = 58$), Arginine 20–Phenylalanine 33 and Asparagine 43–Alanine 58, were chemically synthesized and joined by forming the cystine between Cysteine 30 and Cysteine 51 that occurs naturally in the native protein. This covalent complex, containing only half of the covalent structure of the full-length protein, nevertheless formed a structure²¹⁹ that had some of the structural features assumed by this region in the crystallographic molecular model of the protein. The antiparallel β sheet could be discerned in the nuclear magnetic resonance spectrum but not the α helix. The short, stable α -helical segments of polypeptide discussed earlier have also been proposed as models of nucleation points in protein folding.²²⁰

There are also stable conformations of a few polypeptides, observed under circumstances promoting denaturation, in which condensation has not occurred but elements of structure resembling those in the native state have formed. For example, there is an expanded form of the polypeptide of cytochrome *c* observed at low ionic strength and low pH in which α helices found in the native state of the protein are formed²²¹ and an expanded form of the α subunit of tryptophan synthase from *E. coli* in which a hydrophobic cluster has formed.²²² In the denatured form of ribonuclease from *B. amyloliquifaciens* observed at pH 2 and 25 °C, which is unfolded, two of the α helices found in the native state of the protein are formed in low yield.³⁵ All of these results suggest that portions of the polypeptide, when it is still in an almost fully expanded state, might assume their native structures initially to produce a point of nucleation for overall folding.

What is more likely, however, is that both condensation and nucleation occur during the folding of a polypeptide. The most obvious evidence for such a scenario is that some, but not all, of the secondary structure that is found in the native state of a protein is usually present in its molten globule. Such elements of secondary structure could nucleate the formation of the remainder of the native structure. A fragment of α -lactalbumin

that assumes at equilibrium a structure containing the α helices that are present in its portion of the native structure of the protein has been proposed to represent a point of nucleation for the native state even though it is by itself a molten globule.²²³ These observations suggest that protein folding involves both condensation and nucleation, but not necessarily in that order. The question of the sequence of events in the folding of a polypeptide requires kinetic observations of the process.

Problem 13–1: As urea is added to a solution containing a protein in its native state, the protein usually begins to unfold when the concentration of urea rises above 4–5 M. This unfolding is due to the ability of urea to stabilize the unfolded state.

Consider the side chain of an amino acid that is located in the interior of a protein and cannot see the solvent when the protein is folded. From the point of view of this interior side chain, the following series of equilibria govern the unfolding process:

The standard free energy changes $\Delta G^\circ_{\text{transfer, interior} \rightarrow \text{H}_2\text{O}}$ and $\Delta G^\circ_{\text{transfer, interior} \rightarrow [\text{urea}]}$ are standard free energy changes that occur as the amino acid is transferred from the interior of the protein either into pure water or into a solution of urea, respectively, as the protein unfolds to a random coil, and $\Delta G^\circ_{\text{transfer, H}_2\text{O} \rightarrow [\text{urea}]}$ is the standard free energy change involved in transferring the side chain of an amino acid, which is exposed during unfolding, from water into a solution of urea.

- (A) How are these three values of ΔG° related? What sign must each carry to explain the unfolding caused by urea?

The following is a table⁷ of the solubilities of a series of amino acids in solutions of several concentrations of urea at 25 °C.

amino acid	solubilities [g (100 g of solvent) ⁻¹] at noted concentration of urea				
	0 M	2 M	4 M	6 M	8 M

Thr	0.51
Leu	0.67
Met	0.90
Phe	0.93
Tyr	1.10
Trp	1.34
Asn	0.60
Gln	0.89
His	0.83

- (F) Plot $(\partial \Delta G^\circ_{\text{transfer, H}_2\text{O} \rightarrow [\text{urea}]} / \partial [\text{urea}])$ against accessible surface area, labeling each point on your curve to keep track of the side chain it represents. What is the value of $\partial(\partial \Delta G^\circ_{\text{transfer, H}_2\text{O} \rightarrow [\text{urea}]} / \partial [\text{urea}]) / \partial (\text{surface area})$?

Measurements of a physical property displayed by a protein can be used to obtain a value of the equilibrium constant for the transformation between the native state and the random coil at different concentrations of a denaturant. From each of these equilibrium constants, the standard free energy of folding, $\Delta G^\circ_{\text{Fd, [denaturant]}}$, for the reaction at that concentration of denaturant can be calculated. The figure on the next page is an example of the relationship between $\Delta G^\circ_{\text{Fd, [denaturant]}}$ and the concentration of denaturant for the unfolding of lysozyme promoted by urea and guanidinium chloride.

The slopes of these two lines $(\partial \Delta G^\circ / \partial [\text{denaturant}])$ are relative measures of the effectiveness of the two denaturants. By fitting a straight line to these data it is possible to obtain, by extrapolation, the standard free energy of folding in the absence of denaturant, $\Delta G^\circ_{\text{Fd, H}_2\text{O}}$. The following table gathers the results from four separate proteins, where $[\text{GdmCl}]_{1/2}$ or $[\text{urea}]_{1/2}$ is the concentration of denaturant when $[F] = [U]$ and $\Delta G^\circ_{\text{Fd}} = 0$.

protein	guanidinium chloride		urea	
	$[\text{GdmCl}]_{1/2}$ (M)	$\Delta G^\circ_{\text{Fd, H}_2\text{O}}$ (kJ mol ⁻¹)	$[\text{urea}]_{1/2}$ (M)	$\Delta G^\circ_{\text{Fd, H}_2\text{O}}$ (kJ mol ⁻¹)
bovine ribonuclease A	3.01	-39	6.96	-32
lysozyme <i>G. gallus</i>	3.07	-24	5.21	-24
bovine chymotrypsin	1.90	-32	4.04	-35
ovine β -lactoglobulin	3.23	-52	5.01	-44

- (G) From an examination of the figure and an understanding of where the two points tabulated fall

Apparent standard free energy of folding, $\Delta G^{\circ}_{\text{Fd},[D]}$, of lysozyme as a function of the molar concentrations of urea (●) or guanidinium chloride (○) at pH 2.9.¹⁰⁷ The apparent standard free energy of folding is zero at the concentration of denaturant at which $[U] = [F]$. Adapted with permission from ref 107. Copyright 1974 *Journal of Biological Chemistry*.

upon each line, calculate (Equation 13–23) the slope m of the line ($m = \partial\Delta G^{\circ}/\partial[\text{denaturant}]$) for each combination of protein and denaturant.

(H) Calculate the quantity

$$R_{\text{prot}} = \frac{(\partial\Delta G^{\circ}_{\text{Fd}}/\partial[\text{guanidinium}])_T}{(\partial\Delta G^{\circ}_{\text{Fd}}/\partial[\text{urea}])_T}$$

for each protein. This number will serve as a quantitative estimate of the relative effectiveness of the two denaturants.

(I) In part F you calculated a quantity $\partial(\partial\Delta G^{\circ}_{\text{transfer},\text{H}_2\text{O} \rightarrow [\text{urea}]} / \partial[\text{urea}]) / \partial(\text{surface area})$. Using the same methods, calculate a value for $\partial(\partial\Delta G^{\circ}_{\text{transfer},\text{H}_2\text{O} \rightarrow [\text{GdmCl}]} / \partial[\text{GdmCl}]) / \partial(\text{surface area})$ from the data in the table preceding part C.

(J) Calculate the quantity

$$R_{\text{transfer}} = \frac{(\partial\Delta G^{\circ}_{\text{transfer},\text{H}_2\text{O} \rightarrow [\text{GdmCl}]} / \partial[\text{guanidinium}])_T}{(\partial\Delta G^{\circ}_{\text{transfer},\text{H}_2\text{O} \rightarrow [\text{urea}]} / \partial[\text{urea}])_T}$$

and compare it to R_{prot} .

Problem 13–2: Bovine ribonuclease A is a protein containing 124 amino acids and four cysteines. Ribonuclease was added to a series of solutions containing different concentrations of guanidinium chloride, and the change in its extinction coefficient ($\Delta\epsilon_{287}$) was measured at 287 nm when each of the solutions had come to equilibrium.¹²⁴

[GdmCl] (M)	$\Delta\epsilon_{287}$ (M ⁻¹)	[GdmCl] (M)	$\Delta\epsilon_{287}$ (M ⁻¹)
0.00	0	3.01	–68
0.02	4	3.20	–96
0.34	4	3.30	–102
0.99	4	3.54	–119
1.61	7	4.03	–127
2.20	8	4.37	–126
2.67	–18	4.84	–121
2.81	–44	5.57	–118
2.95	–63	6.04	–114
		6.82	–110

The change in absorbance at 287 nm is a spectral indicator that reflects changes in the environments around the tryptophans in a protein. Make a plot of these data.

(A) What is $\Delta\epsilon_{287}$ of native ribonuclease at 4 M guanidinium chloride?

(B) What is $\Delta\epsilon_{287}$ of unfolded ribonuclease at 1 M guanidinium chloride?

For ribonuclease it has been proven that only the native state and the random coil are present at any concentration of guanidinium chloride.

(C) Calculate K_{Fd} for the equilibrium of Equation 13–1 for each concentration of guanidinium chloride and enter your values into a table.

(D) Plot $\ln K_{\text{Fd}}$ against [GdmCl] and determine, by extrapolation, the standard free energy of folding for ribonuclease in water, $\Delta G^{\circ}_{\text{Fd},\text{H}_2\text{O}}$.

Problem 13–3: In the region of the nuclear magnetic resonance spectrum of bovine ribonuclease A between 8.0 and 9.0 ppm, the only absorptions present are those from the carbons 2 of the imidazole rings of the histidines. The traces⁴⁸ are from this region of the nuclear magnetic resonance spectrum of ribonuclease. Changes in the spectrum occur when guanidinium chloride is added to the sample at the noted concentration.

In the native protein (0.0 M guanidinium chloride), four absorptions from the protons on carbons 2 are observed. They have been assigned to Histidines 48, 119, 12, and 105, the four histidines of ribonuclease.

- (A) Why does each absorption have a unique position in the spectrum of native ribonuclease?
- (B) Why is there only one absorption from the protons on the carbons 2, which integrates as four protons from the protein, when it is dissolved in 3.0 M guanidinium chloride?
- (C) Between 0.0 and 1.7 M guanidinium chloride the resonances shift around, but above 1.7 M the four absorptions coalesce into the one absorption. What process is the spectrometer monitoring between 1.7 and 3.0 M guanidinium chloride?
- (D) What would be the position of the absorption from the protons on the carbons 2 of *N*^α-acetylhistidine ethyl ester in 3.0 M guanidinium chloride?

Problem 13-4: Below are listed several thermodynamic parameters that are involved in the process of protein folding.

- (a) Change in standard free energy for the hydrophobic effect
 - (b) Standard free energy of formation for hydrogen bonds
 - (c) Change in standard electrostatic free energy
 - (d) Configurational entropy of the random coil
 - (e) Configurational entropy of the native state
- (A) Which one is most affected by the steric constraints described in the Ramachandran plot?

Suppose proteins were held together by imine linkages rather than peptide bonds:

- (B) What effect would this have on the parameter you have chosen above?
- (C) How would the value of the standard free energy of folding $\Delta G_{\text{Fd}}^\circ$ be affected by this change?

Kinetics of Folding

The most straightforward way to initiate the folding of the random coil of a polypeptide that has been unfolded to a random coil in a concentrated solution of guanidinium chloride or urea is to dilute that solution. The **dilution** is performed so that the final concentration of denaturant is well below the region of transition so that the equilibrium between the folded state and the unfolded state is shifted from one heavily in favor of the

random coil to one heavily in favor of the folded state (Figure 13-1).*

Often the folding of the polypeptide is complete within a few seconds so the dilution must be performed rapidly. Usually, the solution of the random coil at a high concentration of denaturant is mixed with around 10 volumes of aqueous buffer of the appropriate ionic strength and pH in a **rapid mixing chamber**. The chamber is designed to mix the two solutions completely in less than a millisecond as they are forced through it at high velocity under considerable pressure. There are several different ways in which the solution emerging from the mixing chamber can then be monitored. Usually, a cuvette† is attached to the mixing chamber, and the mixture from the chamber is passed through the cuvette at the high velocity developed in the mixing chamber until it fills the cuvette uniformly. Once a steady state is reached, the flow is abruptly stopped, and changes that occur in the solution in the cuvette after cessation of the flow are monitored. The mean time the solution in the cuvette has spent between being mixed and the cessation of flow coincident with the initiation of the monitoring is the **dead time** of the apparatus. No measurements can be made of events that occur during the dead time. In most cases, the dead time of such a **stopped-flow apparatus** is 1–50 ms. Changes in the absorbance, molar ellipticity, or fluorescence of the solution can be monitored continuously from the dead time onward.

Often, during the folding of a protein, significant changes in absorbance, fluorescence, or molar ellipticity or two or three of these properties occur within the dead time of the apparatus. Type I ribonuclease H from *E. coli* displays such behavior (Figure 13-9).^{225,226} When its molar ellipticity at either 220 nm (Figure 13-9A) or 292 nm (Figure 13-9B) is monitored, the signal observed after flow has stopped decays to the value for the native state in a single, apparently first-order relaxation (Equation 13-13) with a rate constant of 0.6 s^{-1} . When these time courses are extrapolated through the dead time back to the instant of mixing, however, it can be seen that 83% of the change in molar ellipticity at 220 nm and 44% of the change in molar ellipticity at 292 nm did not occur during this apparently homogeneous transformation but in one or more kinetic steps that were much more rapid than the final isomerization. These steps occurred within the dead time of the apparatus, and, consequently, they could not be resolved.

A reaction that is unresolved in a stopped-flow experiment because it is complete during the dead time

* It is also possible to begin the experiment with a solution of the complex between the polypeptide and dodecyl sulfate and then rapidly strip the dodecyl sulfate from the protein.²²⁴ The difficulty with this approach is that the polypeptide in the complex with dodecyl sulfate is completely α -helical rather than a random coil.

† A cuvette is a chamber with transparent walls through which spectrophotometric measurements can be made.

Figure 13-9: Kinetic burst during the refolding of type I ribonuclease H from *E. coli*.²²⁵ Type I ribonuclease H ($n_{aa} = 155$) was dissolved in 3.3 M guanidinium chloride and 10 mM sodium acetate, pH 5.5 at 25 °C. After it had unfolded completely, it was mixed in a stopped-flow apparatus with 10 volumes of 0.65 M guanidinium chloride and 10 mM sodium acetate, pH 5.5 (final concentration = 0.9 M guanidinium chloride), and the effluent from the mixing chamber was monitored following cessation of flow (dead time = 50 ms). (A) Molar ellipticity at a wavelength of 220 nm ($[\theta]_{220}$) in units of degrees centimeter² (decimole of peptide bond)⁻¹ as a function of time (seconds). The molar ellipticity of unfolded ribonuclease H at 220 nm in 0.9 M guanidinium chloride, as determined by extrapolation at equilibrium as in Figures 13-1A and 13-7A, should be 0. (B) Molar ellipticity at a wavelength of 292 nm ($[\theta]_{292}$) in units of degree centimeter² (decimole of peptide bonds)⁻¹ as a function of time (seconds). The molar ellipticity of unfolded ribonuclease H at 292 nm in 0.9 M guanidinium chloride, again as determined by extrapolation at equilibrium, should be 20 (dashed line). (C) Fluorescence of tryptophans in the protein monitored at emission wavelengths of greater than 300 nm with excitation at 280 nm. The scale for fluorescence was not quantified, so the relative fluorescence of the unfolded protein in 0.9 M guanidinium chloride was not reported. The three sets of data were fit with first-order relaxations (smooth curves) with rate constants of (A) 0.59 s⁻¹, (B) 0.74 s⁻¹, and (C) 0.51 s⁻¹ and 1.95 s⁻¹. Reprinted with permission from ref 225. Copyright 1995 American Chemical Society.

is a **kinetic burst**. The observation of a kinetic burst is interpreted to mean that one or more transformations of the random coil have occurred during the dead time and that they have produced an intermediate state. This intermediate state then turns into the native state as the reaction is monitored over time. In the case of type I ribonuclease H, this intermediate state becomes the native state in a reaction that appears by measurements of circular dichroism to display simple first-order kinetics with a rate constant of about 0.6 s⁻¹. This latter transformation is also revealed in the change in fluorescence of the solution (Figure 13-9C).

The kinetics of the folding of apomyoglobin from *Physeter catodon*,²²⁷ of micrococcal nuclease from *Staphylococcus aureus*,^{228,229} of equine cytochrome *c*,²³⁰ of dihydrofolate reductase from *E. coli*,²³¹ of equine β -lactoglobulin,²³² and of equine lysozyme^{233,234} all display similar **kinetic bursts producing intermediate states** that then apparently decay through one or several first-order steps to their native states. The appearance of these intermediates during a kinetic burst and their decay during the period of measurement can be detected by their absorbance, by their molar ellipticities in the range of 220–230 nm (the far ultraviolet), by their molar ellipticities in the range of 270–290 nm (the near ultraviolet), by their fluorescence, or by the transfer of energy between donors and acceptors placed at particular positions in their amino acid sequences. They are observed upon rapid dilution to 0.4–0.8 M urea or to 0.3–0.9 M guanidinium chloride. They are formed usually within less than 10 ms at temperatures between 10 and 25 °C, and they then decay at various rates.

A certain fraction of the changes in molar ellipticity or fluorescence that occurs in each of these kinetic bursts

results from the instantaneous changes in the molar ellipticity or fluorescence that occur in the random coil upon the abrupt decrease in the concentration of denaturant and that may or may not be able to be corrected for by linear extrapolation of the values at equilibrium for these physical properties from beyond the region of transition, as was done in Figure 13-1A.²³⁵ Their magnitude, however, is sufficiently large in most cases that they must reflect significant conformational changes in the unfolded state that produce real intermediates in the process of folding.

Within the range of denaturant concentration in the region of transition where the respective equilibrium constants for folding have been shifted into measurable ranges, most of these proteins display two-state behavior in the isomerization of their folding without evidence for intermediates. Why do intermediates in folding appear at lower concentrations of denaturant? The answer lies in the behavior of the observed rate constant*

* The progress of the folding of a protein monitored spectrophotometrically can usually be fit by a rate equation for one or more sequential first-order steps. Even though this fit is probably an oversimplification of the actual events, the observed apparently uncomplicated first-order rate constants obtained by such numerical analysis will be referred to as observed rate constants.

of folding, k_F , as a function of the concentration of denaturant.

When the logarithm of the observed rate constant for the approach to equilibrium for the folding of type I ribonuclease H from *E. coli* is plotted as a function of the concentration of guanidinium chloride (Figure 13–10),^{225,236} two-state behavior is observed in the region of transition, where the observed rate constant for unfolding dominates at high concentrations of denaturant and the observed rate constant for folding dominates at low concentrations. The logarithm of the observed rate constant for folding, however, does not display a continuous linear decrease below the region of transition as is observed in Figure 13–1B. Instead, its behavior is resolved further into two components, one dominant at intermediate concentrations of denaturant and the other at low concentrations. These two steps are distinguished by the two different slopes of the two distinct linear segments below the region of transition in

Figure 13–10: Observed rate constants for the approach to equilibrium for the folding isomerization of the cysteineless mutant of type I ribonuclease H from *E. coli*.²³⁶ A solution of 110 mM protein, 50 mM KCl, 20 mM sodium acetate, pH 5.5, and either no denaturant (unfolding) or 3 M guanidinium chloride (folding) was mixed in a stopped-flow apparatus with 11 volumes of 50 mM KCl, 20 mM sodium acetate, pH 5.5, and the appropriate concentration of guanidinium chloride to achieve the noted concentration following the mix. The fluorescence emission of the solution at wavelengths greater than 320 nm from an excitation at 295 nm was monitored as a function of time as in Figure 13–9C. The traces of fluorescence as a function of time could each be fit (Equation 13–13) by single-exponential increases (unfolding) or decreases (folding) of fluorescence. The observed rate constants k_{obs} (second⁻¹) for these exponential relaxations are plotted as a function of the concentration (molar) of guanidinium chloride (GdmCl). The dashed line is a fit of the data to an equation derived from a mechanism in which there are three states interconverting: the random coil, the native state, and a kinetic intermediate. It is assumed that the logarithm of each of the four first-order rate constants interconverting those three states is a linear function of the concentration of guanidinium ion as in Figure 13–1B. Reprinted with permission from ref 236. Copyright 1999 Elsevier B.V.

Figure 13–10.* This behavior is characteristic of a **change in rate-limiting step**† and consequently is consistent with a kinetic mechanism for folding in which there are two or more steps and one or more intermediates.²³⁸ At concentrations of guanidinium chloride between 1.5 and 1 M, the folding of type I ribonuclease H (Figure 13–10) has an observed rate constant that is strongly dependent on the concentration of guanidinium chloride. At concentrations of guanidinium chloride between 0.2 and 0.6 M, however, the folding of the protein has an observed rate constant that is only weakly dependent on the concentration of guanidinium chloride. At concentrations of guanidinium chloride between 0.6 and 1.0 M, the change in rate-limiting step occurs from a step strongly dependent on concentration of denaturant to a later step in the process of folding that is weakly dependent.

The two observed rate constants for the two respective steps between which the rate limitation shifts are the rate constant for the production of the intermediate present following the kinetic burst and the rate constant for its decay to the native state, respectively. The observed rate constant for the formation of this intermediate, which is defined by the linear segment of greater slope, is strongly **dependent on the concentration of denaturant**. Because of this strong dependence, above a certain concentration of denaturant the rate at which the intermediate is formed becomes slower than the rate at which it isomerizes to the native state. Consequently, above that concentration of denaturant, the intermediate, although it is still formed every time a polypeptide folds, cannot accumulate because it turns into the native state faster than it is formed, and the reaction, which is at least a three-state process at low concentrations of denaturant or in its absence, appears to become a two-state process above 1 M guanidinium chloride.

Such behavior indicative of a change in the rate-limiting step of folding is also observed for the folding of type I ribonuclease H from *E. coli* in solutions of urea²²⁶ as well as lysozyme from bacteriophage T4 in solutions of guanidinium chloride,²³⁶ the carboxy-terminal domain of the cell surface receptor CD2,²³⁹ the inhibitor barstar of the ribonuclease of *B. amyloliquifaciens*,²⁴⁰ the amino-terminal domain of phosphoglycerate kinase from

* In the simplest cases, where only one continuously varying apparent rate constant seems to control the folding at concentrations of denaturant below those of the region of transition, as in Figure 13–1B, it is observed that the logarithm of that apparent rate constant is a linear function of the concentration of denaturant, much as is the standard free energy of folding. It is customary to designate the slope of such a line with the symbol m , just as the slope is designated in Equation 13–23.

† The **rate-limiting step** in the mechanism of a reaction is the last step in the sequence that exerts any influence on the overall rate.²³⁷ By this definition, all of the steps that follow the rate-limiting step must be so fast that they occur immediately relative to the passage through the rate-limiting step.

Bacillus stearothermophilus,¹² cytochrome c_2 from *Rhodobacter capsulatus*,²⁴¹ and human lysozyme.²⁴²

In addition to explaining the appearance of these kinetic intermediates as the concentrations of denaturant are decreased and providing further evidence for the existence of one or more intermediates in the folding of each of these polypeptides in the absence of denaturant, these observations of a change in the rate-limiting step provide a clue about the structures of the intermediates formed during a kinetic burst. Because the observed rate constants for their formation decrease significantly as the concentration of denaturant is increased while the observed rate constants for their conversion to the respective native states decrease much less significantly, each of these intermediates must be a more **compact, condensed state of the polypeptide** than the random coil. This follows from the proposal that the slope m of the line relating the logarithm of an observed rate constant for the folding of a polypeptide to the concentration of guanidinium chloride or urea (for example, the slopes of the linear segments in Figures 13-1B and 13-10) is a measure of the change in exposure of that polypeptide to the solvent between its initial state and the transition state of either the rate-limiting step in the transformation being monitored^{104,243} or of one or more of the rate-determining steps* that together establish the value of the composite rate constant²⁴⁴ for that transformation or the change in exposure of that polypeptide experienced during an unfavorable preequilibrium that precedes the rate-limiting step for that transformation. Consequently, either during the rate-limiting step or prior to the rate-limiting step of the transformation occurring during the kinetic burst in which the intermediate is formed from the random coil, a significant decrease in the exposure of the polypeptide to the solvent must occur.

Further evidence that these intermediates formed during a kinetic burst are compact, condensed forms of the polypeptide is provided by studies of their **scattering of X-radiation at small angles**. It is possible to measure small-angle scattering of X-radiation from a sample in the cuvette of a stopped-flow apparatus. When the intermediate formed from the polypeptide of apomyoglobin during the kinetic burst²²⁷ was examined in this way, it was found that the angular dependence of its scattering (Figure 12-2) was indistinguishable from that of the native state of the protein but clearly different from that of its unfolded random coil.²⁴⁵ This result indicates that most if not all of the condensation required to occur between the random coil and the native state must be accomplished within the kinetic burst. Similar results were observed for the folding of bovine β -lactoglobu-

lin.²⁴⁶ The rotational relaxation time of 1-anilidonaphthalene-8-sulfonate tightly bound to the intermediate formed in the kinetic burst during the folding of dihydrofolate reductase from *E. coli* is almost identical to that of the same probe bound to the native state, a result also suggesting that most if not all of the condensation of the polypeptide has already occurred in this isomerization.²⁴⁷ Increases in energy transfer by resonance between donors and acceptors covalently attached to particular positions in a polypeptide also indicate that it condenses during one of these isomerizations occurring in a kinetic burst.²²⁸

In addition to being compact, the intermediates formed during a kinetic burst contain **secondary structure**. This conclusion follows from the fact that large changes in molar ellipticity in the far ultraviolet, similar to those accompanying the formation of β structure and α helices (Figure 12-10), usually accompany the burst (Figure 13-9).^{226,227,231,233,248,249} A random coil has a slight positive **molar ellipticity** in the range from 210 to 230 nm while both β structure and α helices have significant, negative molar ellipticities (Figure 12-10), so the changes observed are decreases in molar ellipticity in this range. In fact, the molar ellipticity of the polypeptide of bovine β -lactoglobulin at 222 nm actually decreases to a level 2-fold lower than that of the native state during the kinetic burst before increasing to the proper value during the formation of the native state.²³² This result suggests that extra α -helical secondary structure is transiently forming in the intermediate and then disappearing as the native state forms.

The positions in the amino acid sequence that participate in the secondary structure formed in these intermediates can be defined by measurements of the **exchange of specific amido protons** from the peptide backbone. To perform such measurements, the unfolded polypeptide as a random coil in a concentrated solution of denaturant is passed in turn through a series of mixing chambers (Figure 13-11).²²⁷ In a typical experiment, the unfolded polypeptide in $^1\text{H}_2\text{O}$ is rapidly diluted into aqueous buffer prepared in $^2\text{H}_2\text{O}$ at a pH low enough to suppress proton exchange for the time being (Figure 12-31), and folding commences. After various millisecond intervals, during which the folding of the protein has progressed normally, the pH of the solution is increased, usually to a level greater than 9, in a second rapid mixing chamber to initiate the rapid and complete exchange of all amido protons still exposed to the deuterated solvent (Figure 12-31). The pH and duration of this period of rapid exchange are set so that it is long enough for exposed amido protons to exchange completely but not long enough for buried amido protons to exchange significantly. Finally, in a third rapid mixing chamber the pH is dropped again to slow the exchange and permit folding to be completed in the absence of further exchange.

In the final folded protein, most of the amido protons are well protected from further exchange by its sec-

* A **rate-determining step** in a reaction is any step the rate of which affects the rate of the overall reaction. In other words, if a step is rate-determining, an increase or decrease in its individual rate will cause a change in the overall rate of the reaction, but not necessarily of the same magnitude.

ondary and tertiary structure. Consequently it can be submitted to two-dimensional nuclear magnetic resonance spectroscopy (Figure 12–33) for the periods of time necessary to obtain two-dimensional spectra and determine which amido protons had become protected from exchange during the time spent folding before rapid exchange was initiated. Those positions in the amino acid sequence of the protein that have lost their protons during the experiment are those that were accessible when the jump in pH occurred; those that have not are those that had become protected. The times spent in the various steps and the levels of pH established in each step of these triple mixing experiments vary,^{233,250–252} but the intentions of initiating folding, of performing rapid exchange after folding has progressed for a certain period, and of then locking the information in the native state of the protein remain the same.*

Although most of the amido protons in an intermediate formed during a kinetic burst exchange rapidly during the respective jumps in pH, many are already protected from exchange by the structures of these intermediates.^{226,233,239,249,250} Because amido protons protected from exchange during the kinetic burst are found in segments within which each of a string of consecutive positions in the amino acid sequence is protected, it is assumed that these **segments of continuous protection** represent either α helices or β structure that have already formed in the intermediate.

Proteins during the folding of which intermediates do not accumulate in a kinetic burst nevertheless will often have similar intermediate states that form more slowly, in the milliseconds following the dead time. For example, an intermediate forms during the refolding of cytochrome *c* with a rate constant of 50 s^{-1} at 10°C that is compact and contains several elements of secondary structure but lacks the complete secondary and tertiary structure of the native protein.²⁵¹ These intermediates also have strings of consecutive amido protons protected from exchange.^{251,252}

It seems that some of the same **secondary structures found in the final native state** of the protein are already assembled in their entirety in these early kinetic intermediates formed either during a kinetic burst (Figure 13–11) or in the period immediately following the dead time. To a certain extent, this impression is illusory. Because the secondary structures in the native state are used to store the information about the protection that occurred upon the formation of the intermediate, this information is automatically divided into segments bounded by those elements of native secondary structure. Any information about the regions of the polypeptide outside of these segments of native secondary structure has been automatically erased. Amido protons

in these erased regions may have been protected in the intermediate but not in the native state. It is also possible to identify amido protons on particular amino acids that participate in hydrogen bonds in an intermediate formed in a kinetic burst by examining the effect of the concentration of denaturant on the exchange of amido protons within the native structure of a protein.²⁵³ Again, however, the fact that amido protons formed in the intermediate identified in this way coincide with elements of secondary structure in the crystallographic molecular model may be only a consequence of the fact that exchange from the native protein is being monitored.

The fact that all of the positions within a particular element of native secondary structure register similar levels of protection suggests but cannot prove that many of the same elements of secondary structure found in the native state are formed as discrete units early in the process of folding. There are, however, exceptions to this correspondence. For example, only a portion of the amino acids in helix B of apomyoglobin is protected from exchange in the intermediate formed during the kinetic burst (Figure 13–11).

Many if not most of the intermediates observed during kinetic bursts in stopped-flow experiments are similar if not **identical to stable molten globules** of the same polypeptide that are observed at equilibrium under unphysiological concentrations of denaturant, at unphysiological temperatures, at low pH, in the absence of salt, or with some combination of these perturbations. It has already been noted that, as is a molten globule, these kinetic intermediates are condensed conformations of the polypeptide. In addition, by varying the wavelength at which the kinetic measurements are made, it has been possible to demonstrate that the molar ellipticities at several wavelengths, both in the near ultraviolet and in the far ultraviolet, match the values in the **circular dichroic spectrum** of a stable molten globular state of the same polypeptide formed at equilibrium, usually under acidic conditions (Figure 13–12).^{226,232} Furthermore, the protection factors for the amido protons in the peptide backbone buried during the formation of an intermediate in a kinetic burst²³⁹ are often in the range of those observed for a molten globule at equilibrium rather than in the range of the much larger **protection factors** observed for amido protons locked within the secondary and tertiary structure of the native state. The effects of site-directed mutations of particular isoleucines to leucines and valines or particular leucines to isoleucines and valines in the hydrophobic core of the crystallographic molecular model of dihydrofolate reductase from *E. coli* were dramatically different on the yield of the intermediate observed in the kinetic burst than on the stability of the native state, a result suggesting that the packing of the native structure had not yet been established in the intermediate, as is the case in a molten globule.²⁵⁴

The most explicit evidence that these intermediates

* In most of these experiments the protein is unfolded in $^2\text{H}_2\text{O}$ and then folded in $^1\text{H}_2\text{O}$, and the gain of protons rather than their loss is monitored.

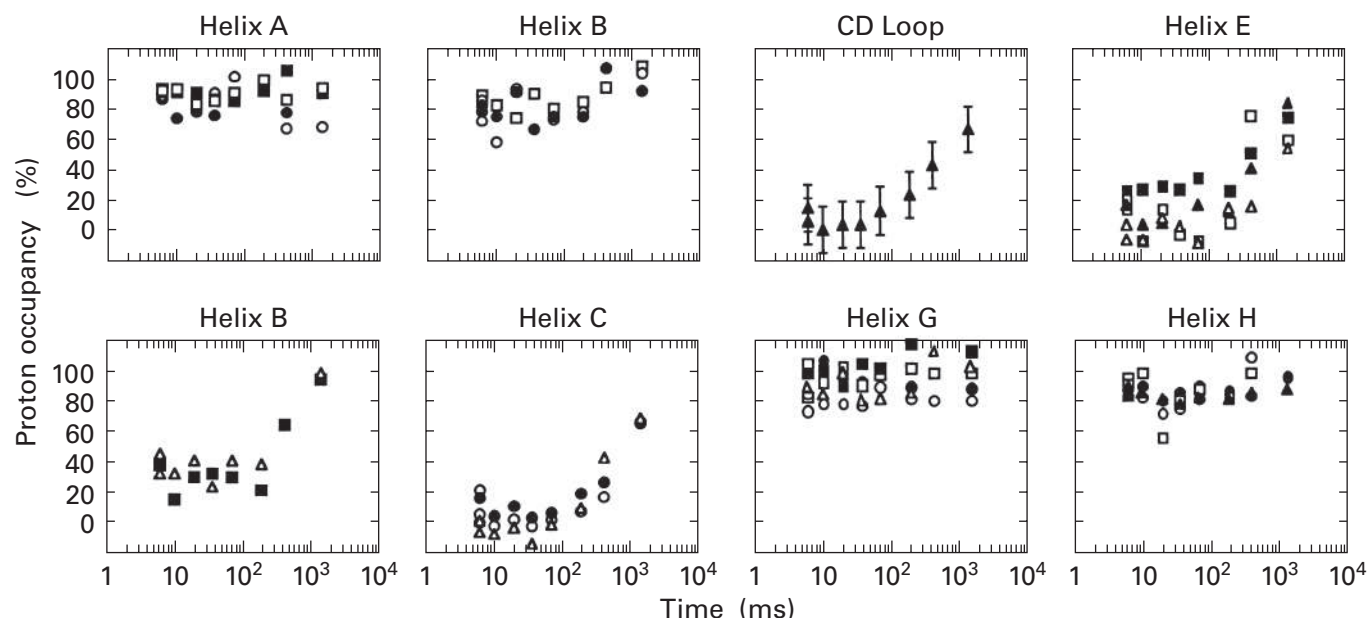

Figure 13-11: Sequestration of amido protons during the folding of apomyoglobin as followed by rapid mixing.²²⁷ A series of three rapid mixing chambers fed by four syringes were assembled in a cold room at 5 °C. Apomyoglobin from *P. catodon* was dissolved in 6 M urea and 10 mM sodium acetate, pH 6.1, in $^1\text{H}_2\text{O}$ and stood until it was fully unfolded. Flow through the mixing chambers was then initiated. The solution was diluted in the first mixing chamber 8.5-fold with 10 mM sodium acetate, pH 6.1, in $^2\text{H}_2\text{O}$. This mixture then travelled in the tubing connecting the first mixing chamber to the second for various periods of time (milliseconds). In the second rapid mixing chamber, the solution was mixed with an equal volume of a solution containing the buffers tris(hydroxymethyl)methylammonium ion, *N*-(ethylsulfonato)morpholinium ion, and acetate ion at a final ionic strength of 0.2 M, pH 10.2 in $^2\text{H}_2\text{O}$, which immediately brought the pH of the mixture to pH 10.2. This second mixture passed through a piece of tubing in which it spent 20 ms in transit to the third mixing chamber. In the third rapid mixing chamber it was diluted by mixing with a solution of the same ionic buffers at an ionic strength of 0.25 M, pH 1.9 in $^2\text{H}_2\text{O}$, that adjusted the final pH to 5.6. The effluent from the last mixing chamber was directed into a solution of hemin to turn the apomyoglobin to myoglobin and lock the protein in its native state. The amplitudes of the absorptions from the amido protons in two-dimensional nuclear magnetic resonance spectra (Figure 12-33) of the final solutions were determined for each sample. The different absorptions had been previously assigned to specific amido protons in the amino acid sequence of the protein.^{216,588} The percentage that each position in a set of representative positions was occupied (percentage occupancy) by a proton is plotted as a function of the time (milliseconds) the polypeptide was allowed to fold before the protons were exchanged with deuterons at pH 10.2. The amido protons are grouped according to the secondary structure they occupy in the crystallographic molecular model of myoglobin.^{216,588} The eight α helices in the crystallographic molecular model are designated in alphabetical order from the amino terminus and the CD loop is the segment of random meander between helix C and helix D. Occupancies of the amides of Leucine 29, Isoleucine 30, and Phenylalanine 33 from helix B are plotted in the upper panel; those of Isoleucine 28 and Arginine 31 from helix B are shown in the lower panel. Reprinted with permission from ref 227. Copyright 1993 American Association for the Advancement of Science.

formed during the kinetic bursts are similar if not identical to well-characterized molten globules of the same polypeptide observed at equilibrium is the **correspondence in the specific amido protons protected** during their formation with the respective amido protons protected in the respective molten globule. For example, in the intermediate formed during the kinetic burst in the folding of apomyoglobin, amido protons in positions in the amino acid sequence that form the first (A), a portion of the second (B), the seventh (G), and the eighth (H) α helices in the native state of the protein²¹⁶ are protected, but those that form the rest of the second, the third (C), and the fifth (E) α helices are not protected (Figure 13-11). This is the same pattern of protection observed in the molten globule of this polypeptide that is the dominant state at equilibrium between pH 4 and 5.⁶⁵ Likewise, in the intermediate formed in the kinetic burst in the folding of the cysteineless version of type I

ribonuclease H from *E. coli*, the pattern in which protected amido protons are distributed over its sequence of amino acids²²⁶ closely matches the pattern in which those amido protons are protected in the molten globule that predominates at equilibrium at levels of pH less than 2.²⁵⁵ When amino acids in regions that have been observed to be protected in the intermediate formed during the kinetic burst are mutated, the yield of the intermediate decreases; but when amino acids that have not been observed to be protected are mutated, the yield of the intermediate is unaffected.²⁵⁶

Apomyoglobin and type I ribonuclease H both seem to form an intermediate that already contains some but not all of the specific secondary structures that will eventually end up in their native states. The kinetic intermediates of β -lactoglobulin, however, which is also a molten globule, displays a circular dichroic spectrum indicating that it contains significant amounts of α helix

Figure 13-12: Circular dichroic spectrum of the kinetic intermediate observed during the kinetic burst in the folding of a cysteineless version of type I ribonuclease H from *E. coli*.²²⁶ Folding was initiated by an 11-fold dilution of the unfolded polypeptide in 7 M urea, and the kinetics of refolding (Figure 13-9) were monitored by following molar ellipticity at 16 different wavelengths, each in a separate run. The molar ellipticity [degrees centimeter² (decimole of peptide bonds)⁻¹] observed at the dead time (burst amplitude; ●) in each run is plotted as a function of the wavelength (nanometers) set for that run. The molar ellipticity observed at the end of each run (final folded state; ○) is also plotted as well as the circular dichroic spectrum of a molten globule of the protein that forms at equilibrium at pH 1.0 (solid line) and the circular dichroic spectrum of the native protein (dashed line). Reprinted with permission from ref 226. Copyright 1997 Nature Publishing Group.

even though only 12% of its native state is α helical.^{232,246} Consequently, in this instance, the intermediate contains at least some secondary structure that will not be present in the final native state.

That stable molten globules of the same polypeptides at equilibrium are similar if not identical to the respective kinetic intermediates formed during kinetic bursts means that the former should be valid models for the latter. From physical characterizations of these equilibrium states at rest, a much better understanding of the structure and dynamics of the kinetic intermediates on the move can be gained. The details of the physical properties of molten globules at equilibrium have already been discussed.

With some proteins, there are intermediates formed during a kinetic burst that are not molten globules. For example, the polypeptide of lysozyme from *G. gallus* isomerizes during the kinetic burst to an intermediate that has a radius of gyration intermediate between that of the random coil and that of the native state.²⁵⁷ A molten globule of this polypeptide would have a radius of gyration much closer to that of the native state. In the folding of dihydrofolate reductase from *E. coli*, little of the accessible surface that is eventually buried in the native state seems to be buried in the kinetic intermediate formed during kinetic burst.²⁵⁸ This

observation, however, seems to be contradicted by the fact that the rotational correlation time of this intermediate is indistinguishable from that of the native state, and therefore it should be as compact as the native state.²⁴⁷

In an observation of folding by stopped-flow, the formation of one of these kinetic molten globular intermediates usually takes place within the dead time of the apparatus. The dead time of such an observation, however, can be shortened by monitoring **continuous flow** through a rapid mixing chamber rather than stopped-flow. A transparent tube is attached directly to the mixing chamber, and the two fluids being mixed flow continuously at a high velocity through both the chamber and the tube. The fluorescence of the sample passing through the tube is monitored as a function of the distance along the tube, and hence the time spent in the tube, following mixing. In this way, events can be followed from about 100 μ s to 2 ms. The drawback is that, because of turbulence,²⁵⁹ only emission of light from the sample rather than absorption of light can be measured at times less than 500 μ s. The purpose of most of these experiments, however, is to monitor the formation of intermediates that have already been characterized extensively by stopped-flow observations and triple mixing experiments and to determine whether the step during which they are formed is preceded by yet an earlier step.

The rate of formation of a molten globular intermediate that appears during a kinetic burst in stopped-flow can often be resolved in continuous flow. For example, the observed rate constants for the formation of molten globular intermediates in the folding of bovine β -lactoglobulin,²⁶⁰ the B1 domain of immunoglobulin G binding protein G from *Streptococcus*,²⁶¹ intestinal fatty acid-binding protein from *Rattus norvegicus*,²⁶² and colicin E7 immunity protein from *E. coli*²⁶³ are 7000 s⁻¹ (20 °C), 2300 s⁻¹ (20 °C), 1500 s⁻¹, and 3000 s⁻¹ (10 °C), respectively. The similarity in the values of all of these observed rate constants may have more to do with the range over which rate constants can be measured by continuous flow than a similarity in the process being measured.

In the case of β -lactoglobulin, the B1 domain, and immunity protein, the isomerizations of the random coil producing the molten globular intermediates at these respective rates appear to be single first-order relaxations that are not preceded by any other kinetic burst, so the transformation of random coil to molten globular intermediate appears to proceed in one step with no prior kinetic intermediates. This conclusion follows from the fact that the kinetic traces of fluorescence extrapolate through the dead times (100–150 μ s) to the value for the fluorescence of the random coil at the final concentration of denaturant. Consequently, in these cases, the random coil appears to isomerize directly to the molten globule. In the case of fatty acid-binding protein, however, the extrapolation did not coincide with the fluores-

cence of the random coil, and the extrapolated values at different wavelengths of emission produced a spectrum for an additional intermediate formed in the kinetic burst that was distinct from the spectrum of the unfolded state. It follows that, in this case, at least one other intermediate precedes the molten globular intermediate.

Events that occur within even shorter intervals can be monitored by **temperature jump**. This approach exploits the fact that at a low temperature, the stability of a protein increases as the temperature is raised (Figure 13–5). A solution of protein in a concentration of denaturant within the region of transition is brought to a low temperature, which increases the concentration of the denatured state at the expense of the folded state. The temperature of the solution is then jumped by the rapid application of heat, and the solution stabilizes at a higher temperature within a hundred nanoseconds. The approach to the new equilibrium now favoring the folded state is then monitored. When the folding of equine cytochrome *c*²⁶⁴ and barstar from *B. amyloliquifaciens*²⁶⁵ are examined after a temperature jump of 10 °C, relaxations with rate constants of 11,000 s^{−1} and 3000 s^{−1} were observed, similar to those observed for other proteins by continuous flow. A much faster relaxation with a rate constant of 200,000 s^{−1} at 10 °C is observed for apomyoglobin, and this rate constant is significantly affected by the viscosity of the solvent, an observation suggesting that it represents the collapse of the denatured state,²⁶⁶ and a relaxation with a similar rate constant has been observed for the folding of bovine ribonuclease A.²⁶⁷ That these very rapid relaxations, however, monitor the initial global collapse of the random coil has been questioned,²⁶⁸ and it is possible that the initial collapse of these proteins usually occurs much more slowly, with rate constants in the range below 10,000 s^{−1}.

When it is dissolved in 0.01 M HCl, equine cytochrome *c* is in a denatured state that is not a random coil but is at least as expanded.^{269,270} Upon jumping of the pH to 4.0, the protein refolds from this expanded state. The refolding can be followed from 45 μs to 1 ms by continuous flow (Figure 13–13).²⁷⁰ It appears to pass through two clearly resolved steps with observed rate constants of 17,000 s^{−1} and 2300 s^{−1}. No kinetic burst is observed. During the first step 60% of the fluorescence from Tryptophan 59, the only tryptophan in the protein, is quenched by the covalently attached heme as the expanded conformation collapses, but no secondary structure forms beyond the residual α helix found in the expanded denatured state.²⁵⁹ During the second step, about 70% of the α-helical content of the native state is regained, to produce a molten globule.

What seems to be the same second step, involving the formation of the same level of α-helical content, occurs more slowly (50 s^{−1} at 10 °C) when the random coil in 4.4 M guanidinium chloride is diluted to 0.7 M guanidinium chloride, so it is possible to determine by rapid

Figure 13–13: Folding of cytochrome *c* monitored by continuous flow.²⁷⁰ Equine cytochrome *c* was dissolved in 0.01 M HCl and deionized by molecular exclusion chromatography in 0.01 M HCl. It was then mixed in a rapid mixing chamber with 10 volumes of 50 mM sodium acetate and 50 mM sodium phosphate, pH 5.1. The final pH of the mixture was 4.5. The effluent from the mixing chamber was passed through a 0.25 mm × 0.25 mm channel in a quartz block at 0.62 mL s^{−1} (0.99 μm μs^{−1}). The block was illuminated with light at 280 nm wavelength, and fluorescence emission at a wavelength greater than 324 nm was measured as a function of the distance along the channel. The fluorescence relative to that of the denatured polypeptide in 0.01 M HCl (1.0) and the folded native state at pH 4.5 (0.0) is presented as a function of time (microseconds). The data are fit with the solid curve, which is the sum of two first-order exponentials with rate constants of 17,000 s^{−1} and 2300 s^{−1} and amplitudes of 0.60 and 0.29. The dead time of the apparatus was measured directly and found to be 45 μs. Reprinted with permission from ref 270. Copyright 1998 Nature Publishing Group.

proton exchange that both the amino- and carboxy-terminal α helices of the native structure form during this step, but not the α helices between positions 60 and 80 in the amino acid sequence (Figure 7–9).²⁵¹ The molten globule formed during this second step, however, displays none of the molar ellipticity at 420 nm indicative of the asymmetric environment of the native structure surrounding the heme.²⁴⁸ Finally the native state arises in a biphasic process with rate constants of 2.5 s^{−1} and 0.25 s^{−1} at 10 °C²⁵¹ or 8 s^{−1} and 0.8 s^{−1} at 25 °C.²⁴⁸

The expanded denatured state of equine cytochrome *c* in 0.01 M HCl has an α-helical content that is 20% that of the native state,²⁵⁹ and although the α-helical content does not increase during its collapse, the earliest observed collapsed intermediate does contain this amount of α helix. Moreover, when the folding is performed by diluting the random coil of cytochrome *c*, which contains no α helix, from 4.4 to 0.4 M guanidinium chloride, there is still no kinetic burst and all of the

change in fluorescence at times less than 1 ms can be resolved into two steps with rate constants of $21,000\text{ s}^{-1}$ and 730 s^{-1} at $22\text{ }^{\circ}\text{C}$.²⁷⁰ The initial collapsed state, however, again has 20–30% of the α -helical content of the native state.^{230,259}

These observations raise the question of whether or not the polypeptide of a protein is able to collapse hydrophobically in an isomerization that involves no formation of secondary structure. Is there a purely **hydrophobic collapse**? Certainly, all of the condensed kinetic intermediates observed during the folding of polypeptides, when they are assayed for secondary structure, do contain it. Furthermore, the fastest events in protein folding involving condensation of the random coil to form a globular state usually have rate constants of less than $20,000\text{ s}^{-1}$, often much less. For example, in the case of the immunoglobulin binding domain of protein L from *Peptococcus magnus*, the condensation of the random coil to a globular state²⁷¹ occurs in a first-order reaction with a rate constant of only 0.12 s^{-1} . Yet there are measurements indicating that the purely hydrophobic collapse of a polypeptide should have a rate constant of at least 10^6 s^{-1} at $20\text{ }^{\circ}\text{C}$,²⁷² and theoretical treatments²⁶⁴ suggest that the rate constant should be 10^7 s^{-1} . Furthermore, a purely hydrophobic collapse should have no energy of activation, but the observed relaxations assigned to the collapses of denatured states do.

Explanations are required for both the slower than expected rate constants observed for these condensations and the fact that most if not all of the initial condensed states contain significant **secondary structure**. Even the extremely rapid relaxation of apomyoglobin with a rate constant of $200,000\text{ s}^{-1}$ observed by temperature jump nevertheless seems to involve an intermediate with significant secondary structure.^{266,268}

Suppose that kinetically, a purely hydrophobic collapse occurs before the formation of any of the secondary structure characteristic of a molten globule, and that the mechanism for folding is

where C is the hydrophobically collapsed state and MG is the subsequent molten globule. If both steps were intrinsically fast reactions, if k_2 were greater than k_1 , and if k_{-1} were greater than k_2 , the reactions would be coupled, and little purely hydrophobically collapsed state would be observed. It has just been noted, however, that k_1 , the hydrophobic collapse, should be much faster than the observed rate for the overall formation of the molten globule.

If $k_{-1} \gg k_2$, then the unfolded state and the hydrophobically collapsed state are in a **rapid preequilibrium** that precedes the step in which the secondary structure, which distinguishes the molten globule from

the hydrophobically collapsed state, is formed. The rate equation for the formation of the molten globule from the unfolded state by this mechanism is

$$[\text{MG}] = [\text{protein}]_{\text{TOT}} \left[1 - \exp \left(- \frac{k_2 K_{\text{cpse}}}{1 + K_{\text{cpse}}} t \right) \right] \quad (13-26)$$

where $[\text{protein}]_{\text{TOT}}$ is the total concentration of protein and K_{cpse} is the equilibrium constant for the hydrophobic collapse:

$$K_{\text{cpse}} = \frac{[\text{C}]}{[\text{U}]} = \frac{k_1}{k_{-1}} \quad (13-27)$$

Equation 13-26 defines a first-order formation of the molten globule with an observed rate constant

$$k_{\text{obs}} = \frac{k_2 K_{\text{cpse}}}{1 + K_{\text{cpse}}} \quad (13-28)$$

Upon initiation of the reaction, the equilibrium between the unfolded state and the hydrophobically collapsed state would be established immediately, and the molten globule would appear in a kinetically first-order reaction. If the equilibrium constant between the unfolded state and the hydrophobically collapsed state is less than 1, no purely hydrophobically collapsed state should be observed, and none is.

It is reasonable that this equilibrium constant should be less than 1. Few if any polypeptides should be able to bury enough hydrogen-carbon bonds upon their hydrophobic collapse to overcome both the unfavorable loss of the configurational entropy of the random coil and the unfavorable loss of solvation arising from the inescapable transfer of donors and acceptors of hydrogen bonds from the water into the interior of the collapsed state. Certainly the small values for standard free energy of folding (Table 13-2) suggest that this must be the case. Many of these unbonded donors and acceptors buried during the collapse, however, do become occupied within the secondary structure of the molten globule when it forms. These buried hydrogen bonds within α helices and β structure of the molten globule, because they are formed in the absence of water, stabilize it relative to a hydrophobically collapsed state lacking any internal hydrogen bonds. Consequently, the molten globule with its characteristic secondary structure can be the first intermediate observed even though the mechanism of folding passes obligatorily through a hydrophobically collapsed state lacking any secondary structure.

This explanation, however, is inconsistent with the observation that the reciprocals of the observed rate con-

stants for the formation of the molten globular intermediates seem to be linearly related to the **viscosity of the solvent**.²⁷³ Because it is a state function, the equilibrium constant for collapse cannot be affected by the viscosity of the solvent. Because neither K_{cpse} nor k_2 should be affected by viscosity, the rate-limiting step in the formation of these intermediates cannot be the formation of secondary structure within an already collapsed state. It could, however, be the collapse of an expanded state already containing sufficient secondary structure to stabilize the collapsed state, much as the expanded acid-denatured form of cytochrome *c* with 20% α helix collapses upon a jump in pH²⁵⁹ or as the expanded cold-denatured form of barstar, which also contains significant residual secondary structure,⁹⁵ collapses upon a jump in temperature. If this is the mechanism for the collapse of an expanded denatured state, the secondary structure that will stabilize the molten globule relative to the hydrophobically collapsed state forms first within the random coil and is then trapped by the collapse of this structured denatured state to form the molten globule directly.

There are indications that, in the unfolded state of a protein in solutions of guanidinium ion or urea, **metastable segments of secondary structure** form and dissolve continuously even though they are not present at significant concentrations.⁹⁵ During the folding of bovine acyl-CoA-binding protein at 0.5 M guanidinium chloride,²⁷⁴ an intermediate forms during a kinetic burst in which considerable protection is afforded to the exchange of amide protons, but this protection seems to result from the formation of a set of relatively stable conformations of the uncollapsed polypeptide that contain elements of secondary structure. It is difficult, however, to determine just how uncollapsed these conformations are. Clusters of secondary structure in either evanescent or more stable conformations of the uncollapsed random coil could be trapped during its collapse to form a molten globule directly. A random coil is an ensemble of conformations in rapid equilibrium with each other, and subsets of those conformations may contain elements of secondary structure waiting to be enclosed.

In this case, the preequilibrium would be not hydrophobic collapse (Equation 13–25) but the formation of these fleeting unstable elements of secondary structure:

where 2° is any subset of the conformations of the random coil containing secondary structure extensive enough and appropriately located to support the stable formation of a molten globular intermediate. The formation of this molten globule would be a first-order reaction (Equation 13–26). If $k_{-1}' > k_2'$, then the observed rate constant for the mechanism of Equation 13–29 is

$$k_{\text{obs}} = \frac{k'_2 K_{2^\circ}}{1 + K_{2^\circ}} \quad (13-30)$$

where K_{2° is the equilibrium constant for the formation of the secondary structure within the random coil the presence of which is required before collapse can occur. No secondary structure would be observed in the random coil because the equilibrium constant for its formation, K_{2° , would be significantly less than 1. If $K_{2^\circ} \ll 1$, then the observed rate constant is $K_{2^\circ} k_2'$. The formation of the molten globular intermediate would exhibit an apparent energy of activation that is the sum of the actual standard free energy of activation for the reaction governed by rate constant k_2' and the change in standard free energy for the reaction governed by the equilibrium constant K_{2° for the preequilibrium in which the secondary structure is formed.

The decision between a mechanism in which hydrophobic collapse precedes any formation of secondary structure (Equation 13–25) and a mechanism in which the formation of sufficient secondary structure to stabilize the collapsed state precedes hydrophobic collapse (Equation 13–29) depends on the interpretation of the effects of solutes that increase the viscosity of the solvent on the observed rate constants for the formation of the molten globular intermediates. If the effects of these solutes are on the stability of intermediates in the process of folding²⁷⁵ rather than exclusively on the viscosity,²⁷³ this decision is ambiguous. It is often impossible to distinguish these two possibilities experimentally.

The transition between one of the molten globular intermediates formed during a kinetic burst and the final native state of a protein appears to occur in one or several consecutive kinetic steps. For example, the molten globular kinetic intermediates of apomyoglobin,²²⁷ intestinal fatty acid binding protein,²⁶² and the B1 domain of protein G²⁶¹ become the respective native state in apparently single first-order steps with rate constants of 1 s^{-1} (5°C), 5 s^{-1} , and 600 s^{-1} (20°C). The molten globular intermediate of type 1 ribonuclease H becomes the native state in what appears to be a single first-order step with a rate constant of 0.6 s^{-1} at 25°C when monitored by molar ellipticity at 220 nm and 292 nm but an additional faster step of 2 s^{-1} is detected by fluorescence (Figure 13–9). This latter result illustrates the fact that some steps in the folding of a protein go unregistered by certain physical measurements.

The apparently single steps that occur following the rapid formation of an intermediate during a kinetic burst and that in turn produce the native state often seem to involve only a portion of the entire protein. The **folding of the rest of the protein** must occur either during the kinetic burst or during rapid unregistered steps following the rate-determining steps and the rate-limiting step that produce this slow observed rate constant. For example, some site-directed mutations of ribonuclease from

B. amyloquifaciens affect the observed rate constant for the production of the native state from the intermediate formed during the kinetic burst, while others affect the stability of that intermediate.²⁷⁶ The observed rate constant (20 s^{-1} at 20°C) for the principal relaxation observed in both molar ellipticity and fluorescence following the kinetic burst during the folding of lysozyme from bacteriophage T4 is affected significantly by site-directed mutations in the carboxy-terminal half of the polypeptides but not by mutations in the amino-terminal half even though the mutations in both halves affect the stability of native state.²⁷⁷ Presumably the process being registered as an apparent single step by both circular dichroism and fluorescence is the folding of only the one half of the protein and not the other.

It is more common to observe two or more steps rather than just one during the transition between a kinetic molten globular intermediate and the native state. For example, four additional steps can be discerned following the formation of the first kinetic intermediate during the folding of β -lactoglobulin;²⁶⁰ two, during the folding of human lysozyme;²⁴² two, during the folding of cytochrome *c*;^{230,251} and two, during the folding of micrococcal nuclease from *S. aureus*.²⁷⁸ Again, the number of phases detected often depends on how many spectral properties have been monitored. For example, five additional steps in the refolding of dihydrofolate reductase from *E. coli* were discerned following the formation of a molten globular intermediate if molar ellipticity at 220 nm, molar ellipticity at 235 nm, absorbance, and intrinsic fluorescence were all monitored.²³¹

Some if not most of these **multiple steps** may each involve the assembly of a particular portion of the final secondary structure of the native state.^{278,279} Intermediates formed after the formation of the initial molten globule, however, often have all of the secondary structure of the native state, but some of that secondary structure is in a less stable state than it will eventually assume upon complete folding,^{230,251} as if the rigid conformation of the native structure maintained by the proper packing of the secondary structures locks in place only in the final step or one of the final steps in the process. The last or almost the last property to appear in the folding of a protein is the spatial arrangement of the constellation of side chains responsible for its function.^{258,280}

The order in which different elements of secondary structure form and lock into place during the transition from the initial molten globular intermediate to the final native state can be inferred from studies of **native-state proton exchange**. The amido protons of the peptide bonds buried in the native state of a protein and defining its secondary structure exchange with deuterons in the solvent at different rates. When standard free energies for the conformational equilibria leading to their exposures are followed as a function of the concentration of a denaturant, it is observed that they generally coalesce

into groups as the concentration of denaturant is increased (Figure 13–14).^{116,117} These groups are groups of amido protons involved in particular secondary structures in the native protein. For example, in the crystallographic molecular model of cytochrome *c* (Figure 7–9), Arginine 91 through Lysine 100 (Figure 13–14A) are within one α helix; Methionine 65 through Asparagine 70 (Figure 13–14B) are within another α helix; and the ϵ amido proton of Tryptophan 59 and the α amido protons of Leucine 64, Lysine 60, Phenylalanine 36, and Glycine 37 are within a cluster of adjacent hydrogen bonds (Figure 13–14C). The coalescence of the respective sets of standard free energies of exposure indicate that each of these elements of secondary structure opens to exchange its amido protons cooperatively.

There are indirect observations suggesting that these openings of the structure, which are occurring all the time in the native protein, actually occur sequentially.²⁸¹ For example, the cluster of hydrogen bonds involving the α amido proton of Lysine 60 must open before the α helix containing Leucine 68, which must open before the α helix containing Leucine 98 during the exchange of the amido protons in the latter α helix. Furthermore, as was the case with the exchange of the amido proton at Methionine 47 in cysteineless type I ribonuclease H from *E. coli* (Figure 13–8), the exchange of the amido protons of the secondary structure that is the last to open, namely the α helix containing Leucine 98 in cytochrome *c*, tracks the global unfolding of the protein.

All of these observations suggest that the exchange of amido protons in the native state of a protein reveal, in reverse, the **steps in the formation of secondary structure** and the **locking in of that secondary structure** as the elements pack next to each other during the normal folding of the protein. In other words, during the folding of cytochrome *c*, the α helix containing Leucine 98 forms before that containing Leucine 68, which forms before the cluster of hydrogen bonds involving the α amido proton of Lysine 60.

The **slowest steps** in the folding of a protein from its random coil are often the **isomerizations of peptide bonds to the amino-terminal side of prolines**. In the crystallographic molecular models of proteins, about 6% of the peptide bonds on the amino-terminal sides of proline are *cis* peptide bonds^{282,283} and the rest are *trans* peptide bonds (Equation 6–1). These are geometric isomers of each other. The peptide bond on the amino-terminal side of a proline at a particular position in the amino acid sequence of a particular protein usually will be either *cis* in every molecule of the native state or *trans* in every molecule of the native state. In the random coil, however, every proline is free to adopt either geometric isomer, and the *cis* and *trans* isomers slowly come to equilibrium. In dipeptides, the equilibrium constants between *cis* and *trans* isomers of proline vary with pH, but they fall between 10 and 1.5 in favor of the *trans* isomer. The more

prolines that must be one or the other isomer before the native state can be achieved, the more random coils with at least one incorrect isomer of proline will be present in the solution.

When bovine ribonuclease A is added to 5 M guanidinium chloride at pH 2.3, the unfolding of the polypeptide is very rapid (<10 s), and the unfolding produces a random coil, cross-linked by its four cysteines.¹³¹ If the solution containing this random coil is diluted within 15 s to 1.3 M guanidinium chloride, pH 6.4, at 25 °C, all of the polypeptide (> 95%)¹³¹ refolds to the native state, capable of full enzymatic activity,²⁸⁴ in an uncomplicated first-order relaxation²⁸⁵ with a rate constant of about 10 s^{-1} . This result demonstrates that a random coil that a moment ago was native ribonuclease can refold rapidly, and with no obvious complications, back into native ribonuclease.

If rapidly unfolded ribonuclease, however, is allowed to sit as a random coil in a solution of guanidinium chloride over a period of 10 min, the kinetics of refolding are split into several phases, one with the same observed rate constant as that of the initially produced random coil and several others that are much slower. Consequently, a portion of the initially produced random coil that all refolds rapidly has isomerized to random coils that refold slowly. At equilibrium, the rapidly folding isomer of the random coil accounts for 20% of the protein; the **slowly folding isomers of the random coil**, for 80%,²⁸⁴ and the rate constant for the approach to this equilibrium between the rapidly folding isomers and the slowly folding isomers is 0.005 s^{-1} at 25 °C.¹³¹

Because the π system of the amide (Figure 2–3) must be broken for conversion to occur between the *cis* and *trans* geometric isomers of a peptide bond, this conversion is a slow process. The rate constants for the approach to the equilibrium between the *cis* and *trans* isomers of a set of dipeptides containing a carboxy-terminal proline are slow, between 0.002 s^{-1} and 0.005 s^{-1} at 25 °C above pH 3,^{286,287} rates that are similar to observed rate constant for the approach to equilibrium of the rapidly and slowly folding forms of ribonuclease.

In addition to this similarity of rates, there are several properties of the transitions between the rapidly

folding form and the slowly folding forms of the random coil of ribonuclease consistent with them being due entirely to isomerization of peptide bonds on the amino-terminal sides of prolines in the sequence. The observed rate constant for the approach to the equilibrium between the rapidly folding form and slowly folding

Figure 13–14: Rates of exchange of particular amido protons along the polypeptide backbone of native equine cytochrome *c* as a function of the concentration of guanidinium chloride.¹¹⁶ Equine cytochrome *c* was dissolved at p²H 7 in ²H₂O at the noted concentrations of guanidinium chloride. After different intervals, samples were removed, the pH was adjusted to 5 to slow the rates of exchange, and a two-dimensional nuclear magnetic resonance spectrum was gathered. The amplitudes of each of the peaks in each of the respective spectra were tabulated as a function of the time spent at p²H 7 in ²H₂O before the pH was lowered, and rates of exchange were calculated from the decreases in these amplitudes as a function of time. Each exchange was at the EX₂ limit, and the equilibrium constant for the formation of the conformation exposing each amido proton at each concentration of guanidinium chloride was calculated (Equation 12–63). From these equilibrium constants, standard free energies for the exposures of each proton, $\Delta G^\circ_{\text{HX}}$, were calculated. These standard free energies of exposure (kilojoules mole⁻¹) are plotted as a function of the concentration (molar) of guanidinium chloride (GdmCl). The standard free energies of exposure coalesced into specific groups as the concentration of guanidinium chloride was raised. Separate plots for three of these groups are presented: (A) the amido protons in the α helix containing Arginine 91 (R91) to Lysine 100 (K100); (B) the α helix containing Methionine 65 (M65) to Asparagine 70 (N70); and (C) a cluster of hydrogen bonds containing the ϵ amido proton of Tryptophan 59 and the α amido protons of Leucine 64 (L64), Lysine 60 (K60), Phenylalanine 36 (F36), and Glycine 37 (G37). In each successive panel, the lines for the most extensively protected amido protons from the previous plots are drawn as a dashed line to identify the discrete groups. forms of the random coil²⁸⁸ and the observed rate constant for the formation of the native state from the slowly folding forms of the random coil of ribonuclease²⁸⁹ are both **increased by strong acid**, as are the rate constants for the *cis*–*trans* isomerization in dipeptides of proline.²⁸⁶

The **standard enthalpy of activation** for the approach to the equilibrium between the rapidly folding form and the slowly folding forms of the random coil is between 75 and 90 kJ mol^{−1}, either at low pH or in 5 M guanidinium chloride,^{288,290} which compares favorably to the values for the standard enthalpy of activation (80–90 kJ mol^{−1}) for the *cis*–*trans* isomerization of dipeptides of proline.²⁸⁶ Neither the rate of the approach to *cis*–*trans* equilibrium of dipeptides of proline nor the approach to the equilibrium between the rapidly folding form and the slowly folding forms of the random coil is affected by the concentration of guanidinium chloride.²⁹¹

In the crystallographic molecular model of bovine ribonuclease A, the peptide bonds on the amino-terminal sides of Proline 93 and Proline 114 are *cis* peptide bonds. The amount of the peptide bond amino-terminal to Proline 93 that is in the *cis* form in the random coil can be monitored by its insensitivity to endopeptidolytic cleavage by Xaa-Pro dipeptidase.²⁸⁷ In 8.5 M urea at 10 °C, 70% of this peptide bond is *cis*. When the urea is diluted to 0.3 M, the 30% of this peptide bond that is *trans* slowly and completely reverts to the *cis* isomer with a rate constant of 0.01 s^{−1}, as the polypeptide folds. Under these conditions, 30% of the random coil refolds in the slowest phase and 30% of the activity of the enzyme is regained in this slowest phase, both with a rate constant of 0.01 s^{−1}. Proline 93 is preceded by Tyrosine 92, and the fluorescence from this tyrosine tracks the slow isomerizations that produce fully native enzyme during the refolding of the equilibrated random coil after a decrease in the concentration of guanidinium chloride.²⁸⁹ It was presumed that the slow process monitored by the fluorescence of Tyrosine 92 is the state of isomerization of the peptide bond between Tyrosine 92 and Proline 93.

If both Proline 93 and Proline 114 are mutated, the former to an alanine and the latter to a glycine, the stability of the native protein is decreased significantly, but its random coil is still able to fold to produce a protein that is enzymatically active.²⁹² The folding of this double mutant, when monitored by molar ellipticity, is a single first-order reaction with a rate constant of 0.07 s^{−1} in 0.4 M guanidinium chloride at 10 °C with no evidence for any slower phase.

It has been concluded from all of these observations that all of the slow isomerizations of the random coil of bovine ribonuclease A that in turn produce the slowly folding forms from the rapidly folding form are isomerizations of peptide bonds on the amino-terminal sides of prolines from the isomer found in the native state and that the most disruptive isomerization of the random coil is to a *trans* proline at position 93. When the equilibrium mixture of rapidly folding and slowly folding

random coils of ribonuclease is diluted into conditions favorable to folding, some of the slowly folding random coils assume **nativelike conformations** in which the critical peptide bonds on the amino-terminal sides of prolines are nevertheless the incorrect isomer. One intermediate, I₁, is sufficiently folded to trap almost 20 amido protons in stable hydrogen bonds,²⁹³ and another, I_N, is compactly folded by several criteria,²⁹⁴ including its insensitivity to digestion by pepsin.²⁹⁵ These compact intermediates, however, differ from the native state and can be distinguished from it by having the incorrect isomers at particular prolines.²⁸⁹

A similar but more dramatic effect of the slow isomerizations of prolines is observed in the folding of ribonuclease T₁ from *A. oryzae*. In the crystallographic molecular model of this even shorter protein (104 aa), the peptide bonds preceding both Proline 39 and Proline 55 are *cis*.²⁹⁶ If the native protein is unfolded in 6.0 M guanidinium chloride, pH 1.6, and the resulting random coil is diluted after 5 s to 1.0 M guanidinium chloride, pH 5.0, 80% refolds in a single first-order relaxation with a rate constant of 6 s^{−1}.²⁹⁷ As it sits in 6.0 M guanidinium chloride, however, the percentage of the fast-folding isomer decreases to 3% and the approach to this equilibrium has a rate constant of around 0.05 s^{−1}. From an analysis of the kinetics of this loss of the rapidly folding state of the random coil in both wild-type protein and protein in which Proline 55 had been mutated to asparagine, it could be concluded that the random coil with both prolines in the *cis* isomer folds to the native state with full enzymatic activity at 6 s^{−1}, that the isomerization of *cis*-Proline 55 to *trans*-Proline 55 has a rate constant of 0.05 s^{−1} and a *cis*–*trans* equilibrium constant of 0.16, and that the isomerization of *cis*-Proline 39 to *trans*-Proline 39 has a rate constant of 0.02 s^{−1} and a *cis*–*trans* equilibrium constant of 0.1. At equilibrium, 78% of the random coils have both prolines in the *trans* conformation.

Nevertheless, when this mixture of geometric isomers of the random coil is diluted to 1 M guanidinium chloride, pH 5.0, at least 70% of the random coils collapse at a rate of 50 s^{−1} to molten globules in which the central β sheet has formed²⁹⁸ and the α helix of the native state then forms within these molten globules with a rate constant of 20 s^{−1}. When the same equilibrium mixture is diluted to 0.15 M guanidinium chloride, the entire far-ultraviolet circular dichroic spectrum of the native protein is regained in a few seconds.²⁹⁹ The resulting condensed, molten globular states, however, do not become native protein until both Proline 55 and Proline 39 have become *cis*. The isomerizations that produce the proper *cis* isomers, and hence the native state, proceed in these molten globular states with rate constants between 0.01 s^{−1} and 0.0003 s^{−1} at 10 °C (Figure 13–15A).²⁹⁹ The isomerization of Proline 39 is retarded significantly by the formation of these partially folded molten globules, and this retardation is in part responsible for the slowest rate constant of 0.0003 s^{−1} for 66% of the protein.³⁰⁰

In the laboratory, the foldings of many polypeptides have slow phases with rate constants between 0.1 s^{-1} and 0.002 s^{-1} at $25\text{ }^{\circ}\text{C}$ that are attributed to proline isomerization.^{228,240,286,301–306} Many of these attributions have been validated by demonstrating that when particular prolines in the polypeptide are eliminated by **site-directed mutation**, the slow phases disappear.^{228,240,301–303} A problem with this approach is that if the proline that must be mutated is critical to the structure of the protein, in particular if it is *cis* in the native state, its removal often destabilizes the protein significantly and alters the kinetics of folding.³⁰⁷ For example, the double mutant of bovine ribonuclease A folds about 100-fold more slowly than the wild-type polypeptide with both Proline 93 and Proline 114 in the *cis* isomer.²⁹²

In the folding of small proteins that contain only one or two domains, most if not all of the steps that have rate constants less than 0.1 s^{-1} result from required isomerizations of one or more prolines. The **rate constants for the isomerization of proline** between *cis* and *trans* isomers in a random coil are in the range from 0.1 s^{-1} to 0.002 s^{-1} at $25\text{ }^{\circ}\text{C}$.²⁹⁷ The isomerization of *trans* to *cis* is always slower by a factor of 2–10 because of the equilibrium constants, so if the proline is *cis* in the native state, which because of its peculiar geometry is usually the more critical for proper folding, any step during folding that involves the formation of that *cis* isomer will be quite slow (Figure 13–15).

A related set of isomerizations proceed at a more rapid rate than those for *cis*-prolines. In the fully equilibrated random coil, about 0.0015 of the peptide bonds amino-terminal to amino acids other than proline are in the *cis* conformation.³⁰⁸ Although this is a small fraction, in a protein with 100 amino acids only 86% of the random coils will be all *trans* at equilibrium. If the native state has a *cis* peptide bond amino-terminal to an amino acid other than proline or if a significant percentage of its positions cannot tolerate *cis* peptide bonds during its folding, a fraction of the random coils will be in geometric isomers incapable of folding to the native state. The monocationic or monoanionic forms of dipeptides approach the equilibrium between their *cis* and *trans* isomers at a rate constant of about 1 s^{-1} at $25\text{ }^{\circ}\text{C}$,³⁰⁹ and a slow phase with a rate constant of 2.5 s^{-1} at $25\text{ }^{\circ}\text{C}$ involving 5% of the random coils during the folding of α -amylase inhibitor HOE-467A ($n_{\text{aa}} = 74$) from *Streptomyces tendae* has been attributed to random coils in which critical peptide bonds are in the incompatible *cis* isomer.³⁰⁸

Most of the time, the isomerizations of only a few prolines, usually to the *cis* isomer, are required steps in the complete folding of a protein. The isomerizations of many of the peptide bonds amino-terminal to prolines in a protein have no effect on its kinetics of folding,³¹⁰ and the folding of a number of proteins show no slow phases that result from proline isomerization.²⁴² In fact, the native states of some proteins have two conformations in slow equilibrium with each other, one in which a proline

is in the *cis* isomer and the other in which it is in the *trans* isomer.^{304,311} Because the slow isomerizations of the prolines significantly complicate the kinetics of folding, most of the proteins chosen for detailed studies of folding are those that do not have prolines that have to isomerize.

This choice is appropriate because in the cytoplasm and the extracytoplasmic spaces in which all polypeptides normally fold, as opposed to the laboratory, the isomerizations between the *cis* and *trans* isomers of the peptide bonds to the amino-terminal sides of prolines are catalyzed by **peptidylprolyl isomerases**. The first enzyme with this catalytic activity that was purified to homogeneity^{312,313} was assayed by its ability to catalyze the *cis*–*trans* isomerization in *N*-glutaryl-Ala-Ala-Pro-Phe 4-nitrophenylanilide.³¹⁴ This particular enzyme is able to increase the rates of the slowest phases in the refolding of, among other proteins, ribonuclease A,^{315,316} the light chain of immunoglobulin,³¹⁷ human acylphosphatase,³⁰⁶ and type III collagen.³¹⁸

In most of these instances, the increases observed in the rate constants for these slowest phases in folding were relatively unremarkable (less than a factor of 10) even at high concentrations of the peptidylprolyl isomerase. It has been found, however, that there are many **different isoforms** of peptidylprolyl isomerase in a given organism; for example, there are at least 25 different peptidylprolyl isomerases encoded by the human genome, and several are often found within the same cell.^{319,320} It is possible that if the folding protein were matched with its proper peptidylprolyl isomerase under conditions resembling those encountered by the folding protein in the cytoplasm, much more effective rates of catalysis would be observed, but peptidylprolyl isomerases from bacteria, fungi, and animals are about as effective when catalyzing the folding of the same protein.³²¹ Within an intact mitochondrion, the increase in the rate of folding catalyzed by endogenous peptidylprolyl isomerase was observed to be a factor of only 2–6.³²² It is possible that the effect of peptidylprolyl isomerases on the rate of folding in the cytoplasm and the various extracytoplasmic spaces is usually modest.

Peptidylprolyl isomerases have been isolated from bacteria,³²³ fungi,³²⁴ and plants³²⁵ as well as from animals. The peptidylprolyl isomerase associated with the ribosome in *E. coli* appears to be one of the most effective.³²⁶

The **extent of exposure** of the peptide bonds amino-terminal to proline is an important factor in the efficiency with which peptidylprolyl isomerases can function^{299,327} because they must be able to find the bond before they can isomerize it. For example, peptidylprolyl isomerase is able to catalyze the faster of the isomerizations of proline that must occur during the folding of ribonuclease T₁ to its native state, but not the slowest (Figure 13–15). This slowest step involves the isomerization of Proline 39, which has already been slowed considerably from its rate in the random coil²⁹⁷ by being

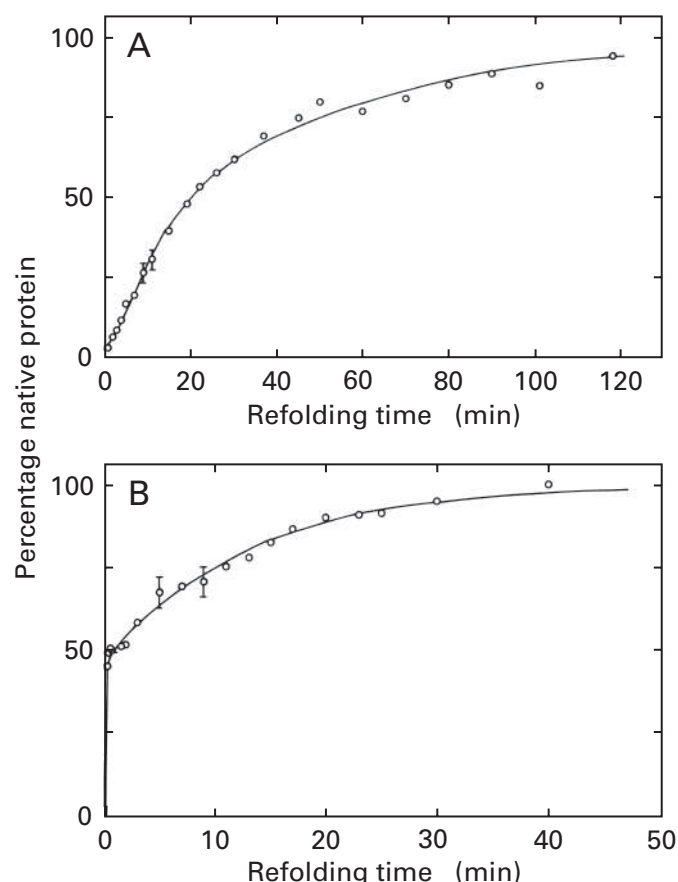

Figure 13-15: Slow steps in the folding of ribonuclease T_1 from *A. oryzae* due to isomerization of the peptide bonds amino-terminal to prolines.²⁹⁹ Unfolded ribonuclease T_1 at 0.3 mM in (A) 6.0 M guanidinium chloride, pH 1.9, or (B) 8 M urea, pH 8.0, was diluted 40-fold with 0.1 M tris(hydroxymethyl)ammonium chloride, pH 8.0, to initiate folding. At various times, the percentage of the protein in its native state was determined by monitoring the decrease in fluorescence (emission at wavelengths greater than 320 nm; excitation at 268 nm) that occurred upon dilution of the sample to 5.6 M guanidinium chloride, pH 2.0. (A) Refolding in the absence of prolyl isomerase. (B) Refolding in the presence of 0.7 μ M prolyl isomerase. The percentage of the molecules in their native state is plotted as a function of time (minutes). The curves are multiexponential fits to the data with first-order rate constants of (A) 0.01 s^{-1} , 0.005 s^{-1} , 0.002 s^{-1} (31%), and 0.0003 s^{-1} (66%) and (B) 0.1 s^{-1} , 0.04 s^{-1} , 0.5 s^{-1} (46%), and 0.0013 s^{-1} (51%). For both fits an unresolved kinetic burst of 3% was assumed. Reprinted with permission from ref 299. Copyright 1990 American Chemical Society.

buried in a molten globular intermediate.³⁰⁰ In the molten globules formed during the folding of isoform 2 of cytochrome *c* from *S. cerevisiae*, peptidylprolyl isomerase is unable to hasten any of the slow isomerizations at prolines in the final steps, even though it can if the equilibrium between molten globule and unfolded forms is shifted significantly by adding guanidinium chloride.³²⁸ How this problem of accessibility is solved in the cytoplasm of a cell is unclear.

There are a number of small proteins or small domains removed from larger proteins that fold in what

kinetically appear to be single steps with the formation of no intermediates. One example of such a protein is the cold shock-like protein from *T. maritima* (Figure 13-1).^{109,329} Even at 0.5 M guanidinium chloride, this small protein ($n_{aa} = 66$) folds in what kinetically appears to be a simple first-order isomerization, and there is no obvious change in rate-limiting step observed in the plot of the observed first-order rate constant for folding as a function of the concentration of guanidinium chloride (Figure 13-1B). **Folding with no kinetic intermediates** has been observed for the competent proline isomer of the random coil of chymotrypsin inhibitor 2A ($n_{aa} = 83$) from *Hordeum vulgare*,³⁰⁵ for which the observed first-order rate constant for folding shows no evidence of a change in rate-limiting step even in the absence of any denaturant, as well as for, among others, human acylphosphatase ($n_{aa} = 98$),³³⁰ protein S6 from the 30S subunit of ribosomes from *Thermus thermophilus* ($n_{aa} = 101$),³³¹ the engrailed homeodomain from *Drosophila melanogaster* ($n_{aa} = 61$),³³² and human ubiquitin ($n_{aa} = 76$).³³³

It is also possible to follow even faster folding reactions that exhibit apparently two-state behavior in the region of transition down to low concentrations of denaturant by analysis of the line widths of the absorptions or analysis of relaxation rates in nuclear magnetic resonance. In this way, it can be demonstrated for some proteins and the detached domains of other proteins that there is no evidence of a change in rate-limiting step and that their folding remains kinetically a one-step reaction even in the absence of denaturant. Such demonstrations have been made for the amino-terminal domain of the repressor from bacteriophage λ ($n_{aa} = 80$),^{334,335} the B-domain of protein A from *S. aureus* ($n_{aa} = 58$),¹¹⁰ and the peripheral subunit binding domain of dihydrolipoyl-sine-residue acetyltransferase of *B. stearothermophilus* ($n_{aa} = 41$).³³⁶

All of these foldings appear to occur in a kinetically single step because there is **no change in the rate-limiting step** as denaturant is decreased to zero. In the foldings in which there is a change in the rate-limiting step (Figure 13-10), it is slower steps unaffected or less affected by the concentration of denaturant, such as the progression of the formation of secondary structure within the molten globular intermediate, the final locking together of the secondary structures into their native packing, and isomerizations of peptide bonds amino-terminal to prolines, that become slower than the initial condensation of the random coil to the molten globule as the concentration of denaturant is lowered. In the foldings that appear to proceed in a single kinetic step, these later steps simply remain faster than the initial condensation; they still must occur, but they are kinetically silent because they occur after the rate-limiting step.

The observed rate constant for the first-order relaxation of one of these foldings that appear to proceed in a single kinetic step is determined by the rate constant of

the rate-limiting step, the rate constants of any rate-determining steps preceding the rate-limiting step, and the equilibrium constants of any unfavorable preequilibria that precede the rate-limiting step (Equations 13–28 and 13–30). Favorable preequilibria preceding the rate-limiting step would require the formation of observable intermediates in the reaction.

The following facts indicate that, immediately upon completion of the rate-limiting step in one of these foldings that appears to proceed through a single kinetic step, a **molten globular intermediate** containing significant secondary structure has formed from the random coil. The observed rate constants of these foldings are significantly affected by the concentration of denaturant (Figure 13–1B); they increase by factors as large as 10,000 between a solution containing a concentration of denaturant within the region of transition and one containing no denaturant.³³¹ This fact requires that considerable accessible surface area be lost either in the transition state of the rate-limiting step, during rate-determining steps preceding the rate-limiting step, or during preequilibria preceding the rate-limiting step. The **apparent molar activation volume** for one of these foldings is positive and even larger than the positive change in molar volume between random coil and native state,³³⁷ an observation indicating that the transition state for the rate-limiting step or for rate-determining steps that precede it is globular or that an intermediate formed in an unfavorable preequilibrium is globular, as is the native state, but is somewhat less compact than the native state. All³³⁸ or most³³⁹ of the **change in standard heat capacity** between random coil and native state has occurred by the time the transition state in the rate-limiting step appears, an observation indicating that the hydrophobic functional groups buried in the native state are buried during the rate-limiting step or before it. The **effect of pH** on the observed first-order rate constant for one of these foldings indicates that some carboxylates have been sequestered from the solvent, but far fewer than those sequestered in the native state, by the time the transition state of the rate-limiting step has formed.³³⁹ In the case of the carboxy-terminal domain of protein L9 from the 50S subunit of the ribosome from *E. coli*, the mutation of Histidine 134, the histidine in the protein with the lowest pK_a in the native state, caused the most dramatic change in the dependence of the rate constant k_f on pH, a result suggesting that this same histidine is also the most buried by the time the transition state of the rate-limiting step has formed and that at this point the protein resembles the native state.¹¹³

It is the effects of **site-directed mutations** on the observed rate constants of these foldings appearing to proceed in a single kinetic step which indicate that secondary structure has formed before or during the rate-limiting step. For example, when one or the other of the two α helices in acylphosphatase is stabilized by mutating one of its amino acids to alanine, the observed rate

constant for its folding increases if the mutation is in the second α helix but not if it is in the first.³⁴⁰ When the two α helices of transcriptional repressor *arc* from bacteriophage P22 were destabilized by mutations of alanines to glycines, the observed rate constants of folding decreased significantly,³⁴¹ while alanine to glycine mutations in only one of the α helices in the amino-terminal domain of the repressor from bacteriophage λ affect the observed rate constant of its folding.³⁴² The magnitudes of the changes in the observed rate constants of folding relative to the change in the standard free energy of folding for mutations at 37 positions in chymotrypsin inhibitor 2A suggest that some elements of secondary structure have formed by the time the transition state of the rate-limiting step has been reached but that they are less stable than they are in the native state.³⁴³ The effects of site-directed mutation on the folding of the WW domain from peptidylprolyl isomerase Pin 1, however, indicate that its folding is most sensitive to changes in what is an external loop in its crystallographic molecular model,³⁴⁴ an observation suggesting that secondary structure in the native state may not correspond to secondary structure in a molten globular intermediate.

All of the observations discussed so far can be explained as effects either on the rate-limiting step or on one or more unfavorable preequilibria preceding the rate-limiting step. It is the case, however, that the observed rate constant for at least one of these foldings that appears to proceed in a single kinetic step is linearly related to the inverse of the **viscosity of the solvent**.²⁷³ This fact requires that the condensation of a conformation or set of conformations of the random coil occur during the rate-limiting step, not before it. This conclusion follows from the fact that the viscosity of the solvent must affect both contraction and expansion of a polypeptide equally and hence an equilibrium constant for contraction not at all.

The observed rate constants for these foldings that appear to proceed in a single kinetic step span a wide range from 0.2 s^{-1} (28 °C) to $120,000 \text{ s}^{-1}$ (37 °C). The fact that these rate constants span such a wide range and the fact that nevertheless they all seem to register condensations producing molten globular intermediates suggest that their rate-limiting steps are not hydrophobic collapse, for which the observed rate constant would be related solely to the length of the polypeptide and would not vary so dramatically,²⁷² but hydrophobic collapse of a conformation or set of conformations of the random coil that are present at low occupancy; the lower that occupancy, the slower the observed rate constant (Equation 13–30). Presumably, the subset of conformations of the random coil that are present at such low levels of occupancy are those that contain sufficient secondary structure to condense to a stable molten globule. Consistent with this presumption is the fact that the observed rate constant for at least one of these foldings that appears to occur in a single step is significantly

increased by the addition of low concentrations (0.006 mole fraction) of trifluoroethanol or 1,1,1,3,3,3-hexafluoro-2-propanol.³³⁰ These cosolvents are known to stabilize secondary structure in unfolded polypeptides.

The apparent single step registered in each of these foldings is equivalent to the step producing the molten globular intermediates formed during the kinetic burst in the foldings of proteins that proceed through multiple steps. In the case of the proteins folding in an apparent single step, the steps following the molten globular intermediate are kinetically silent. The advantage of the foldings in a single step is that attention can be directed exclusively on this one step, uncomplicated by the later ones; the disadvantage is that the later steps cannot be studied at all.

What seems to occur during folding of a polypeptide can be summarized. The random coil has conformations within its ensemble that are evanescently present at low concentrations and that contain sufficient secondary structure to stabilize a molten globular intermediate. One or more of these minor conformations of the random coil collapses hydrophobically to form one or more molten globules.* Within these molten globules, some of the secondary structure of the native state is present and the rest forms in a series of steps before or as it locks into its proper packing to produce the native state. Superimposed on this progression are the slow isomerizations of the peptide bonds amino-terminal to prolines, each of which has the potential to decrease the observed rate constant of any one of these steps dramatically but only for those isomers of the polypeptide that happen to contain an incompatible isomer of proline. If isomerizations of peptide bonds amino-terminal to prolines were not or are not involved, the folding of a polypeptide would be or is usually complete within less than 10 s at 25 °C, which is remarkably fast for such a complicated process.

Up to this point, for the sake of clarity, the transformations between each of the major intermediate states encountered during the folding of a protein have been presented as if they were uncomplicated first-order reactions proceeding in single steps just as the bimolecular nucleophilic displacement of an iodide in the alkylation of a thiolate anion (Equation 3–17) is an uncomplicated second-order reaction proceeding in a single step through a single transition state. It is certainly the case, however, that in a process as complicated as protein folding none of these transformations between the denatured state, major intermediate states, and the final native state proceeds in a single step. Consequently, the transformations **only appear to be single steps**, and the

observed rate constants are only apparent rate constants. For example, the kinetic progress of the folding of cytochrome *c'* from *Rhodopseudomonas palustris*, although apparently proceeding through four steps when the absorbance of the heme is followed at 440 nm, can be fit more exactly by a set of 80 rate constants spanning a range from 10^5 to 10^{-2} s⁻¹.³⁴⁵ This observation by itself is not surprising. Were the kinetic measurements of a simple chemical reaction that definitely had only four steps to be fit with an equation derived for 80 steps, the fit for 80 steps would necessarily be better than the fit for four steps. Nevertheless, this exercise suggests that there are more than just four steps involved in the folding of this cytochrome *c'*. Careful examination of Figure 13–13 also suggests that a mechanism involving more than two steps in the range monitored would yield a rate equation more successful at fitting the actual data.

It has been shown that the apparently first-order rates of the transformations between apparently discrete intermediate states in the folding of a protein and the behavior of those rates as a function of the concentration of denaturant are more successfully fit by kinetic models involving a large number of intermediate states in sequence.²³⁶ It has already been noted that the number of transitions observed during the folding of a polypeptide usually increases in number as more and more physical properties are monitored during the same process, so observations based on only one physical property usually fail to register all of the discrete steps in the process of folding. It has also been proposed that the differences observed among the effects of denaturant on the rates of exchange of different amide protons along the backbone of a polypeptide (Figures 13–8 and 13–14) are evidence for the existence of a **continuum of intermediate states** in the process of folding.³⁴⁶ These various intermediate states are in preequilibrium with each other prior to a rate-limiting step, represent a set of rate-determining steps, are in a steady state with each other so that the observed first-order rate constant is actually a composite rate constant,²⁴⁴ or are related to each other in some combination of these three possibilities. Because it is so unlikely that any one of these apparently first-order transformations is actually a simple single step, a discussion of the transition state associated with the observed first-order rate constant for any one of these transformations is meaningless.

Another complication is the existence of multiple, **parallel pathways** in the folding of a protein. The most obvious example of such a situation results from the isomerization of prolines. Each geometric isomer of the random coil at each proline that is required to have a particular configuration for proper folding folds along its own distinct pathway (Figure 13–15). In the case of lysozyme from *G. gallus*^{347–349} and dihydrofolate reductase from *E. coli*,^{350,351} however, there are two and four parallel pathways, respectively, through which these foldings progress, none of which are distinguished by

* If the effect of solutes increasing the viscosity of the solution have been misinterpreted, it is also possible that hydrophobic collapse is the unfavorable preequilibrium preceding the formation of sufficient secondary structure to stabilize the molten globule or molten globules.

differences in the isomerization of prolines. At one or more points in the process of folding, some of the molecules assume one state and the others assume another state, and from there on, each of the two populations proceeds through a different sequence of steps to form the same final native state of the protein. In the case of dihydrofolate reductase, the existence of parallel pathways may be related to the fact that there are two different conformations of the native state in equilibrium with each other that are both substantially occupied under most circumstances.^{352,353}

There are also **kinetic dead-ends** that can complicate the process of folding. For example, during the folding of equine cytochrome *c* from its random coil, the wrong side chains can form the fifth and sixth ligands to the covalently bound heme,³⁵⁴ and they must dissociate and the proper side chains must associate before folding can proceed successfully.³⁵⁵

One of the most consequential kinetic dead-ends is aggregation of the folding polypeptides. When, in the laboratory, the concentration of urea or guanidinium chloride is rapidly lowered by dilution, the hydrophobic side chains on a random coil are no longer favorably solvated. They can either promote the desired intramolecular hydrophobic collapse, or they can associate with hydrophobic side chains on other unsolvated polypeptides to form an undesired intermolecular aggregate, which just as successfully removes them from contact with the water. When the **intermolecular aggregation** is reversible so that the aggregate is in equilibrium with an unaggregated, denatured intermediate produced during some step in the process of proper folding, the aggregation has the effect of lowering the concentration of that intermediate on the pathway to the native state and decreasing the rate of folding. In this situation, the amount of intermolecular aggregate decreases as the total concentration of protein is decreased, and the rate of folding increases³⁵⁶ as the concentration of protein is decreased. The aggregate at the dead end can also appear to be an intermediate in the folding process, forming rapidly and then disappearing as the folding depletes the solution of the intermediate in equilibrium with the aggregate.³⁵⁷

When the intermolecular aggregation of the folding polypeptide is **irreversible**, however, it competes with proper folding, and the final yield of the native state, rather than its rate of formation, is decreased accordingly. Often such irreversible aggregation can be minimized by lowering the total concentration of protein,^{358,359} but in many instances the folding protein passes through an intermediate so prone to aggregation that very little if any native state forms at any concentration of protein. This catastrophic problem is solved within the cell by the chaperones.

A **chaperone** is a protein that intercepts and suppresses the unproductive, nonspecific, irreversible intermolecular aggregation of a folding polypeptide so that it

can fold intramolecularly to achieve its native state.^{360,361}

There are two species of chaperones that are responsible for most of this suppression of aggregation and protection of proper folding. These two species are represented by **chaperonin 60** (the product of the *groEL* gene) and **heat shock protein 70** (the product of the *dnaK* gene), respectively, from *E. coli*. Chaperonins 60 have been purified from fungi,³⁶² chloroplasts,³⁶³ mitochondria,³⁶⁴ and eukaryotic cytoplasm,³⁶⁵ and heat shock proteins 70 are also universally distributed. The most obvious distinction between these two different species of chaperones, other than their unrelated amino acid sequences, is that chaperonins 60 are all large oligomers of 14–16 subunits arranged with the respective symmetries of the point group 722(*D*₇) or the point group 822(*D*₈),^{366–368} while heat shock proteins 70 are monomers or dimers.

The chaperone about which the most is known is chaperonin 60 from *E. coli*. It is a homotetradecamer with symmetry of the point group 722(*D*₇) enclosing a large central cavity (Figure 13–16)^{366,369–371} that is divided into two halves (upper and lower heptamers in Figure 13–16) at its middle by a thick septum formed from the irregular coalescence of the 14 carboxy-terminal segments, each 23 amino acids long, which are disordered in the crystallographic molecular model.³⁷² Each of the 14 subunits in turn is divided into three domains (arranged one on top of the other and consequently difficult to distinguish in the view presented in Figure 13–16). The apical domains are symmetrically arrayed around the central 7-fold rotational axis of symmetry to form the entrances to the upper and lower cavities, the equatorial domains surround the central septum, and each of the intermediate domains connects its apical domain to its respective equatorial domain.

Chaperonin 60 prevents proteins that aggregate irreversibly during their folding in its absence from doing so in its presence.^{373,374} It accomplishes this task by recognizing and associating with **intermediates in the pathway of folding that are prone to aggregation**.³⁷⁵ By itself, chaperonin 60 forms a tight complex with such an intermediate.^{376,377} If it were the only capability of chaperonin 60, the formation of this **tight complex** would interrupt the folding of a protein and prevent its completion. Consequently, the bound intermediate must dissociate so that folding can proceed. If, however, the bound intermediate were to dissociate from chaperonin 60 unchanged, it would then proceed to aggregate as it was about to do just before it was bound. Consequently, the structure of the bound intermediate must be altered so that it dissociates in a form that is not prone to aggregation. The standard free energy necessary to promote the dissociation of the bound intermediate and to change its structure before it dissociates is provided by the binding and hydrolysis of MgATP.

The structure of the form of the folding protein recognized and bound by chaperonin 60 has not been clearly defined. In theory, chaperonin 60 should recog-

Figure 13-16: Chaperonin 60 and chaperonin 10 from *E. coli*. The α -carbon skeleton of the tetradecamer of chaperonin 60 (upper structure) is drawn from the crystallographic molecular model of the protein in a complex with 14 molecules of MgKATP.³⁶⁹ The tetradecamer is viewed down the 7-fold rotational axis of symmetry. The seven identical subunits ($n_{aa} = 547$) in the upper heptamer are drawn with line segments of different widths. Those in the lower heptamer are drawn with gray lines. In the crystallographic molecular model, the carboxy-terminal 22 amino acids of each subunit are disordered, unresolved, and, consequently, absent from the model. They extend in the plane of the page from the 14 carboxy termini of the crystallographic molecular model protruding into the center of the central cavity and are thought to coalesce³⁷² to form the thick equatorial septum observed in image reconstructions from electron micrographs³⁷⁰ that divides the central cavity into upper and lower halves. The seven 2-fold rotational axes of symmetry of the point group 722 (D_7) are in the plane of the page and run through the center of the drawing so the structures of the upper and lower cavities are identical to each other. The α -carbon skeleton of chaperonin 10 is drawn below that of chaperonin 60. It is drawn from the crystallographic molecular model of the complex between chaperonin 60 and chaperonin 10.³⁷¹ Chaperonin 10, a symmetrical heptamer of seven identical subunits ($n_{aa} = 97$), is a cap that can sit upon the top of the chaperonin 60 with its 7-fold rotational axis of symmetry coincident with the 7-fold rotational axis of symmetry of the tetradecamer and seal the respective cavity. It is drawn so that a -135° flip around the x axis puts the cap on the upper cavity of the chaperonin 60.

nize only intermediates in the process of folding that are prone to aggregation and ignore intermediates that are not, but when it is added in the absence of MgATP to solutions of some proteins that are in the process of folding, their folding slows dramatically^{378,379} or ceases,³⁸⁰ as if almost all or all of the states of these proteins other than the native state are recognized and bound. With other proteins, the rate of their folding is unaffected or slightly accelerated upon the addition of chaperonin 60,³⁸¹ but these are usually proteins that are not susceptible to aggregation during their folding. Chaperonin 60 also forms complexes when added to solutions of certain native proteins,^{382,383} presumably by recognizing denatured forms in equilibrium with the native state and shifting that equilibrium by sequestering those denatured forms.³⁸⁴ Site-directed mutants in which hydrophobic amino acids have been replaced with alanine or glycine are recognized and bound by chaperonin 60 less successfully during their folding,³⁷⁸ suggesting that it is exposed hydrophobic side chains that elicit the attention of the chaperone.

After it has been bound by chaperonin 60, a folding protein is usually in a **molten globular state in the complex**.³⁸⁵ This conclusion follows from the fact that the rates of the exchange of its amido protons are rapid.^{380,382,383,386,387} With some proteins, unlike what is observed in the usual molten globular state, the exposure of all amido protons is increased to the same extent,^{383,388} a result suggesting that the association of the folding protein with the chaperone has disrupted all secondary structure. With other proteins exposure of amido protons varies along the sequence,³⁸⁰ a result suggesting that some secondary structure is preferentially preserved in the bound form of the protein. With yet other proteins almost no difference in exchange rates between the bound form of the protein and the native state is observed,³⁸⁹ a result suggesting that the bound protein is similar in its structure to the native state. It has also been observed that a tridecapeptide that is structureless in solution is an α helix when bound to chaperonin 60.³⁹⁰

Because it is not known which conformation or set of conformations of a folding protein is recognized and bound by a chaperonin 60, it is possible that the structure of that folding protein once it has been bound is identical to the structure that it had when it was recognized and bound, but it is also possible that the structure of the protein has been altered significantly during its binding to the chaperone to produce the conformation or set of conformations that are observed in the complex. This alteration in structure caused by the binding itself would be at least a portion of the alteration required so that a form of the protein that is not prone to aggregation can dissociate from the chaperone.

The folding protein is bound by one or more of the **apical domains** that surround the entrances to each of the two central cavities in chaperonin 60 (Figure 13-16).^{370,391} In some cases, the bound protein protrudes

outward from the cavity;³⁹¹ in other cases, it protrudes into the cavity and fills it.^{392,393} Whether the bound protein **ends up within the cavity** or protruding away from it is in part a function of its size;^{369,394} the larger proteins protrude outward because they do not fit within. A folding polypeptide larger than 600 aa is too large to fit in the cavity.³⁹⁵

When the apical domains of chaperonin 60 are detached genetically and expressed separately, they may³⁹⁶ retain the ability to recognize and bind forms of a folding protein that are prone to aggregation.³⁹⁷ A site in the crystallographic molecular model of a detached apical domain to which an extended hydrophobic segment of polypeptide has bound has been tentatively assigned as the site for binding of the folding protein to the apical domain.^{369,398}

The next step in the rescue of a folding protein from aggregation performed by chaperonin 60 is its **dissociation from this bound state**. This dissociation requires the addition of MgATP. When MgATP is added to a complex of chaperonin 60 and denatured protein, it promotes the dissociation of that protein, permitting its folding to recommence.^{399–405} The dissociation of the denatured protein from the complex is more rapid than the hydrolysis of the MgATP^{400,404} and also occurs when analogues of ATP that cannot be hydrolyzed are used instead of ATP,^{376,402,403,406} so it is the **binding of MgATP** and not its hydrolysis that promotes the dissociation. The binding of MgATP to chaperonin 60 occurs at a site located in each equatorial domain,⁴⁰⁷ while the folding protein is bound to the apical domain. These two sites are 3.2 nm apart at their closest approach, so no direct interaction between them is possible. Consequently, there must be two global conformations of chaperonin 60 in equilibrium with each other, one of which binds denatured protein at the apical domain strongly and MgATP at the equatorial zone weakly and the other of which binds denatured protein weakly and MgATP strongly, and the binding of MgATP must shift the equilibrium between these two conformations in favor of the one that binds denatured protein weakly.^{244,403,404,407}

In the conformation of chaperonin 60 that is stabilized by the binding of MgATP, an α helix in the apical domain that forms part of the site at which the folding protein is thought to bind³⁹⁸ is rotated by 102° relative to its orientation in the conformation of the protein that is the more stable in the absence of MgATP.³⁶⁹ This rotation sequesters a set of hydrophobic side chains and makes the site considerably less hydrophobic, perhaps promoting the dissociation of the folding protein.

The subsequent **slow hydrolysis of the MgATP** (0.06 s^{-1} at 25 °C),⁴⁰⁸ at all seven of the sites in one half of the protein,⁴⁰⁹ serves to regenerate the conformation of the chaperone that can again recognize intermediates prone to aggregation. During the folding of a protein that requires significant assistance to avoid aggregation, several cycles of binding to chaperonin 60 and release are

needed before the native state is achieved.^{404,410} Each cycle of binding and release requires that the MgATP be hydrolyzed to regenerate the competent conformation of the chaperone, so the presence of a folding protein in need of assistance elicits an ATPase activity from chaperonin 60.⁴⁰⁴

The dissociation of the folding protein from chaperonin 60 that is promoted by the binding of MgATP is accelerated by the addition of chaperonin 10.⁴⁰² Chaperonin 10 is a homoheptamer of subunits 97 aa in length that can sit as a cap upon the seven apical domains of chaperonin 60 and seal off the respective cavity from the solution (Figure 13–16).^{371,393,411} Its addition is required for the maximum yield of the native state of some folding proteins prone to aggregation; with other proteins that are prone to aggregation, its addition increases the rate of their folding.

When the folding protein is too large to fit in the cavity, chaperonin 10 nevertheless still increases the rate of folding or the yield of properly folded protein or both of these outcomes but does so by binding to the opposite end of chaperonin 60 from the end at which the folding protein was bound.³⁹⁴ When the folding protein is small enough, chaperonin 10 binds at the end to which it is associated and traps it within the respective cavity of chaperonin 60,^{408,412} where it is definitely protected from intramolecular aggregation because it is alone. In the presence of chaperonin 10, a **trapped folding protein**, although it has been dissociated from its binding site on chaperonin 60 by the binding of MgATP, remains associated with the complex of chaperonin 60 and chaperonin 10. Only after the MgATP has been hydrolyzed is the folding protein released from the complex along with the chaperonin 10.^{408,409,413,414} Because the hydrolysis of the MgATP is so slow, however, this means that the complex remains intact for, on the average, about 15 s, which is a long period of time in the folding of a protein and during which considerable progress towards the native state can be achieved.

The requirement that chaperonin 60 alter the structure of the folding protein and release it in a form not prone to aggregation seems to be accomplished both before and after MgATP is bound. The alterations in the structure of the folding protein before MgATP is bound have already been described, but it has been noted that the addition of MgATP and chaperonin 10 to the complex between a folding protein and chaperonin 60 further increases the rates of amide proton exchange of the folding protein,⁴¹⁵ a result suggesting that significant structural alterations are made to the folding protein after the binding of MgATP but before it dissociates from its binding site on chaperonin 60.

The chaperones of the species of heat shock proteins 70, for which heat shock protein 70 from *E. coli* is the paradigm, also rescue folding proteins from aggregation by binding them and releasing them in associations and dissociations that are coupled to the binding and

hydrolysis of MgATP,⁴¹⁶ but the details of the process are much less clear. It is the complex between heat shock protein 70 and MgATP that binds the folding protein in a rapidly reversible equilibrium, and upon hydrolysis of the MgATP, the folding protein is locked onto the chaperone.^{417–419} The binding of the next molecule of MgATP rapidly releases the bound protein into the solution, presumably in an altered conformation. In a crystallographic molecular model of the complex between heat shock protein 70 and a peptide thought to mimic the bound folding protein, the peptide is bound in an unstructured extended conformation.⁴²⁰ Heat shock protein 40 increases the rate at which the ATPase recycles heat shock protein 70 among its various conformations,⁴¹⁹ as does the chaperonin 10 with chaperonin 60. There is, however, no cavity in any of these proteins similar to that in the tetradecamer of chaperonin 60.

As a polypeptide folds to its native state in the cytoplasm of a cell, the high concentration of reduced glutathione (3–5), or some other mercaptan with the same function,⁴²¹ prevents its cysteines from forming adventitious cystines, and for the same reason, the cysteines of the native protein remain reduced throughout its lifetime. Most of the proteins, however, that are excreted from a cell into the extracellular spaces contain **cystines**. In a eukaryotic cell, these cystines are formed as these soon to be excreted proteins fold within the lumen of the endoplasmic reticulum. In the lumen of the endoplasmic reticulum, the ratio of oxidized glutathione to reduced glutathione is much higher (0.5)⁴²² than it is in the cytoplasm (0.02). The native conformation of the protein juxtaposes the two cysteines that will form a correctly paired cystine.⁴²³ This juxtaposition increases the equilibrium constant for the formation of that cystine dramatically,⁴²⁴ so the ambient ratio of oxidized to reduced **glutathione** in the endoplasmic reticulum is sufficient to form a cystine from the two cysteines once they have been juxtaposed.^{423,425}

where C_A and C_B are the two cysteines juxtaposed, GSSG is oxidized glutathione, and GSH is reduced glutathione. The fact that one mole of oxidized glutathione yields two moles of reduced glutathione pulls the reaction to the right.

The problem, however, is that the ratio of oxidized to reduced glutathione in the endoplasmic reticulum is also high enough to produce adventitious cystines within intermediates in the pathway of folding that happen to juxtapose incorrect cysteines. This problem, which would lead to the accumulation of stable, improperly folded forms of the protein, is solved by the enzyme **protein disulfide-isomerase**,⁴²⁶ which is present at high con-

centration in the lumen of the endoplasmic reticulum.⁴²⁵ This enzyme fulfills two roles in the formation of correct cystines during the folding of a protein. It breaks cystines to reverse their incorrect formation, and it oxidatively couples pairs of adjacent cysteines to form cystines.⁴²⁷ Consequently, it catalyzes the rapid rearrangement of cystines in a folding protein until the correct partners are joined to produce the native state of the protein. In fact, there are some proteins, for example mammalian pancreatic human insulin-like growth factor⁴²⁸ and bovine ribonuclease A,⁶¹ that cannot fold stably unless all of their cystines have formed correctly, so their folding is required to proceed in tandem with the rearrangement of their cystines by protein disulfide-isomerase until the combination of the correct tertiary structure and the correct pairing of cysteines as cystines is reached. It is both the packing of the tertiary structure and the properly paired cystines that create their native states.

Protein disulfide-isomerase (490 aa) contains two domains (amino acids 5–100 and 350–440) that are homologous to each other and to thioredoxin (110 aa).⁴²⁹ As is the case with thioredoxin, each domain contains a **pair of cysteines** in the sequence –VEFYAPWCGHCK–. It is these pairs of cysteines found in protein disulfide-isomerase that are responsible for the catalysis of the rearrangement and formation of cystines in a folding protein. Two shorter proteins, thiol:disulfide interchange protein DsbA (218 aa) and thiol:disulfide interchange protein DsbC (216 aa), each with only one pair of cysteines in the sequences –LEFFSFFCPHCY– and –TVFTDITCGYCH–, respectively, fulfill the roles of protein disulfide-isomerase for proteins excreted from bacteria. The former can form cystines, but the latter is the enzyme responsible for the shuffling of incorrectly formed cystines.^{430–433}

The two domains in each molecule of protein disulfide-isomerase, which each contain an identical pair of cysteines, are similar in their catalytic abilities and act independently.⁴²⁵ The second cysteine in each of these pairs of cysteines is responsible for **breaking and rearranging cystines** by disulfide interchange during the folding of a protein:

where C_C is a cysteine elsewhere in the folding protein that contains cysteines C_A and C_B . The central intermediate in this shuffling is the **mixed disulfide** between protein disulfide-isomerase and the folding protein (upper right complex in Equation 13–32). The cystine that forms between a pair of cysteines in protein disulfide-iso-

merase by disulfide interchange with oxidized glutathione

is able to convert a pair of juxtaposed cysteines in a folding protein into a cystine (reverse of the reactions on the lower right and top of Equation 13-32).⁴²⁵ Protein disulfide-isomerase also catalyzes the formation of a mixed disulfide between glutathione and a cysteine on a folding protein,⁴³⁴ which is also a central intermediate⁴³⁵ in the formation of cystines by oxidized glutathione (Equation 13-31).⁴²⁵

Because protein disulfide-isomerase contains one pair of cysteines in each of its two domains, and because most folding proteins have enough cysteines to give rise to two or more cystines while they are folding, at the proper molar ratios protein disulfide-isomerase and a folding protein form a precipitate,⁴³⁶ just as an antigen and a set of polyclonal immunoglobulins form a precipitate at equivalence. The existence of this precipitate serves to demonstrate the importance of the mixed disulfide in Equation 13-32 in the reactions catalyzed by protein disulfide-isomerase.

In order to participate in any of these reactions, in particular the formation of the mixed disulfide between it and the folding protein, protein disulfide-isomerase must be able to find the cystine or the cysteine on the folding protein. This necessity requires both that the folding protein be molten enough to expose unpaired cysteines or mispaired cystines on its surface and that the reaction between protein disulfide-isomerase and those exposed cysteines and cystines be rapid and efficient.^{61,423} In a role that may be connected to this **search for incorrect cystines**, protein disulfide-isomerase also acts as a chaperone.⁴³⁷ Once the proper cystines are formed, however, they can be buried without penalty. It is probably the burial of the correctly paired cystines within the proper native structure that terminates the rearrangements of the cystines catalyzed by protein disulfide-isomerase. The same problem of accessibility is faced by peptidylprolyl isomerase, and it is interesting that protein disulfide-isomerase and peptidylprolyl isomerase function synergistically to catalyze the folding of a protein.⁴³⁸

The histidine between the two cysteines in each domain of protein disulfide-isomerase, as opposed to a proline at the homologous position in thioredoxin, causes the cystine in the former protein to have a **reduction potential** 30–40 mV more positive than that in the latter.^{439,440} This higher reduction potential causes a cystine in protein disulfide-isomerase to be more effective at forming cystines in folding proteins by disulfide interchange than a cystine in thioredoxin would be. The homologous cystine in thiol:disulfide interchange protein DsbA from *E. coli* is also exceptionally reactive.⁴³¹

In order to perform both the rearrangement of cystines and their formation most efficiently during its catalysis of the folding of a protein (Equation 13-32), protein disulfide-isomerase must be poised at a level of reduction potential where only a portion of its cysteines are cystines, and in the laboratory, the optimal potential for the catalysis of the folding of a protein is reached at a ratio of oxidized glutathione to reduced glutathione of 0.2–0.5.⁴²⁷ This ratio is not significantly different from the ratio found in the endoplasmic reticulum.

The proteins the foldings of which have been discussed so far have been fairly small and in each case the entire protein has folded as a unit to produce the native state. The folding of a larger protein is usually complicated not only by the larger number of prolines it contains but also by the fact that larger proteins usually contain **domains**, which often fold independently of each other. For example, lysozyme, itself not a large protein, nevertheless contains two structural domains. On the basis of measurements of amide proton exchange, it was demonstrated that one of these domains folds more rapidly than the other,⁴⁴¹ and the completion of the foldings of the two domains is followed by a step in which they become properly oriented and associate correctly with each other to form the native state.³⁴⁹ The rates of the final slow steps in the foldings of both aspartate kinase-homoserine dehydrogenase from *E. coli*³⁵⁹ and D-octopine dehydrogenase from *Pecten jacobaeus*⁴⁴² are inversely proportional to the viscosity of the solvent and are thought to represent the association of independently folding domains. The transfer of energy by resonance between donors and acceptors positioned at several locations on phosphoglycerate kinase from *S. cerevisiae* has been used to follow the changes in the distances between these locations during the unfolding of the protein.⁴⁴³ To the extent that unfolding is the reverse of folding, the fact that the first step in the unfolding of the protein is the dissociation of its two domains suggests that the last step in its folding is the association of these two domains.

The results of these experiments suggest that, in larger proteins, the individual domains fold independently as if they were the small unitary proteins that have been discussed in detail until there is sufficient structure developed for them to recognize each other and associate. Following their association, the information developed during this association may or may not dictate further folding to reach the final native state depending on the intimacy and interdependence of their interaction.

Problem 13–5: The figure displays the behavior of the observed rate constants, k_{obs} , in units of seconds⁻¹ for folding and unfolding of human lysozyme. The rate constants for folding were obtained by rapidly diluting the unfolded polypeptide from a solution of 4.5 M guanidinium chloride to the noted final concentration; and those for refolding, by rapidly mixing the native protein with a solution of guanidinium chloride to produce the noted final concentration.

- The rate at which the unfolded protein refolds is governed by Equation 13–10. Derive a similar equation describing the change in the concentration of the folded form ($[F]$) as a function of time.
- Why is the curve for the observed rate constant of folding continuous with the curve for the observed rate constant of unfolding?
- Which intrinsic rate constant dominates the observed rate constant in the unfolding region?
- Which dominates in the folding region?
- Why does the behavior of k_F as a function of the concentration of guanidinium chloride indicate that there is at least one kinetic intermediate in the folding reaction?
- Estimate the rate constant for the formation of this intermediate in the absence of guanidinium chloride.
- Estimate the rate constant for the formation of the native state from the intermediate state or the

intermediate states in the absence of guanidinium chloride.

- Is the isomerization of peptide bonds amino-terminal to prolines involved in the folding of human lysozyme? How did you decide?
- How does the value of k_U change as the concentration of guanidinium is increased up to 5 M?
- In the transition region in which the equilibrium constant for folding can be measured, what are the relative values of the rate constants k_F and k_U ?

Problem 13–6: Using the notation of Equations 13–31 through 13–33, write a set of equations that describes the possible ways that protein disulfide-isomerase could catalyze the formation of the mixed disulfide between glutathione and a cysteine on a folding protein.

Assembly of Oligomeric Proteins

When oligomeric proteins are dissolved in solutions of guanidinium chloride, they dissociate into their constitutive polypeptides that unfold to random coils. When the guanidinium chloride is removed from the solution, the random coils refold, and the **refolding monomers reassociate to form the native state**. For example, the inorganic diphosphatase from *E. coli* is an $(\alpha_3)_2$ hexamer in its native state. When dissolved in 5 M guanidinium chloride at pH 7, it dissociates into single α polypeptides ($n_{\text{aa}} = 175$), as judged by sedimentation equilibrium, that are random coils, as judged by their sedimentation coefficient ($s_{20,w}^0 = 0.59$ S) and intrinsic viscosity ($[\eta] = 22$ cm³ g⁻¹). When the guanidinium chloride is removed by dialysis, 80–90% of the enzymatic activity slowly returns, and the protein that results is an $(\alpha_3)_2$ hexamer indistinguishable in sedimentation coefficient, optical rotatory dispersion, or ultraviolet absorption spectrum from the original native enzyme.⁴⁴⁴ The native protein contains no cystines, but it does contain cysteines. Renaturation is successful only if an external mercaptan, which mimics the reduced glutathione normally present in the cytoplasm, is added to prevent adventitious intermolecular and intramolecular formation of cystine, a reaction that interferes with proper refolding.

The steps in the assembly of an oligomeric protein can be followed by **quantitative cross-linking**. Phosphoglycerate mutase from *S. cerevisiae* is an $(\alpha_2)_2$ tetramer. When it is dissolved in 4 M guanidinium chloride, it dissociates into random coils of the α polypeptide as judged by circular dichroism (Figure 13–17A).⁴⁴⁵ When the solution is diluted 40-fold to 0.1 M guanidinium chloride, greater than 80% of the molar ellipticity of the native state is regained in less than 30 s (Figure 13–17B). At this point greater than 80% of the protein is still monomeric. The appearance of dimers and tetramers as a function of time could be followed by quantitative cross-linking to cata-

Figure 13-17: Assembly of yeast phosphoglycerate mutase following dilution from 4 to 0.1 M guanidinium chloride.⁴⁴⁵ (A) Far-ultraviolet circular dichroic spectra of native enzyme (●), native enzyme in 0.1 M guanidinium chloride (△), and enzyme in 4 M guanidinium chloride (○); all measurements were made at a concentration of protein of 1.7 mg mL⁻¹. Molar ellipticity ($[\theta]$) in units of degree centimeter² (decimole of peptide bonds)⁻¹ is presented as a function of wavelength (nanometers). (B) Regain of molar ellipticity at 225 nm upon dilution from 4 to 0.1 M guanidinium chloride. Ellipticity is presented as a function of time (minutes) in relative units where 0% is the molar ellipticity of fully unfolded protein and 100% is the molar ellipticity of the native protein (see panel A). (C-E) Assembly of the oligomer. At the noted times after initiation of folding by dilution from 4 to 0.1 M guanidinium chloride, samples were removed and cross-linked quantitatively with 1% glutaraldehyde for 2 min, and the complexes between the resulting covalent oligomers and dodecyl sulfate were submitted to electrophoresis on gels of polyacrylamide in the presence of dodecyl sulfate. The amounts of monomer (●), dimer (△), and tetramer (□) were assessed by scanning the stained gels for absorbance. The relative amounts of monomer, dimer, and tetramer (as a percentage of the sum of the three amounts) are plotted as a function of the time (hours) between dilution of the guanidinium chloride and the addition of the glutaraldehyde. The final concentrations of protein were (C) 11, (D) 21, and (E) 37 $\mu\text{g mL}^{-1}$. The solid curves were drawn in all three panels with integrated rate equations based on Equation 13-34 with $k_1 = 6.25 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$, $k_{-1} = 6.0 \times 10^{-3} \text{ s}^{-1}$, and $k_2 = 2.75 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$. The temperature for all of these experiments was 20 °C, and they were run at pH 7.5. Reprinted with permission from ref 445. Copyright 1983 *Journal of Biological Chemistry*.

logue the species present at each point (Figure 13-17C-E).⁴⁴⁵ No trimers were observed, as would be expected. From an examination of the progress of the reaction, it could be concluded that the dimer was the initial oligomer, which, as it built up in concentration, dimerized to produce tetramer. Although the circular dichroism of the sample changed insignificantly as the reaction progressed (Figure 13-17B), the intrinsic fluorescence of the protein increased in concert with the oligomerization. Both the rate of the oligomerization (Figure 13-17C-E) and the rate of the increase in fluorescence (except for a small immediate increase of 20% that was invariant) were dependent on the absolute concentration of the protein.

The **kinetics** of both the oligomerization of phosphoglycerate mutase and the increase in fluorescence could be accounted for quantitatively⁴⁴⁵ by the mechanism

wherein all unfolded polypeptides, α_U , have folded in the first 30 s; the folded monomer, α_F , regains 20% of the fluorescence of the native state; and both the dimer and the tetramer have the full fluorescence of the native state. That the folded monomer and reassembled dimer can be digested with trypsin while the reassembled tetramer cannot⁴⁴⁶ suggests that the polypeptides in the monomer and the dimer are loosely folded and regain their fully compact native state only following tetramerization. That both the monomer and the dimer possess some enzymatic activity⁴⁴⁶ suggests that they are properly folded. The tetramer is produced in quantitative yield

with full enzymatic activity at these concentrations of protein ($<50 \mu\text{g mL}^{-1}$).⁴⁴⁶ In this oligomerization, the association of two dimers to form the tetramer is the rate-limiting step in the reaction (Equation 13–34), but in the oligomerization of the tetramerization domain ($n_{\text{aa}} = 30$) of human cellular tumor antigen p53, it is the association of two monomers to form a dimer that is the rate-limiting step, and the association of the two dimers to form the tetramer is so rapid that it is kinetically silent.⁴⁴⁷

The assembly of a dimer from its dissociated random coils is an even simpler reaction. Porcine mitochondrial malate dehydrogenase is an α_2 dimer that can be reversibly unfolded in several different ways. After random coils, α_{U} , of the α polypeptide are transferred to a solution at neutral pH, coincident with the dilution of the denaturant, the reappearance of enzymatic activity shows the same time course regardless of the mode of the original denaturation (Figure 13–18).⁴⁴⁸ The time course displays two phases, a lag followed by an increase. The increase in activity has a second-order dependence on the concentration of protein. The lag is unaffected by the concentration of protein and is a first-order process. The results can be explained quantitatively with the following mechanism:

if only the dimer, $(\alpha_{\text{F}})_2$, and not the folded monomer, α_{F} , is enzymatically active. At pH 7.6 and 20 °C,

Figure 13–18: Reassembly and reactivation of porcine mitochondrial malate dehydrogenase at a concentration of 60 nM and at pH 7.6 and 20 °C after dilution from various denaturants.⁴⁴⁸ The protein was unfolded at pH 2.3 alone (●), in 6 M guanidinium chloride (■), or in 6 M urea (▲). After it was fully unfolded and dissociated into its separate polypeptides in each instance, it was diluted to initiate refolding and reassembly. Samples were removed at the noted times and assayed for enzymatic activity; the enzymatic activity is presented in relative units with 0% being the immediately observed enzymatic activity ($<4\%$ of the final) and 100% being the enzymatic activity after full reactivation (>24 h). The curve is for the integrated rate equation for the mechanism of Equation 13–35 with $k_1 = 6.5 \times 10^{-4} \text{ s}^{-1}$ and $k_2 = 3 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$. Reprinted with permission from ref 448. Copyright 1979 American Chemical Society.

$k_1 = 0.0006 \text{ s}^{-1}$ and $k_2 = 30,000 \text{ M}^{-1} \text{ s}^{-1}$. The value of k_{F} is too small to be the rate constant for the rapid refolding of a polypeptide with the correct proline isomers to form a structure with no domains. The rate is probably slow because isomerizations of peptide bonds amino-terminal to prolines are required or because the two structural domains of the monomer observed in the crystallographic molecular model of the protein⁴⁴⁹ associate slowly or because both of these problems must be overcome before the monomer has regained **sufficient native structure to recognize another monomer** and dimerize with it.

In the case of the reassembly of the dimer of aspartate transaminase from *E. coli*, there are two consecutive, slow, first-order, unimolecular steps which produce a molten globular monomer that is enzymatically inactive but that has sufficient native structure to dimerize. This monomer displays a circular dichroic spectrum in the far ultraviolet similar to that of the native protein. Its dimerization and the formation of the final enzymatically active native state are rapid, and because these later steps follow the slow rate-limiting formation of the molten globular monomer, they are kinetically silent.⁴⁵⁰ In the folding and assembly of the dimer of steroid Δ -isomerase from *Pseudomonas testosteroni*, however, all three steps, the unimolecular formation of an enzymatically inactive monomeric intermediate (60 s^{-1} at 25 °C), its bimolecular association ($60,000 \text{ M}^{-1} \text{ s}^{-1}$ at 25 °C), and the formation of the final enzymatically active native structure (0.017 s^{-1} at 25 °C) could be resolved kinetically.⁴⁵¹ These experiments demonstrate that a monomeric intermediate does not have to assume its fully native state before it oligomerizes and that, in such a situation, **further isomerizations** can then occur within each subunit **following oligomerization** to produce the final native state. The final step in the reactivation has a rate constant suggesting that the isomerization of a peptide bond amino-terminal to a proline is involved.

Transcriptional repressor arc from bacteriophage P22 is also an α_2 dimer but of much smaller subunits ($n_{\text{aa}} = 53$). At low concentrations, its rate of folding and assembly is second-order in the concentration of protein, can be fit by a bimolecular rate equation, shows no evidence of any intermediates, and is complete in less than a second. Because the reaction is second-order, the rate-limiting step is dimerization (Equation 13–35) under these conditions. As the concentration of protein is increased above $20 \mu\text{M}$, however, there is a change in the rate-limiting step as the rate of dimerization becomes so fast that a preceding unimolecular step (Equation 13–35), the rate constant of which does not depend on the concentration of protein, becomes rate-limiting.⁴⁵² Because the change in fluorescence with time shows no evidence for the formation of any intermediate when the dimerization is the rate-limiting step,⁴⁵³ the unimolecular step is probably an **unfavorable preequilibrium** producing

an unstable monomeric state that is competent to dimerize. This unstable monomer is then captured and stabilized by the favorable dimerization.

The assembly of a trimer (Figure 9–11) is somewhat more complicated than that of either a tetramer or a dimer because the addition of the third subunit to the dimer is quite different from the initial combination of two monomers to form the dimer. The catalytic subunit of aspartate carbamoyltransferase (Figure 9–37) is an α_3 trimer. The assembly of trimers of the catalytic subunit from random coils of the α polypeptide is a first-order process with no evident intermediates and a rate constant of $2 \times 10^{-4} \text{ s}^{-1}$ at 0°C .⁴⁵⁴ It seems that again a slow isomerization of the partially folded, monomeric α polypeptide is the rate-limiting step in the assembly from random coils. To circumvent the barrier presented by this isomerization to the kinetic observation of intermediates in the process, native α_3 trimer was dissociated into globular rather than unfolded α monomers with thiocyanate ion ($\text{S}=\text{C}=\text{N}^-$),⁴⁵⁵ which is a milder denaturant than either urea or guanidinium ion. It is an anion that salts in protein as does urea or guanidinium but not so vigorously. The enzymatically inactive α monomers that result retain most of the circular dichroic ellipticity and ultraviolet absorption of the native α_3 trimers and have a frictional ratio f/f_0 of 1.27.⁴⁵⁵ These **globular α monomers** assemble readily to form α_3 trimers after the dilution of the thiocyanate.

When the assembly was followed by quantitative cross-linking, α monomers turned directly into α_3 trimers with no evidence for the formation of any α_2 dimers (<3%). The appearance of α_3 trimers was coincident with the return of enzymatic activity. Both of these processes, however, were strictly second-order in the concentration of α monomer:⁴⁵⁵

$$\frac{d[\alpha_3]}{dt} = k_{\text{obs}}[\alpha]^2 \quad (13-36)$$

A mechanism consistent with both of these results is

where $k_2 \gg k_1$. When the third monomer adds to the dimer, two interfaces form simultaneously, and this reaction could have a much lower standard free energy of activation than the formation of the dimer itself. Because the second step in Equation 13–37 is so much faster than the first, no α_2 dimer accumulates. The first step in Equation 13–37, however, a bimolecular reaction, is the rate-limiting step.

When homooligomeric proteins are assembled from random coils, the observations are consistent with the first step in the process being the folding of the random coil to a globular structure. In many instances,

this structure is loosely folded. For example, it may be sensitive to endopeptidolytic cleavage. This globular monomer either combines directly with other globular monomers to form the oligomer or it undergoes one or more isomerizations before it is competent to assemble. These isomerizations may be isomerizations of peptide bonds amino-terminal to critical prolines or rearrangements of domains, but these possibilities have not been validated. The competent monomers then assemble in simple, reasonable bimolecular steps to form the enzymatically active oligomer. When the reactions can be observed, the rate constants measured for these bimolecular steps are between 10^4 and $10^6 \text{ M}^{-1} \text{ s}^{-1}$ at 25°C ,^{445,448,455} several orders of magnitude below diffusion-controlled rates for the collision of molecules of this size. Therefore, they proceed with significant standard free energies of activation.

Whether or not **enzymatic activity** is displayed by the various compact intermediates in this process seems to be a property of the individual protein. Both α monomer and α_2 dimer of phosphoglycerate mutase have enzymatic activity.⁴⁴⁶ Fumarate hydratase, an $(\alpha_2)_2$ tetramer, can be denatured to random coils and reassembled to an α_2 dimer. The α_2 dimer is enzymatically inactive until it assembles to the $(\alpha_2)_2$ tetramer.⁴⁵⁶ Porphobilinogen synthase from *Pisum sativum*, an $[(\alpha_2)_2]_2$ octamer, can be disassembled to α_2 dimers by dilution. Only the octamer and the $(\alpha_2)_2$ tetramer are enzymatically active.⁴⁵⁷ The single active site of HIV-1 retropepsin from human immunodeficiency virus type 1 is formed from both subunits of the α_2 dimer, so it is not surprising that the α monomer has no enzymatic activity.⁴⁵⁸ When fructose-bisphosphate aldolase, an $(\alpha_2)_2$ tetramer, is denatured to random coils that are then transferred to a solution at pH 5.5, the random coils fold to form α monomers that have the sedimentation coefficient of a globular protein of their length and the circular dichroic spectra and ultraviolet spectra of the native protein. Their enzymatic activity cannot be determined because these α monomers oligomerize too rapidly to $(\alpha_2)_2$ tetramers when mixed with substrates,⁴⁵⁹ but they must bind those substrates for their assembly to be affected by them.

The **assembly of heterooligomers** constructed from several copies of each of two or more different polypeptides is somewhat more complex than that of homooligomers. When the assembly of a heterooligomer is studied, the reactants employed are the globular, homooligomeric subunits, such as catalytic subunits and regulatory subunits of aspartate carbamoyltransferase (Figure 9–37). It is generally assumed, in the absence of any evidence, that under physiological circumstances the homooligomeric subunits assemble first and then combine to form the heterooligomer. Only those proteins formed from two or more polypeptides translated from different messenger RNAs are of interest. Proteins containing different polypeptides arising from the post-

translational cleavage of identical larger polypeptides fold and assemble as simple homooligomers before the posttranslational modification occurs.

Alkanal monooxygenase (FMN-linked) from *Vibrio harveyi* is an $\alpha\beta$ heterodimer in which the α subunit ($n_{aa} = 355$) and the β subunit ($n_{aa} = 324$) are homologous and superposable, but neither of these subunits will form a homodimer. When they are expressed separately, each is a globular monomer containing about 50–60% of the α helix of a monomer in the native heterodimer but no discernible tertiary structure as judged from their nuclear magnetic resonance spectra. These properties are consistent with these two monomers being molten globules. Nevertheless, when they are mixed together, these α monomers and β monomers heterodimerize and form native alkanal monooxygenase.⁴⁶⁰ Either the two molten globular forms dimerize and then assume their native states while in the dimer, or the fully native states of the α monomer and the β monomer are present in the separate solutions of each at undetectably low equilibrium concentrations, and it is these forms that dimerize while the dimerization pulls the equilibria in the direction of the native states.

Tryptophan synthase from *E. coli* is another simple example of the assembly of a heterooligomer.⁴⁶¹ This protein is an $\alpha\beta_2\alpha$ heterotetramer.⁴⁶² When it is dissociated into its components, the products are α monomers and β_2 dimers, and both can be obtained in globular, folded states. When α monomer is mixed with excess β_2 dimer, the major product is the complex $\alpha\beta_2^*$. It forms in a reaction the kinetics of which are consistent with the mechanism

where the complex $\alpha\beta_2^*$ is an isomerized form of the initial intermediate $\alpha\beta_2$. The rate constants k_R , k_D , k_f , and k_b for this process at 25 °C are $1 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, 3 s^{-1} , 6 s^{-1} , and 0.001 s^{-1} , respectively. When excess α monomer is then added to the $\alpha\beta_2^*$ complex, the next step in the assembly has kinetic behavior consistent with the mechanism

and the rate constants k'_R , k'_D , k'_f , and k'_b for this process at 25 °C are $1.6 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, 26 s^{-1} , 16 s^{-1} , and 0.002 s^{-1} , respectively.

Each time an interface forms between an α monomer and one of the two β monomers in the β_2 dimer of tryptophan synthase, an isomerization of the structure of either the participating β monomer or the conjoined α monomer, or both, occurs, producing the asterisked conformer. The isomerizations producing

the conformers $\alpha\beta_2^*$ or $\alpha\beta_2^{**}$ are too rapid to be isomerizations of prolines. They presumably represent **rearrangements of the structures after the association** of the α and β subunits and are similar to the changes that permit the tetramer of phosphoglycerate mutase to resist endopeptidolytic degradation or that permit enzymatically inactive subunits to regain full enzymatic activity after oligomers such as malate dehydrogenase, aspartate transaminase, and fumarate hydratase reach the native stoichiometry. The equilibrium constant ($K_{is} = k_f/k_b$) for the isomerization following the addition of the first α monomer ($K_{is} = 6000$) is the same as that following the addition of the second α monomer ($K'_{is} = 8000$), indicating that the same local adjustments are occurring after each α monomer adds in turn.

Aspartate carbamoyltransferase is constructed from two catalytic C subunits that are α_3 trimers and three regulatory R subunits that are β_2 dimers. From its crystallographic molecular model (Figure 9–37), it is clear that only certain steps are possible in its assembly from separated C subunits and R subunits (Figure 13–19).⁴⁶³ The intermediates that appear during the assembly of the intact $(\alpha_3)_2(\beta_2)_3$ heterododecamer (C_2R_3 heteropentamer) have been followed by quenching the assembly of radioactive catalytic or regulatory subunits and their unradioactive complements with large excesses of unradioactive catalytic or succinylated catalytic subunits, respectively.⁴⁶³ The specific radioactivity of the various mosaic oligomers, which, because of the excess negative

Figure 13-19: Intermediates in the assembly of aspartate carbamoyltransferase.⁴⁶³ Catalytic (C) or regulatory (R) subunits that had been made radioactive by iodinating their tyrosines with ¹²⁵I (Reaction 10–33) were mixed with excess unradioactive R or C subunits, respectively, to initiate assembly. At various times, the assembly reaction was quenched with either excess C subunit or excess succinylated C subunit to cap off partially formed complexes and scavenge all unreacted R subunit. From examining the specific radioactivity of complexes separated by electrophoresis, an estimate of the relative concentrations of all of the intermediates in the process of assembly at each time point could be made. The changes in these relative concentrations with time were used to formulate the assembly diagram displayed in the figure. Four of the steps in this process are rapidly reversible: $C + R \rightleftharpoons CR$, $CR + R \rightleftharpoons CR_2$, $CR_2 + R \rightleftharpoons CR_3$, and $CR + C \rightleftharpoons C_2R$. In contrast, processes forming the complexes C_2R_2 and C_2R_3 are essentially irreversible because these complexes are so stable. Reprinted with permission from ref 463. Copyright 1980 *Journal of Biological Chemistry*.

charge (Equation 10–27) on the succinylated C subunits, can be separated from each other by electrophoresis, permits the concentrations of the various intermediates at the time the reaction was quenched to be calculated.

When a limiting concentration of C subunit is mixed with various excesses of R subunit, equilibrium mixtures of the intermediates CR, CR₂, and CR₃ are formed. Subsequent addition of excess C subunit causes CR₃ to be trapped as CR₃C, the intact native protein, and CR₂ to be trapped as CR₂C.⁴⁶³ When excess C subunit is mixed with a limiting concentration of R subunit, the only two products other than unreacted C subunit are CR₃C and CR₂C, with the former in the majority.^{464,465} The complex CR₂C can be isolated as a stable protein. When it is combined with R subunit, it produces CR₃C in a clean bimolecular reaction.⁴⁶⁴ In these experiments, most of the intermediates in the general scheme (Figure 13–19) have been directly observed, and rate constants and equilibrium constants for their interconversion have been established.⁴⁶⁶ Most of the steps in the scheme seem to occur simultaneously, and **different pathways** become more or less important as concentrations of the subunits are changed.

The pyruvate dehydrogenase complex of *E. coli* is composed of three different polypeptide chains, α , β , and γ . The protein can be resolved into these three independent components. These are the dihydrolipoyllysine-residue acetyltransferase core, the pyruvate dehydrogenase (acetyl-transferring) subunits, and the dihydrolipoyl dehydrogenase subunits. The dihydrolipoyllysine-residue acetyltransferase core is an octahedral α_{24} oligomer (Figure 9–23), pyruvate dehydrogenase (acetyl-transferring) is a β_2 dimer, and dihydrolipoyl dehydrogenase is a γ_2 dimer. No association can be detected between the β_2 dimers of pyruvate dehydrogenase (acetyl-transferring) and the γ_2 dimers of dihydrolipoyl dehydrogenase.⁴⁶⁷ Therefore, the α_{24} oligomer of the dihydrolipoyllysine-residue acetyltransferase serves as the **point of attachment** of the other components.

Unlike the closely related dihydrolipoyllysine-residue succinyltransferase from the 2-oxoglutarate dehydrogenase complex, which can associate with only six β_2 dimers of oxoglutarate dehydrogenase (succinyl-transferring) at saturation because of a steric effect,⁴⁶⁸ the empty α_{24} oligomer of the dihydrolipoyllysine-residue acetyltransferase from *E. coli* can associate with up to 24 β_2 dimers of pyruvate dehydrogenase (acetyl-transferring).^{467,469} Presumably, in the saturated complex, one of the two faces on each of the 24 β_2 dimers occupies one of the 24 equivalent faces of the octahedral α_{24} oligomer with no steric hindrance. The empty α_{24} oligomer of the dihydrolipoyllysine-residue acetyltransferase can also associate with as many as 20 γ_2 dimers of dihydrolipoyl dehydrogenase in the absence of pyruvate dehydrogenase (acetyl-transferring).⁴⁶⁹

When both β_2 dimers of pyruvate dehydrogenase

(acetyl-transferring) and γ_2 dimers of dihydrolipoyl dehydrogenase are added together to the dihydrolipoyllysine-residue acetyltransferase core, substoichiometric amounts of each are bound,⁴⁶⁹ presumably because of **steric crowding**. Certainly the native protein, which has an average of about 12 γ_2 dimers of dihydrolipoyl dehydrogenase and an average of somewhat less than 24 β_2 dimers of pyruvate dehydrogenase (acetyl-transferring),⁴⁶⁷ appears to be a crowded structure (Figure 13–20).⁴⁷⁰ When a preformed complex containing an average of 12 γ_2 dimers of dihydrolipoyl dehydrogenase for each α_{24} oligomer of dihydrolipoyllysine-residue acetyltransferase is mixed with increasing amounts of pyruvate dehydrogenase (acetyl-transferring), about 22 β_2 dimers of pyruvate dehydrogenase (acetyl-transferring) bind to the α_{24} oligomers at saturation, and the overall enzymatic activity increases in direct proportion to the number bound.⁴⁶⁷ All of these results suggest that β_2 dimers of pyruvate dehydrogenase (acetyl-transferring) and γ_2 dimers of dihydrolipoyl dehydrogenase add at random to the respective faces on the α_{24} oligomer of dihydrolipoyllysine-residue acetyltransferase, at least under the circumstances of these experiments, until there is no more room left around the core. What is not clear is whether the dimers of dihydrolipoyl dehydrogenase and pyruvate dehydrogenase (acetyl-transferring) add at random to the core during normal assembly within the cell until no more can fit or there is some ordered sequence that determines the final stoichiometry.

The 30S subunit of a ribosome from *E. coli* (Figure 11–5) is composed of a single strand of 16S ribosomal RNA ($n_{\text{nuc}} = 1541$)⁴⁷¹ and 21 polypeptides that, when

Figure 13–20: Electron micrographs of (A) the pyruvate dehydrogenase complex from *E. coli* and (B) the core of dihydrolipoyllysine-residue acetyltransferase from the same protein.⁴⁷⁰ Both specimens were adsorbed onto a thin, supported layer of amorphous carbon on an electron microscopic grid and negatively stained with sodium methylphosphotungstate. Magnification is 300000 \times . The complete complex was purified directly from a homogenate of the bacteria; the acetyltransferase core was prepared from the complete complex by stripping away dihydrolipoyl dehydrogenase and pyruvate dehydrogenase (acetyl-transferring). Reprinted with permission from ref 470. Copyright 1971 Cold Spring Harbor Laboratory.

folded and assembled, constitute its 21 subunits. When the ribosomal RNA and the separated individual polypeptides are mixed together, they spontaneously reassemble in high yield to form 30S subunits that are fully competent to participate in protein biosynthesis.⁴⁷² The assembly of the intact 30S subunit from its components (Figure 13–21)⁴⁷³ proceeds through an **explicit sequence of steps** beginning with the binding of a few of the subunits to the 16S ribosomal RNA itself. As the assembly progresses, the binding to the 16S ribosomal RNA of the subunits earlier in the sequence of events or the binding of polypeptides to complexes between the 16S ribosomal RNA and other polypeptides creates sites to which subunits later in the sequence of events can attach (Figure 13–21). If a polypeptide is added to the mixture before all of the subunits that must precede it have been incorporated, it will not bind to the partially assembled 30S subunit. An **assembly map**, necessarily of greater complexity but describing a similar hierarchically ordered process, has been drawn for the assembly of the

Figure 13–21: Assembly diagram for the 30S subunit of the ribosome from *E. coli*.⁴⁷³ The sequence of events was determined by mixing, in various combinations, the 21 purified polypeptides with the purified 16S RNA and assaying for formation of a complex or complexes among the components. For example, only polypeptides S15, S17, S4, and S8 would bind alone to 16S ribosomal RNA. Polypeptide S20 will form a complex with 16S RNA only when subunits S4 and S8 have been incorporated. Polypeptide S13 binds to 16S RNA only when subunits S4, S8, and S20 have been incorporated, and so forth. Upon binding each polypeptide becomes a subunit of the assembling 30S ribosomal subunit. 50S ribosomal subunit of *E. coli* from 23S ribosomal RNA, 5S ribosomal RNA, and 31 polypeptides.⁴⁷⁴

From the crystallographic molecular model of the 30S subunit,⁴⁷⁵ some inferences can be drawn to explain the order in which its subunits are incorporated into the assembling particle (Figure 13–21). None of the polypeptides except S4, S8, S17, and S15 can add until other subunits have been incorporated. Subunits S6 and S18 form an intimate complex in one corner of the complete 30S subunit, and subunits S10, S14, and S3 form an intimate complex in another corner. These close associations explain the interdependences between the additions of the polypeptides of these subunits during assembly. Most of the subunits of the intact 30S subunit, however, have little if any contact with each other in the final particle.

The last polypeptides to add to the assembling particle, S3, S10, S14, S11, S18, S5, S12, and S9 (Figure 13–21), all form contacts with at least one and as many as five double helices of RNA also contacted by the subunit or subunits that must precede them onto the particle. These relationships suggest that the preceding subunit or subunits control the **orientations of these double helices** so that the site for the binding of the following subunit among these double helices is either created or stabilized.

The earlier subunits to add to the assembling particle, however, subunits S19, S13, S7, and S20, do not share either direct contacts or contacts with double helices in common with the subunits that must precede them. This fact suggests that **global conformational changes** of the 16S ribosomal RNA are effected by the earliest polypeptides to add, namely those of subunits S4, S8, S20, and S7, to create the distant sites for the polypeptides of subunits S19, S13, S7, and S20.

Not only does the structure of the 16S ribosomal RNA seem to adjust upon the association of the individual subunits but also the conformations of the separated subunits seem to adjust, sometimes dramatically, upon their association. One polypeptide that seems to be almost structureless before it associates with the 16S ribosomal RNA is polypeptide S4 ($n_{aa} = 203$). The nuclear magnetic resonance spectrum of polypeptide S4 under the conditions in which assembly takes place is almost indistinguishable from its spectrum in 8 M urea, which is the spectrum of the sum of the amino acids from which it is composed.⁴⁷⁶ This result indicates that, when alone in solution, polypeptide S4 cannot assume a unique native state. The circular dichroic spectrum⁴⁷⁶ and frictional ratio ($f/f_0 = 1.7$), however, are not those of a fully random coil ($f/f_0 = 2.4$ for $n_{aa} = 245$),⁴⁷⁷ and an explanation of these results and those from nuclear magnetic resonance spectroscopy would be that the polypeptide in solution is rapidly passing through an array of loosely folded conformations, none of which is unique. When it is bound to the 16S ribosomal RNA, the subunit S4 assumes a defined structure with seven α helices and

four strands of β structure, but it is flattened and spread over the surface of the 30S subunit.⁴⁷⁵ As it associates with the 16S ribosomal RNA, its final structure could easily be dictated solely by the noncovalent interactions in which it participates as it spreads over the surface of the folded polynucleotide.

Some ribosomal polypeptides seem to enter the assembling 30S subunit as folded globular proteins. For example, polypeptide S17 ($n_{aa} = 83$) under the conditions of assembly has both the frictional ratio ($f/f_0 = 1.24$; calculated from its sedimentation coefficient) and the intrinsic viscosity ($[\eta] = 4.2 \text{ cm}^3 \text{ g}^{-1}$) of a globular protein and the molar mass, as determined by sedimentation equilibrium, of a monomer.⁴⁷⁸ Other polypeptides, however, seem to be elongated but compact proteins under the conditions of assembly. For example, polypeptides S3, S5, S6, and S7 have frictional ratios $f/f_0 = 1.4\text{--}1.6$ that are too large to be those of globular proteins.^{477,478} Like subunit S4, subunit S3 is flattened against the surface of the assembled, intact 30S subunit. Subunit S5 also assumes a flattened, elongated conformation, but subunits S6 and S7 are both globular in the final structure and must become so as they associate with the assembling particle.

Problem 13-7: The dissociation constant for the first step in the assembly of tryptophan synthase (Equation 13-38) is

$$K_{d1} = \frac{2[\alpha][\beta_2]}{[\alpha\beta_2^*]}$$

(A) Why is the 2 present in the numerator?

The dissociation constant for the second step (Equation 13-39) is

$$K_{d2} = \frac{[\alpha][\alpha\beta_2^*]}{2[\alpha_2\beta_2^{**}]}$$

(B) Why is the 2 present in the denominator?

(C) Calculate the equilibrium constants K_{d1} and K_{d2} at 25 °C. Recall that at equilibrium

$$k_R[\alpha][\beta_2] = k_D[\alpha\beta_2]$$

and

$$k_f[\alpha\beta_2] = k_b[\alpha\beta_2^*]$$

Assembly of Helical Polymeric Proteins

There are two classes into which helical polymeric proteins can be divided when the question of assembly is considered: those that assemble irreversibly and those that assemble reversibly. Those that assemble irreversibly polymerize initially by the noncovalent assembly of monomeric subunits, but the polymers are often strengthened secondarily by the formation of naturally occurring covalent cross-links between adjacent subunits (Figure 3-19). Those that assemble reversibly require that reversibility for their biological role, and their assembly is not an approach to equilibrium but the result of a steady state.

Examples of helical polymeric proteins that assemble irreversibly are collagen (Figure 9-34), intermediate filaments (Figure 9-35), thick filaments, and fibrin.

The thick fibers of **fibrin** that form clots of blood are readily observed in scanning electron micrographs. They are lateral aggregates of thinner protofibrils of fibrin; these **protofibrils** of fibrin are assembled irreversibly from a protomeric unit known as **fibrinogen** (Figure 13-22A),⁴⁷⁹⁻⁴⁸¹ which is a freely soluble $(\alpha\beta\gamma)_2$ heterohexamer.⁴⁷⁹ Each molecule of fibrinogen is constructed from two $\alpha\beta\gamma$ heterotrimers arrayed about a 2-fold rotational axis of symmetry. Each of the two $\alpha\beta\gamma$ heterotrimers contains a long segment of rope (111 amino acids) in which the three strands, one from each of the α , β , and γ polypeptides, are wound around each other in a triple α -helical coiled coil (Figure 6-28). At the two ends of each rope are globular domains known as the terminal domain and the central domain, respectively. A terminal domain is composed of the carboxy-terminal domains of the β subunit and the γ subunit; the central domain is composed of the folded amino-terminal regions of all three polypeptides. Two $\alpha\beta\gamma$ heterotrimers are associated at their central domains around the 2-fold rotational axis of symmetry^{481,482} to produce the molecule of fibrinogen with two terminal domains.

Fibrinogen does not assemble into a protofibril until four short peptides, two **fibrinopeptides A** and two **fibrinopeptides B**, are removed by the endopeptidase thrombin from the amino-terminal ends of the two α polypeptides and the two β polypeptides to produce **fibrin monomers**. The fibrinopeptides have sequences that vary extensively among species (Problem 7-5) and seem to satisfy only the requirement that they be polar and structureless. Carboxy-terminal to the arginines at which the endopeptidolytic cleavages occur that remove the four fibrinopeptides, the amino acid sequences of the α and β polypeptides become highly conserved among

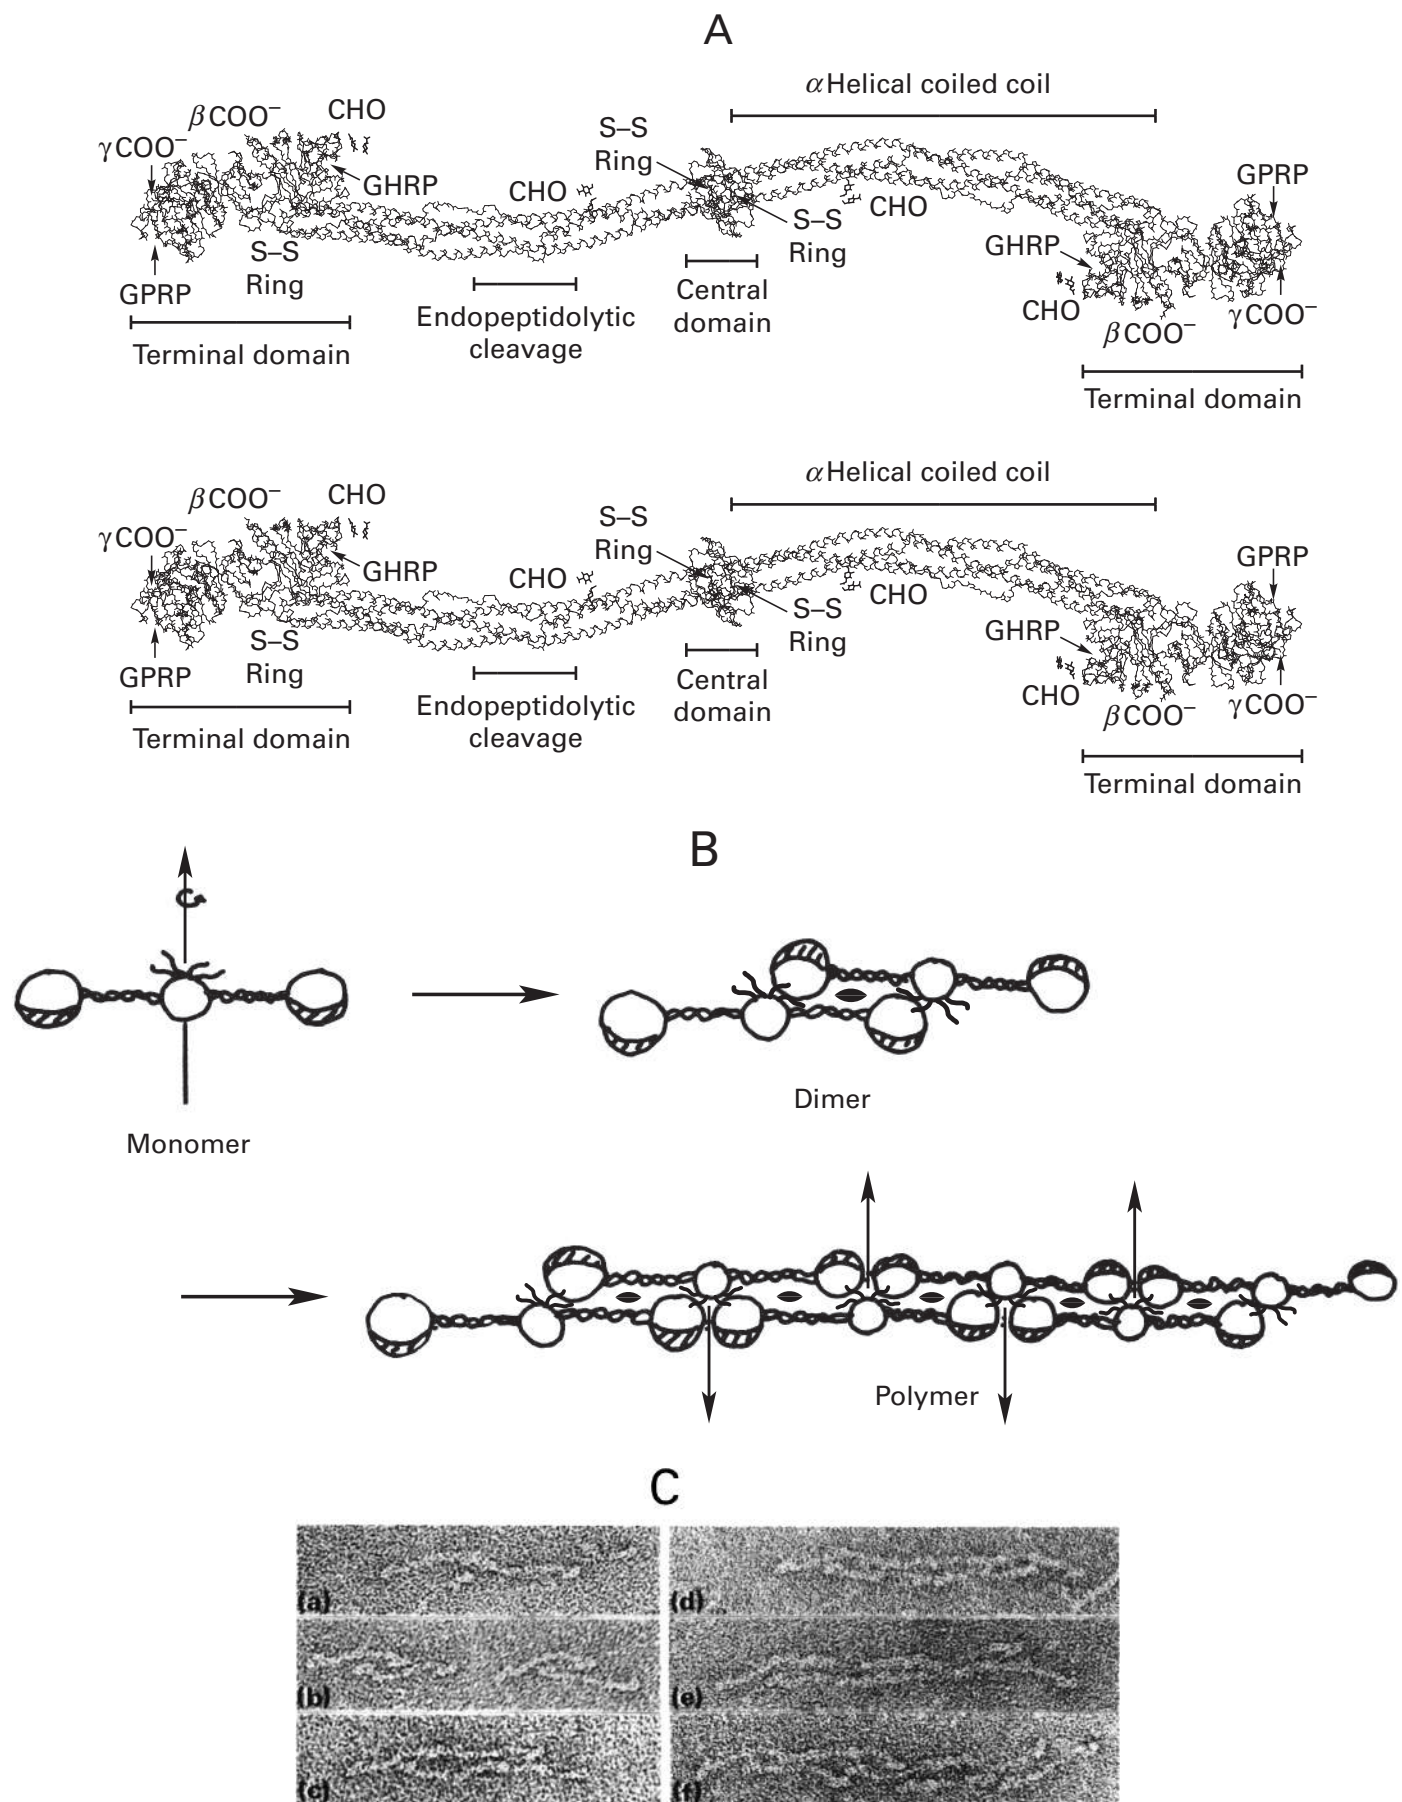

Figure 13-22: Assembly of fibrin from fibrinogen. (A) Skeletal drawing in stereo of the polypeptide backbones of the subunits in the crystallographic molecular model of fibrinogen from *G. gallus*.⁴⁸¹ The molecule is an $(\alpha\beta\gamma)_2$ heterohexamer with a rotational axis of symmetry normal to the plane of the page passing through the center of the central domain. Features noted on only one side of the molecule are reproduced symmetrically on the other. The amino termini of the six polypeptides α , α' , β , β' , γ , and γ' are all in the central domain, but the amino-terminal 26, 62, and 3 aa are missing from the maps of electron density of the α , β , and γ polypeptides, respectively, because these segments are disordered in the crystals. Two symmetrically displayed, identical rings of cystines (S-S rings) each connect Cysteine $\alpha 45$ to Cysteine $\gamma 23$, Cysteine $\gamma 19$ to Cysteine $\beta 80$, and Cysteine $\beta 76$ to Cysteine $\alpha 49$. One of these rings is on each side of the central domain, and together they mark its boundaries. At these rings, the two symmetrically displayed, three-stranded α -helical coiled coils commence in opposite directions, and each proceeds for 16 nm (111 aa) until terminating in another ring of cystines. In the middle of each coiled coil, there are intentional disruptions that make each susceptible to the endopeptidolytic cleavages that dissolve the fibrin clot. At each of the peripheral rings of cystines, each of the two terminal domains commences. The globularly and homologously folded carboxy-terminal 262 aa of a β subunit and 270 aa of a γ subunit together, side by side, form each terminal domain. The structures of these two halves of each of the peripheral domains are superposable.⁴⁸⁵ The carboxy-terminal 16 amino acids of the γ polypeptide, which contain the sites of intermolecular cross-linking, are disordered in the crystals. The carboxy-termini of each of these polypeptides in the crystallographic molecular model (βCOO^- and γCOO^- , respectively) are indicated. The carboxy-terminal 557 aa of each α polypeptide emerges from the respective peripheral ring of cystines, proceeds towards the center of the molecule along the α -helical coiled coil, and then disappears in disorder beyond Glutamate 218. There are oligosaccharides (CHO) at Asparagines $\gamma 52$ and Asparagines $\beta 363$. The binding sites for the tetrapeptides GPRP and GHRP that were cocrystallized with the fibrinogen are indicated. These are mimics of the amino termini from within an α polypeptide (GPRIL-) and a β polypeptide (AHRPL-) produced by thrombin cleavage. (B) Schematic drawing of the initial events in the polymerization of fibrin monomers to form a protofibril. Removal of the fibrinopeptides exposes new amino termini on the central domain (the four tails) that can then interact with complementary sites on terminal domains of other molecules. An additional set of contacts (end-to-end) comes into play upon addition of the third molecule. There are orthogonal 2-fold axes of symmetry (designated by arrow and sharpened ellipse) that alternate along the protofibril (polymer). Reprinted with permission from ref 479. Copyright 1984 Annual Reviews Inc. (C) Electron micrographs of intermediates in the polymerization of fibrin monomers. Thrombin was added to a solution of bovine fibrinogen (0.3 mg mL⁻¹) to initiate polymerization. At short times after nucleation of polymerization (about 10 min), the macroscopic clot was removed and samples of the clear solution that remained were placed on hydrophilic films of carbon supported by networks of formvar. The adsorbed complexes of fibrin monomers were negatively stained with 1.0% uranyl acetate.⁴⁸⁰ Magnification 290000 \times . species.⁴⁸³ The α polypeptide of a mammalian fibrin monomer has the amino-terminal sequence GPRAlk-, where Alk is the alkyl group of valine, leucine, or isoleucine; and the β polypeptide of a fibrin monomer

has the amino-terminal sequence GHRP-. A synthetic peptide of the sequence GPRP can inhibit completely the polymerization of fibrin monomers to fibrin polymer.⁴⁸⁴ It does so by competing with the amino termini of the α polypeptides of those fibrin monomers, which are in the central domain, for a binding site on the globular, carboxy-terminal domain of a γ subunit,^{485,486} which together with the homologous globular, carboxy-terminal domain of a β subunit⁴⁸⁵ forms one of the two terminal domains of the fibrin monomer (Figure 13-22A).

These facts suggest that the protofibril is assembled by the noncovalent binding of the central domain and terminal domain of one molecule of the fibrin monomer to the terminal domain and central domain, respectively, of another fibrin monomer to form a rotationally symmetric, doubly bonded dimer (Figure 13-22B).⁴⁷⁹ The dimer would be elongated to the polymer by adding other fibrin monomers, dimers, or oligomers through steps each creating identical interfaces (Figure 13-22B). Each of the consecutive, individual noncovalent interactions holding the helical polymer together is between the amino terminus of an α polypeptide on a central domain exposed by the cleavage produced by thrombin and the **binding site for its amino-terminal sequence, GPR-, on one of the terminal domains** of another fibrin monomer. Electron micrographs of intermediates in the polymerization of fibrin monomers are consistent with this structural proposal (Figure 13-22C).⁴⁸⁰

The binding site for the GPR- has been located in a crystallographic molecular model of the terminal domain.⁴⁸⁵ It is a **hole on the surface of the globular carboxy-terminal domain of the γ subunit** into which the amino-terminal sequence GPR- inserts with the glycine at the bottom of the hole. The amino-terminal 26 amino acids of the α polypeptide, amino-terminal to the symmetric interchain cystine between Cysteine $\alpha 28$ and Cysteine $\alpha' 28$, are missing from the crystallographic molecular models of both a detached central domain⁴⁸⁷ and a complete molecule of fibrinogen.⁴⁸¹ Consequently, the amino-terminal 11 aa of an α polypeptide in a fibrin monomer are probably structureless, and as a result, they are able to reach out to the hole on the peripheral domain. The cystine between Cysteine $\alpha 28$ and Cysteine $\alpha' 28$ itself forms a loop that juts out from the central domain. Both of these structural characteristics make it easier for the GPR- to find its site on the terminal domain of another fibrin monomer and suggest that the connection it forms between a central domain of the one fibrin monomer and the terminal domain of the other is a flexible tether.

A fibrin monomer is a knotted segment of rope with a 2-fold rotational axis of symmetry centered on the knot. It assembles into a protofibril, which is a helical cable. An infinite helix defined by a smooth curve is a geometric structure with 2-fold **rotational axes of symmetry** intersecting every one of its points, so the creation of an infinite helical polymer from a monomer with a molecular

2-fold axis of symmetry produces a structure with a 2-fold rotational axis of symmetry at each molecular 2-fold rotational axis of symmetry. When this polymer is finite, the two ends are necessarily identical in structure.

The protofibril that forms as the assembly proceeds has a thickness, as determined by light scattering,⁴⁸⁸ of about two fibrin monomers (Figure 13-22B,C). When fibrin monomers are created instantly by adding a large excess of thrombin to a solution of fibrinogen, the initial rate of formation of these protofibrils as monitored by light scattering is bimolecular in the concentration of fibrin monomers (Figure 13-23A)⁴⁸⁸ and shows no evidence of a lag. The time required for half of the final light scattering to be established is inversely proportional to the initial concentration of fibrin monomers (Figure 13-23B). Because light scattering is not proportional to bulk concentration of polymer, this is simply the time required for a particular fraction α of the polymer to form.

It can be shown¹⁹³ that such behavior is that expected from a polymerization in which end-to-end connections among monomers, dimers, and oligomers

Figure 13-23: Dependence of the initial rate for the polymerization of fibrin (A) and the time required to reach half of the total increase in light scattering (B) on the initial concentration of fibrin monomer.⁴⁸⁸ Solutions of fibrinogen (0.05–0.35 mg mL⁻¹ final concentration) were mixed rapidly (<0.5 s) with solutions of thrombin at concentrations high enough to remove the fibrinopeptides from the molecules of fibrinogen immediately (<0.5 s). The polymerization of the fibrin was then followed by monitoring the increase in light scattering of the solution at 633 nm as a function of time (seconds). The initial rate of increase in light scattering was determined for each trace as well as the time (2–25 s) required for the light scattering to reach half its final value. The logarithm of the initial rate and the logarithm of the time required to reach half of the final value of light scattering, $\log t_{1/2}$, are presented, respectively, as functions of the logarithm of the concentration (molar) of fibrinogen. The concentration of protein (micromolar) is also noted at the top of each graph. The polymerization was performed at 23 °C in 0.5 M NaCl. The high ionic strength prevented side-to-side aggregation of the polymers so that only formation and elongation of protofibrils were occurring during the measurements. The solid lines are linear least-squares fits to the data; the dashed lines are lines of slope 2 and -1, respectively. Adapted with permission from ref 488. Copyright 1979 *Journal of Biological Chemistry*.

form at random with no initiation required and in which each connection has the same rate constant of formation regardless of the lengths of the two participants, including unconnected monomers. It is possible that, during the polymerization of fibrin monomers, an interface forms between the two adjacent terminal domains of two different fibrinogen molecules in a protofibril, which cannot form in the initial dimer (Figure 13-22B). Either this interface is much slower to form than the interface formed by the insertion of the amino terminus of an α subunit into the hole on a γ subunit or the difference in rate between the formation of a dimer and formation of a longer protofibril is irrelevant because almost all interfaces form between oligomers and between oligomers and monomers.

If the assumption is made that the degree of polymerization is equal to the molar concentration of connected interfaces between monomers, [interfaces], and it is realized that the molar concentration of amino termini of α polypeptides on central domains is always equal to the molar concentration of holes on terminal domains, then

$$\frac{d[\text{interfaces}]}{dt} = k[\text{faces}]^2 \quad (13-40)$$

where [faces] is the total molar concentration at any time, t , of **open faces**, each of which is an amino terminus and a hole on the same monomer and each of which is located at the **open end** of a fibrin monomer, dimer, or oligomer (Figure 13-22B), and each open end has both an amino terminus and a hole. The initial rate of polymer formation will be second-order in the concentration of fibrin monomer because $[\text{faces}]_0 = 2[\text{monomer}]_0$, where $[\text{faces}]_0$ and $[\text{monomer}]_0$ are the initial concentrations of faces and fibrin monomers, respectively.

Because one interface is formed from two faces, one from each monomer (Figure 13-22B)

$$2 \frac{d[\text{interfaces}]}{dt} = - \frac{d[\text{faces}]}{dt} \quad (13-41)$$

Upon combination of Equations 13-40 and 13-41 and rearrangement

$$- \frac{d[\text{faces}]}{[\text{faces}]^2} = 2k dt \quad (13-42)$$

Upon integration between $t = 0$ and t

$$\frac{1}{[\text{faces}]} - \frac{1}{[\text{faces}]_0} = 2kt \quad (13-43)$$

Choose any time, t_α , at which a particular fraction α of the polymer has formed. Because that fraction of the

faces has disappeared, $[\text{faces}] = (1-\alpha)[\text{faces}]_0$. When this equality is inserted into Equation 13-43

$$\frac{1}{[\text{faces}]_0} = 2 \left(\frac{1-\alpha}{\alpha} \right) k t_\alpha \quad (13-44)$$

It follows that the time at which any particular fraction, α , of the polymer has formed will be inversely proportional to the initial concentration of monomer, as was observed. The kinetic mechanism just described, based on the assumption that the combination of two faces is independent of whether they are faces on fibrin monomers, dimers, or oligomers, is completely consistent with the proposed molecular mechanism (Figure 13-22B).

The final step in the irreversible polymerization of fibrin is the **covalent cross-linking of the fibrin** monomers among themselves by the enzyme protein-glutamine γ -glutamyltransferase. This enzyme catalyzes replacement of the ammonia in a glutamine on one monomer with the ϵ amine of a lysine on another monomer:

Two symmetrically disposed pairs of lysines and glutamines near the carboxy termini of two γ subunits are cross-linked in this way to produce a covalent dimer of γ polypeptides with the following structure:⁴⁸⁹

where each valine is the carboxy terminus of a γ polypeptide. The covalently symmetric juxtaposition of these two sequences from the γ polypeptides of different fibrin monomers in the protofibril produced by the protein-glutamine γ -glutamyltransferase is consistent with a structural model in which there is a 2-fold rotational axis of symmetry at this location in the protofibril. Amide cross-links are also formed among α polypeptides juxtaposed during the lateral association of the protofibrils.⁴⁹⁰ The pairing in these cross-links reflects the side-by-side orientation of the α polypeptides in different protofibrils in the final fiber of fibrin.

After it has polymerized and been covalently cross-linked, fibrin cannot depolymerize. The fibrin clot is eliminated when necessary by the endopeptidolytic cleavage of the three polypeptides within the α helical coiled coils (Figure 13-22A) by plasmin. Collagen, also

because it is covalently cross-linked, cannot depolymerize. It too is eliminated, when necessary, by endopeptidolytic digestion. These two proteins are examples of helical polymeric proteins that are **assembled irreversibly**. Examples of helical polymeric proteins that **assemble reversibly** are actin (Figure 9-1B) and microtubules. These helical polymeric proteins are continuously assembled and disassembled during the life of a cell.

Microtubules are hollow cylinders of indefinite length. The overall radius of a microtubule is about 12 nm, and it has a hollow center with a radius of about 6 nm. When viewed in the electron microscope, by negative staining, microtubules are tubular bundles of 10-16 indistinguishable rows of protein (Figure 13-24A).^{491,492} Each row is parallel to all of the others and parallel to the axis of the microtubule for microtubules of 13 rows but skewed somewhat relative to the axis for microtubules with 10, 11, 12, 14, 15, or 16 rows.⁴⁹² At the end of a microtubule these rows can be frayed into individual threads.⁴⁹³ From this observation it can be concluded that the interfaces forming the rows are stronger than the interfaces between them.⁴⁹¹ Each thread of protein forming one of these rows is a **protofilament**.⁴⁹²

Each of the protofilaments in an intact microtubule is a string of globular protein subunits. Each of the subunits is pointed in the same direction. The top of one of these subunits is joined to the bottom of the subunit above it in the same protofilament by an interface. Each subunit is related to the one above it by a screw axis of symmetry coincident with the axis of the microtubule. Because each of the protofilaments in a microtubule of 13 rows is parallel to the axis of the tubule, the angle relating two consecutive subunits by the screw axis of symmetry is zero in this type of microtubule. In the other types of microtubules in which the protofilaments are skewed relative to the central axis, the angles of the screw axes are somewhat less or somewhat more than zero. In each case, however, the translation along the screw axis of symmetry that superposes a subunit in a protofilament upon the one above it is 4.0 nm.

The primordial microtubule was a polymer composed of identical monomeric subunits each related to its neighbor above by the screw axis of symmetry defined by the strong interfaces creating a protofilament. At some point, the gene encoding the subunit duplicated and the two resulting isoforms of the common ancestral subunit began to evolve separately. The results of this evolution are that along a protofilament, the two isoforms, the α subunit and the β subunit, alternate; that the interface between a β subunit and the α subunit above it is stronger than the interface between a β subunit and the α subunit below it; and that as a result, when a microtubule dissociates, it dissociates into $\alpha\beta$ heterodimers.^{494,495} Because the individual identical subunits in the primordial microtubule were related to each other by a screw axis of symmetry with a rise of

4.0 nm and an angle of rotation equal to about zero, the two subunits in the $\alpha\beta$ heterodimer are now related to each other by a screw axis of pseudosymmetry with the same rise and a rotation of almost zero.

The protomer from which a microtubule is now formed is this **$\alpha\beta$ heterodimer**. It is composed of an α subunit ($n_{aa} = 450$)⁴⁹⁶ and a β subunit ($n_{aa} = 445$)⁴⁹⁷ the amino acid sequences of which are homologous to each other [41% identity with 1.1 gaps (100 aa)⁻¹].⁴⁹⁷ Their native structures are also homologous and superposable and indistinguishable at low resolution. In the $\alpha\beta$ heterodimer, they sit one on top of the other, each

pointed in the same direction.^{498–500} This $\alpha\beta$ heterodimer is **tubulin**, the monomer from which a microtubule is formed by its polymerization. The $\alpha\beta$ heterodimer of tubulin in free solution will be referred to as **monomeric tubulin**; $\alpha\beta$ heterodimers of tubulin within a microtubule will be referred to as **protomeric tubulin**.

Upon the microtubule there is a **helical surface lattice**.⁴⁹¹ This lattice was originally defined by image reconstruction of electron micrographic images of intact microtubules formed from 13 rows (Figure 13–24A).^{491,492} The reciprocal lattice of the Fourier transform of digitized images from electron micrographs was assigned to

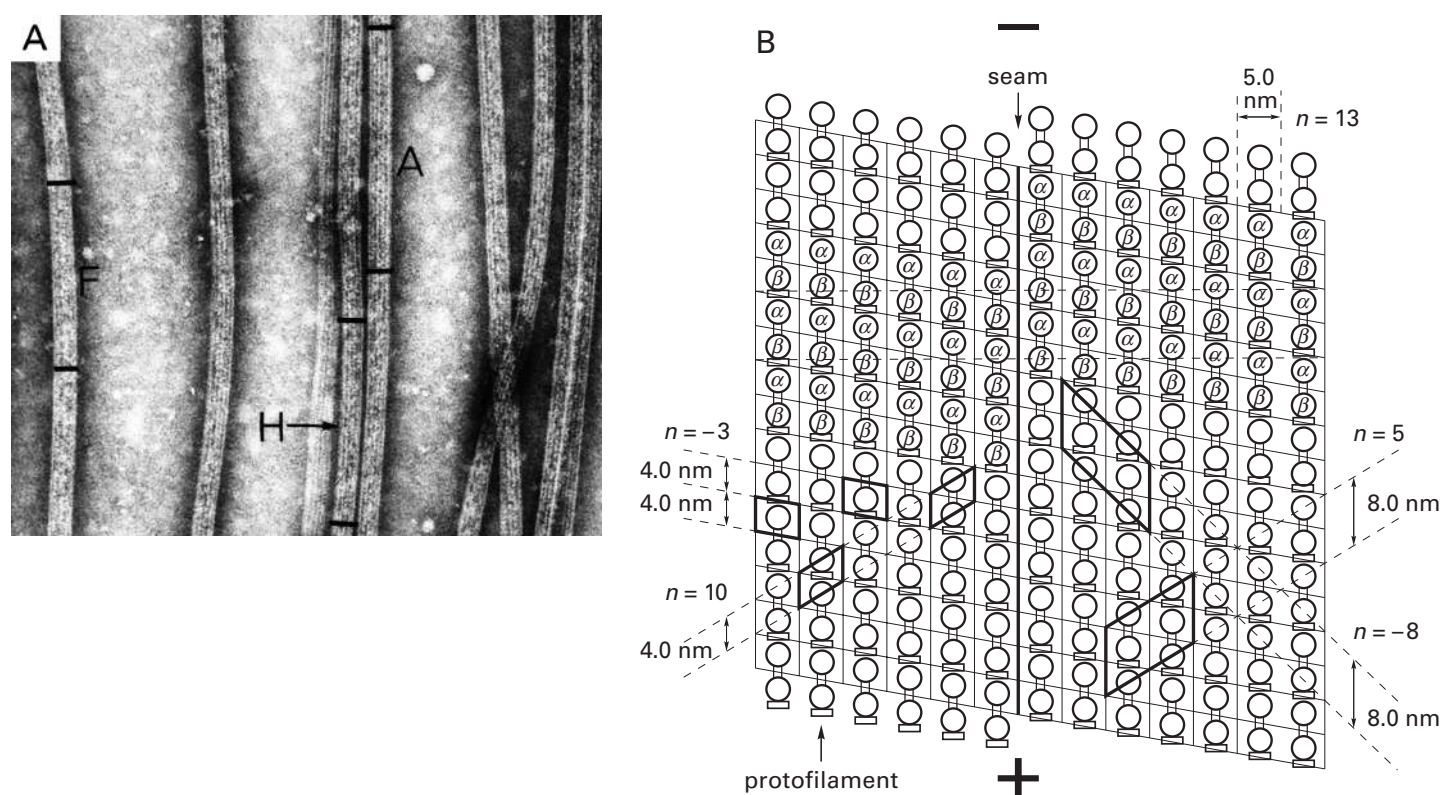

Figure 13–24: Helical surface lattice of $\alpha\beta$ heterodimers of tubulin producing a microtubule.⁴⁹¹ *Trichonympha agilis*, flagellated protists from the gut of the termite *Zootermopsis angusticollis*, were mixed with 1% phosphotungstate, pH 7, and applied to a film of amorphous carbon supported by a network of collodion. The excess negative stain was drained, the preparation was dried, and the negatively stained specimens were examined in the electron microscope. (A) Although the flagella of the *Trichonympha*, over most of their length, are composed of pairs of microtubules in which two microtubules are fused to each other, at the distal end of a flagellum these pairs dwindle to single microtubules. The electron micrograph is of a group of these individual, unpaired microtubules. Regions marked F, H, and A were chosen for image enhancement. The optical density of each of these images was digitized with an optical densitometer, and the Fourier transform of the digitized image was calculated. From examination of this calculated Fourier transform and from optical diffraction patterns of the images themselves, the reflections arising from the helical array of protomers were identified and indexed. These reflections defined the helical lattice in which the $\alpha\beta$ heterodimers of tubulin are arrayed in a microtubule. (B) A schematic diagram of that lattice is presented. The $\alpha\beta$ dimers of tubulin are aligned in 13 protofilaments parallel to the axis of the cylinder (see panel A). The cylinder on which the lattice is arrayed was cut along one of the lattice lines between two protofilaments on the side of the microtubule opposite to the seam and parallel to its axis, and the cylindrical surface was flattened onto the page. Individual subunits, if no distinction is made between α and β , lie on a triply threaded, left-handed screw ($n = -3$) and a decuply threaded, right-handed screw ($n = 10$). The two different unit cells arrayed along the resulting helices, respectively, are indicated by parallelograms. $\alpha\beta$ Heterodimers lie on a pentuply threaded right-handed screw ($n = 5$) and an octuply threaded left-handed screw ($n = -8$). Each unit cell along each of the resulting helices is identical and contains the equivalent of two $\alpha\beta$ heterodimers. The dimensions of each of these helices and of the parallel protofilaments are noted in nanometers. The horizontal dashed lines indicate the points of fusion for the flattened array when it is rolled into the cylinder. The heterodimers are in register in the adjacent protofilaments except at the seam. The locations of the binding sites for GTP on the β subunits are indicated by rectangles. The sites for the nonexchangeable GTP on the α subunits sit between the two subunits in the heterodimer. The end of the microtubule displaying only β subunits is the plus end; that displaying only α subunits is the minus end. Reprinted with permission from ref 491. Copyright 1974 Biochemical Society.

that of the Fourier transform of a triply threaded, left-handed ($n = -3$) screw the three helices of which are spaced at 4.0-nm intervals along the axis (Figure 13–24B). Because the array is built upon the 13 parallel protofilaments, the three left-handed helices ($n = -3$) of subunits with spacing of 4.0 nm create 10 right-handed helices ($n = 10$) with spacing of 4.0 nm, and together these sets of helices form a $(-3,10)$ lattice. These sets of three and ten parallel, contiguous helices are helices of unit cells each of which contains the equivalent of one individual subunit, where α subunits are indistinguishable from β subunits, but because α subunits and β subunits actually are different from each other, there are two different but indistinguishable unit cells arrayed translationally along each of these sets of helices. A set of $(8.0 \text{ nm})^{-1}$ reflections also appears in the Fourier transform of the images, and these reflections result from an octuply threaded, left-handed ($n = -8$) screw and the resulting pentuply threaded screw ($n = 5$) with spacing of 8.0 nm between the threads, a $(-8,5)$ lattice. In these sets of eight and five, the helices are helices of identical, translationally arrayed unit cells, each containing the equivalent of two $\alpha\beta$ heterodimers.

Because an α subunit is different from a β subunit and because they sit one on top of the other in the $\alpha\beta$ heterodimer, the two ends of a microtubule are different, and a microtubule is **polar**. This has been verified by the observation that growth at one end of a microtubule during assembly is slower than growth at the other end.⁵⁰¹ In the arrangement depicted in Figure 13–24B, one end would display only α subunits; and the other end, only β subunits.

The most peculiar structural feature of an extant microtubule, which was not a feature of the primordial microtubule, is its **seam** (Figure 13–24B). In all microtubules except those with 10 and 16 protofilaments, the protofilaments are in register, α subunit next to α subunit and β subunit next to β subunit, except at one junction, at which they are out of register. This junction is a seam of discontinuity that runs parallel or almost parallel to the axis of the microtubule along its surface.^{502–504} At the seam, there is a discontinuity in the $(-8,5)$ lattice of $\alpha\beta$ heterodimers but not in the $(-3,10)$ lattice of indistinguishable subunits.

When a solution of purified monomeric tubulin is brought to the proper conditions of temperature and pH and is mixed with the proper substrates, the tubulin spontaneously polymerizes to form microtubules. The process can be divided into two phases, nucleation and elongation.⁵⁰⁵ **Nucleation** is the sequence of events that leads to the formation of a large enough oligomer of tubulin to act as an origin from which a microtubule can then elongate by the consecutive, repetitive addition of more tubulin. **Elongation** is the addition of tubulin to one end or the other of a microtubule in such a way that each successive addition at that end is formally equivalent regardless of the length of the microtubule. Until

such a stage is reached, the steps in the assembly of a microtubule are steps in the process of nucleation.

Under all experimental conditions, **spontaneous nucleation** of microtubules in an originally monodisperse solution of tubulin is a complicated process that involves a number of intermediates of peculiar structure.^{506,507} It also depends on the twelfth power of the concentration of tubulin.⁵⁰⁸ This is not surprising because the steps between monodisperse tubulin in free solution and an oligomer of tubulin large enough to offer the end of a cylinder of 10–16 rows equivalent to the end of the cylinder in an established microtubule are not easy to accomplish. Furthermore, even though it occurs with even the most highly purified preparations of tubulin,⁵⁰⁸ spontaneous nucleation seems to involve a minor component contaminating the preparation of purified tubulin.⁵⁰⁹ At concentrations of tubulin high enough to support spontaneous nucleation, it proceeds slowly and continuously, independent of any decreases in the concentration of free tubulin caused by its incorporation into elongating microtubules. All of these properties make it difficult to separate cleanly the kinetics of spontaneous nucleation from those of elongation.

These complexities of spontaneous nucleation in the laboratory, however, may be irrelevant to the polymerization of tubulin within a cell, the process for which the protein has evolved. In a living cell almost all of the microtubules originate in only one region of the cytoplasm.⁵¹⁰ In cells containing centrosomes, it is the pericentriolar material that serves as the origin. The pericentriolar material is a diffuse structure surrounding the centriole that lies in the center of the **centrosome**. In cells lacking centrosomes, the point of origin is associated with structures resembling centrosomes. Within the pericentriolar material, it is rings of a different isoform of tubulin, γ tubulin, that serve as the nuclei upon which $\alpha\beta$ tubulin polymerizes.⁵¹¹ The rings of γ tubulin embedded in purified centrosomes are able to initiate the formation of microtubules readily⁵¹² and do so at lower concentrations of free tubulin than are necessary for spontaneous nucleation.^{509,510} From these observations, it becomes clear that spontaneous nucleation in the absence of centrosomes is an adventitious process for which $\alpha\beta$ tubulin was probably not designed.

Elongation of microtubules in the absence of the complications of spontaneous nucleation can also be accomplished by adding **seeds**, which are short, uniform fragments of preformed microtubules, to solutions containing high enough concentrations of unpolymerized monomeric tubulin to support the elongation of those seeds.⁵⁰⁵ Seeds have already passed through the steps of spontaneous nucleation. The fragments of preformed microtubules used as seeds can be stabilized by cross-linking with ethylene glycol bis(succinimidylsuccinate)⁵¹³ or by preparing the seeds with guanylyl 5'-(β , γ -methylenediphosphonate). Solutions of tubulin of high purity are reasonably unsusceptible to sponta-

neous initiation⁵¹⁰ but readily support the elongation of seeds in a reaction that assumes its maximum rate immediately after the seeds are added to the solution.

Consider a polymerization in which monomers, such as monomeric tubulin, are successively adding to only one end of a polymer, such as a microtubule elongating at only one of its ends from a centrosome, by the reaction

where polymer_n is a polymer composed of n protomeric units and polymer_{n+1} is a polymer composed of $(n + 1)$ protomeric units. When the reaction has come to equilibrium, the dissociation constant, $K_{dn,\text{poly}}$, of a monomer from the end of a polymer $n + 1$ units in length is

$$K_{dn,\text{poly}} = \frac{[\text{polymer}_n]_{\text{eq}} [\text{monomer}]_{\text{eq}}}{[\text{polymer}_{n+1}]_{\text{eq}}} = \frac{k_{-n}}{k_n} \quad (13-47)$$

When all values of n are large enough so that only elongation is being considered, $K_{dn,\text{poly}}$, k_n , and k_{-n} , respectively, have the same mean values for all values of n . The ends of all the polymers are indistinguishable because each is elongating from the same one of its two ends. In the case of microtubules elongating from a centrosome, the other end is not elongating because it is anchored in the centrosome.

Two measures of the solution of a polymer can be separately defined. The **bulk concentration** of polymer, $[\text{polymer}]_b$, or bulk concentration of microtubules, $[\text{microtubule}]_b$, is equal to the molar concentration of protomers, or of protomeric tubulin, that are incorporated into polymers. The bulk concentration is directly proportional to the total length of polymer in the solution. In the case of microtubules the bulk concentration is usually determined by light scattering, which is linearly related to the total length of microtubule present. Normally, a significant fraction of the light is scattered by these solutions, and the absorbance, which is decreased by the amount of light scattered, is measured rather than the amplitude of the scattered light. The **number concentration** of polymer, $[\text{polymer}]_n$, or number concentration of microtubules, $[\text{microtubule}]_n$, is equal to the molar concentration of individual, intact molecules of polymer, or microtubules, regardless of their individual lengths. The number concentration of microtubules is measured by quantitative electron microscopy.⁵¹⁴ Individual microtubules in a field on an electron micrograph are counted, and their density is related to their density in the original solution. The number concentration of a polymer elongating at only one end is equal to the molar concentration of that end, $[\text{end}]$.

Assume still that elongation is occurring at only one end of a polymer and that

$$\frac{d[\text{polymer}]_b}{dt} = k_n [\text{end}] [\text{monomer}] - k_{-n} [\text{end}] \quad (13-48)$$

If the reaction has been initiated by adding origins of nucleation, such as centrosomes, to a solution of monomer, and if no spontaneous nucleation occurs, the molar concentration of ends at which elongation is proceeding must remain constant, and the initial rate for the formation of bulk polymer is defined by the relationship

$$\left(\frac{d[\text{polymer}]_b}{dt} \right)_0 = [\text{end}]_0 (k_n [\text{monomer}]_0 - k_{-n}) \quad (13-49)$$

where the subscripts indicate initial quantities. It has been shown, in agreement with this equation, that the initial rate at which the bulk concentration of microtubules increases is **directly proportional to the molar concentration of seeds** added to a series of reactions (Figure 13-25).⁵⁰⁵

The initial rate of formation of bulk polymer at only one end should also be directly proportional to the term $(k_n [\text{monomer}]_0 - k_{-n})$, and a plot of initial rate against initial concentration of monomer should be linear and pass through zero when $k_n [\text{monomer}]_0 = k_{-n}$. Immediately after addition of seeds, if the seeds were simply fragments of polymer equivalent to the polymer about to be formed by elongation, the bulk concentration of polymer $[\text{polymer}]_b$ should increase when $k_n [\text{monomer}]_0 > k_{-n}$ and decrease when $k_n [\text{monomer}]_0 < k_{-n}$. When the bulk concentration of polymer is decreasing rather than increasing, the individual molecules of the polymer forming the seeds would be depolymerizing by shedding monomer from their ends and decreasing in length. The **critical concentration** is the initial concentration of monomer at which neither net elongation nor net depolymerization occurs. If only one molecule of polymer were being observed, its initial rate of elongation (in monomers second⁻¹) at only one of its ends should be equal to $(k_n [\text{monomer}]_0 - k_{-n})$. When $k_n [\text{monomer}]_0 > k_{-n}$, that molecule of polymer should elongate; and when $k_n [\text{monomer}]_0 < k_{-n}$, it should depolymerize.

If monomer adds to a population of elongating polymers until the concentration of monomer free in solution and the concentration of monomer within polymers reach equilibrium with each other, the total bulk concentration of polymer will be linearly related to the total concentration of monomer, and the line relating these two variables will intersect the abscissa at the value of the critical concentration (Figure 13-26).⁵¹⁵ This behavior necessarily follows from the facts that the amount of monomer incorporated into polymer when equilibrium is reached is equal to $[\text{monomer}]_{\text{tot}} - [\text{monomer}]_{\text{eq}}$; that $[\text{monomer}]_{\text{eq}}$, the critical concentra-

Figure 13-25: Initial rate of tubulin polymerization as a function of the initial concentration of fragmented whole microtubules.⁵⁰⁵ A preparation of microtubules ($70 \mu\text{M}$) that had been polymerized separately by spontaneous nucleation was sheared by passing it through a 22-gauge needle to produce fragments about $1 \mu\text{m}$ in length referred to as seeds. The seeds were immediately added to a solution of unpolymerized monomeric tubulin at a concentration high enough ($18 \mu\text{M}$) to elongate the seeds. The solution was 0.1 mM MgCl_2 and 0.5 mM GTP , pH 6.9. The elongation of the fragments was followed by an increase in absorbance at 320 nm due to light scattering. The initial rate of increase in absorbance ($A_{320} \text{ second}^{-1}$) is plotted against the initial number concentration (nanomolar) of sheared microtubules added to initiate elongation. Note that the initial molar concentration of monomeric tubulin is always more than 2000 times that of the seeds. Adapted with permission from ref 505. Copyright 1977 Academic Press.

tion, is the same for each point; and that when $[\text{monomer}]_{\text{eq}}$ equals the critical concentration, no increase in $[\text{polymer}]_{\text{b}}$ can occur.

Seeds were added to a series of solutions containing increasing concentrations of unpolymerized, monodisperse monomeric tubulin at concentrations below those at which significant spontaneous nucleation occurs.⁵⁰⁹ At various times after the addition, samples were taken from each mixture. They were quenched by quantitative cross-linking with glutaraldehyde, sedimented onto a specimen grid, and examined in the electron microscope.⁵¹⁴ The seeds that were used were fragments of **axonemes**, which are naturally occurring, rigid bundles of microtubules the polarity of which can be determined visually. The two ends of a fragment of an axoneme are arbitrarily termed the **plus end** and the **minus end**. The

Figure 13-26: Demonstration of the critical concentration for the polymerization of the monomer of cell division protein FtsZ from *E. coli*,⁵¹⁵ a bacterial homologue of tubulin.^{589–591} Solutions containing the noted total concentrations of cell division protein FtsZ, which had been stripped of all nucleotides, were prepared in 50 mM KCl and 10 mM MgCl_2 , pH 6.5 at 55°C . After equilibrium was reached, polymer was collected by centrifugation, and its bulk concentration was determined by direct analysis of the amount of protein in the pellet. The bulk concentration (micromolar) of sedimentable polymer ($[\text{polymerized FtsZ}]_{\text{bulk}}$) is presented as a function of the total concentration (micromolar) of monomer in the solution ($[\text{FtsZ}]_{\text{tot}}$). The observed critical concentration is $3.4 \mu\text{M}$.

plus end and minus end were originally defined in terms of the appearance of an axoneme in an electron micrograph. It is now known that the end of a microtubule at the plus end of an axoneme displays only β subunits^{516,517} and the end at the minus end displays only α subunits (Figure 13-24B).⁵¹⁸ Elongation was found to proceed from both ends of the axonemes. The initial rate of increase in the length of the microtubules projecting from each end of the axoneme could be measured and plotted against the initial concentration of tubulin (Figure 13-27).⁵¹⁴ The initial rate of elongation is linearly related to the initial concentration of monomeric tubulin, $[\text{monomer}]_0$, as predicted by Equation 13-49, but k_{-n} is too small to be estimated accurately.*

When elongation occurs because seeds are added to a solution of monomer above the critical concentration, the free concentration of monomer should decrease as polymer is formed until equilibrium is reached and further elongation ceases. If elongation were occurring from only one end of the polymer, from Equation 13-48 it follows that

* At rates of elongation around $10 \mu\text{m min}^{-1}$, a rate beyond those observed in Figure 13-26, there is a change in the rate-limiting step of elongation, and the rate becomes independent of the concentration of monomeric tubulin,⁵⁰⁹ presumably because it is limited by the rate of some step that must occur between the addition of the last monomer of tubulin and the addition of the next monomer of tubulin to the growing end.

$$\frac{d[\text{polymer}]_b}{dt} = - \frac{d[\text{monomer}]}{dt} = [\text{end}] (k_n [\text{monomer}] - k_{-n}) \quad (13-50)$$

When this relationship is rearranged and integrated between $t = 0$ and t

$$\ln(k_n [\text{monomer}] - k_{-n}) = \ln(k_n [\text{monomer}]_0 - k_{-n}) - k_n [\text{end}] t \quad (13-51)$$

when $t = \infty$ and $[\text{monomer}] = [\text{monomer}]_{\text{eq}}$, $k_n [\text{monomer}]_{\text{eq}} = k_{-n}$. Therefore, the concentration of monomer at equilibrium should be equal to the critical concentration at which no elongation occurs when seeds are added to a solution of monomer.

But a microtubule has two ends, and both are elongating in the experiment. Consider any linear polymer such as a microtubule in which an arrangement of protomers, such as the 13 protomers of tubulin across the microtubule that are labeled α and β in Figure 13-24B, repeats precisely along the polymer to create its structure. Remove a complete set of these protomers, for example the 13 protomers of tubulin at the minus end, from one end of the polymer, and add them to the other end in such a way that the newly added protomers duplicate the arrangement that was at that end before. For example, add one of these monomers of tubulin to each of the 13 protofilaments at the plus end. The structure of the altered polymer is identical to that of the initial polymer because of the linear repeat with which it is created. Because free energy is a state function, the standard free energy change for this reaction must be zero. Because this is true for whatever structure is present at the two ends initially, the mean value for the dissociation constants, $K_{d,\text{tbn}}$, for tubulin at either end of a microtubule must be the same. Because $K_{d,\text{tbn}} = k_{-n}/k_n = [\text{tubulin}]_{\text{eq}}$ (Equation 13-47), the concentration of monomeric tubulin in equilibrium with either end, the critical concentration, is the same. If only mass action were governing the reaction, a microtubule on average could not elongate preferentially at one end while it is depolymerizing at the other. The two ends, however, can, and do, have different rate constants of elongation (Figure 13-27) and depolymerization.

One of the ingredients that is essential for the elongation of microtubules is **GTP**.⁵¹⁹ Either GTP or GDP is bound by monomeric tubulin at one site on each of the two homologous subunits in the $\alpha\beta$ heterodimer.^{498,520} In monomeric tubulin, the site for binding GTP on the surface of the α subunit is enclosed within the interface of the $\alpha\beta$ heterodimer. Consequently, because of the screw axis

Figure 13-27: Rate of elongation (upper quadrant; \square , \blacksquare , \circ , \bullet ; micrometers minute⁻¹) and rate of depolymerization (lower quadrant; \bullet , \circ ; -micrometers minute⁻¹) of microtubules from the plus end (\bullet , \blacksquare) and the minus end (\circ , \square) of fragments of axonemes.⁵¹⁴ Fragments of axonemes from *Tetrahymena pyriformis* were added to final number concentrations of 10^7 mL^{-1} to solutions of monomeric tubulin at the noted concentrations (micromolar). Each of these solutions was 1 mM MgCl_2 , 1 mM EDTA, and 1 mM GTP, pH 6.8. At a series of time points, samples were withdrawn from these solutions and rapidly fixed with glutaraldehyde, and the products were sedimented onto electron microscopic grids or glass coverslips. The elongated axonemes were examined, following negative staining, in the electron microscope or, following staining with fluorescent anti-tubulin immunoglobulin G, in a fluorescence microscope (inset). The boundary between the original axoneme (white bar in inset) and the newly elongated microtubules was clearly defined because the newly elongated tubules splayed from the rigid cylinder of the bundle of microtubules making up the axoneme. Rates of elongation were calculated from direct measurements of the length (micrometers) of the newly elongated microtubules elongating from the ends of the axonemes as a function of time (minutes). The circles (\circ , \bullet) in the upper quadrant of the graph are measurements made by electron microscopy, and the squares (\square , \blacksquare) are measurements made by immunofluorescence. At concentrations of monomeric tubulin greater than $3 \mu\text{M}$, microtubules would elongate from axonemes, and the rate of elongation was linearly related to the concentration of initial unpolymerized monomeric tubulin. At initial concentrations of monomeric tubulin below $3 \mu\text{M}$, no elongation would occur. If microtubules, however, were grown on axonemes to $20 \mu\text{m}$ on the plus end and $7.5 \mu\text{m}$ on the minus end at a high monomeric tubulin concentration and the concentration of monomeric tubulin was then dropped to one of the noted concentrations less than $3 \mu\text{M}$, the microtubules would begin to depolymerize at the noted rates (circles with minus values of rates in the lower quadrant of the graph), which were independent of the concentration of unpolymerized tubulin. Reprinted with permission from *Nature*, ref 514. Copyright 1984 Macmillan Magazines Limited.

of pseudosymmetry, the site for binding GTP on the surface of the β subunit is on the opposite side of the β subunit from that interface, but at a position (indicated by the rectangles in Figure 13-24B) that becomes enclosed within the interface that is formed in a protofilament when a β subunit enters the elongating tubule at the minus end. At the positive end of a microtubule, each β subunit has a site for binding GTP that is displayed at its open end and

that is enclosed in the interface formed when monomeric tubulin associates with it during elongation at that end. A molecule of GTP bound to the α subunit of monomeric tubulin, which is within the interface that is stable and does not dissociate, remains unhydrolyzed, does not exchange with GTP in solution, and is an inert feature of the protein.^{520–522} It is the descendant of the GTP molecule that was at a dissociable interface in the primordial microtubule but now serves only a structural role uninvolved in the dynamics of elongation and depolymerization of an extant microtubule. Consequently, only the GTP or GDP and inorganic phosphate bound to the site on the β subunit is relevant to the roles of tubulin in the dynamic behavior of a microtubule.

At the open site on the β subunit in monomeric tubulin, the bound GTP exchanges readily with GTP or GDP in the solution, and molecules of bound GTP are **slowly hydrolyzed** to GDP and inorganic phosphate at that site but only after the incorporation of this site into a microtubule coincident with the addition of the monomeric GTP-tubulin to an elongating microtubule.⁵²² At 37 °C, the rate of this hydrolysis within a microtubule is 0.06 s^{-1} , and the rate for release of the inorganic phosphate into the solution is 0.02 s^{-1} .⁵²³ The molecules of GDP that are formed by this hydrolysis, however, remain trapped at the site while the protomeric GDP-tubulin is within the microtubule.^{522,524} This peculiar feature of elongation causes an elongating microtubule to have a region at its end in which all the tubulin has GTP bound to it because it has recently been added. Beyond this **cap of protomeric GTP-tubulin**, however, the frequency of protomeric GDP-tubulin increases until the main body of the microtubule is reached, which is entirely formed from protomeric GDP-tubulin. In the cytoplasm of a cell, in which the concentration of GTP is much greater than that of GDP, when a protomer of GDP-tubulin leaves a microtubule, the GDP rapidly dissociates from it and is replaced by GTP from the solution.

Although there is one measurement⁵²⁵ giving a critical concentration for GDP-tubulin of $3\text{ }\mu\text{M}$, which is contradicted by measurements from a similar preparation of tubulin⁵²⁶ giving a critical concentration of greater than $30\text{ }\mu\text{M}$, it is generally believed that “the critical concentration for assembly of Tu-GDP is apparently very high, effectively infinite for practical purposes.”⁵²⁷ The critical concentration for (GTP)-tubulin, however, is immeasurably small. This conclusion follows from the fact that the intercepts with the horizontal axis in Figure 13–27 are indistinguishable from zero and the fact that the measured critical concentration for tubulin to which guanylyl 5'-(β , γ -methylenediphosphonate) has been bound, which is an analogue of GTP that is very slowly hydrolyzed, is less than $0.2\text{ }\mu\text{M}$.⁵²⁸ Unfortunately, although the difference in critical concentrations between GDP-tubulin and GTP-tubulin is probably large, no direct measurement of that difference is available.

The **rate constants for elongation** of a microtubule

can be distinguished separately by the following convention. Those for elongation at the positive end can be identified with a plus sign (+); those for elongation at the negative end, with a minus sign (–); those for GTP-tubulin, with the letter T; and those for GDP-tubulin, with the letter D. From the results in Figure 13–27, $k_{n,T+} = 3.8 \times 10^6\text{ M}^{-1}\text{ s}^{-1}$ and $k_{n,T-} = 1.2 \times 10^6\text{ M}^{-1}\text{ s}^{-1}$ at 37 °C. Both $k_{n,T+}$ and $k_{n,T-}$ are too small ($\leq 1\text{ s}^{-1}$) to be measured accurately.⁵¹⁴ Under most circumstances in which elongation occurs in the presence of GTP ($[\text{monomer}] \geq 4\text{ }\mu\text{M}$), it is governed by $k_{n,T+}$ and $k_{n,T-}$. Even though the dissociation constants for GTP-tubulin to both ends of the microtubule must be the same, the rate constants for association and dissociation are not the same because the microtubule is a polar structure. It happens that a microtubule elongates about 3-fold more rapidly from its plus end than from its minus end.

When microtubules depolymerize, for example, upon dilution, the cap of protomeric GTP-tubulin near the end that was formed from recently added monomeric GTP-tubulin is rapidly lost, and depolymerization then proceeds by the dissociation of monomers of GDP-tubulin. If the dilution has been great enough, ends cannot be recapped and only $k_{n,D+}$ and $k_{n,D-}$ govern the rates of depolymerization. The values for these observed **rate constants for depolymerization** upon dilution (Figure 13–27),⁵¹⁴ under the same conditions in which $k_{n,T+}$ and $k_{n,T-}$ were measured, are $k_{n,D+} = 340\text{ s}^{-1}$ and $k_{n,D-} = 210\text{ s}^{-1}$ at 37 °C.

This arrangement of reactions—elongation by GTP-tubulin, hydrolysis of the GTP within the microtubule, and the consequent dissociation of mainly GDP-tubulin upon depolymerization—creates a peculiar **steady state** when the concentration of bulk polymer has reached its maximum level. At all times and at random, regions of protomeric GDP-tubulin are overtaking the now slowly elongating ends of individual microtubules and switching those microtubules from ones that are elongating to ones that are catastrophically depolymerizing (Figure 13–28).⁵¹⁴ The monomeric tubulin released during depolymerization picks up new molecules of GTP and reenters a microtubule that happens by chance still to be outdistancing its protomeric GDP-tubulin.

If the concentration of monomeric GTP-tubulin is less than a certain **apparent critical concentration**, the boundary of protomeric GDP-tubulin, whose rate of propagation is independent of the concentration of monomeric GTP-tubulin, will move along the microtubule faster than the rate of its elongation, which is dependent on the concentration of monomeric GTP-tubulin, and the microtubules will be switched (Figure 13–28) and begin to depolymerize with the rate constants $k_{n,D+}$ and $k_{n,D-}$. At concentrations of tubulin in excess of this apparent critical concentration, elongation will be faster than the rate at which the boundary of protomeric GDP-tubulin can move, and the microtubules will elongate with rate constants $k_{n,T+}$ and $k_{n,T-}$ as if they

Figure 13-28: Schematic model describing the role of GTP in the elongation of microtubules.⁵¹⁴ The dark circles represent protomers of tubulin to which GTP is bound, and the open circles represent protomers of tubulin on which the GTP has hydrolyzed to GDP. As long as the tubule is elongating at a significant rate, the end of the microtubule is occupied by protomeric GTP-tubulin, and the end has a low critical concentration (Figure 13-27). In this state, it will not depolymerize catastrophically, and this is the growing phase. If elongation slows down because the concentration of monomeric GTP-tubulin decreases, at a certain point the spreading boundary of GTP hydrolysis will reach the end of the microtubule. The end of the microtubule will then be occupied mostly by protomeric GDP-tubulin and the end will then have a much higher critical concentration. It has passed through a phase transition into the shrinking phase and will rapidly depolymerize. Reprinted with permission from *Nature*, ref 514. Copyright 1984 Macmillan Magazines Limited.

contained only GTP-tubulin. At the apparent critical concentration, the rate of depolymerization from uncapped ends will be equal in magnitude to the rate of elongation from capped ends. This apparent critical concentration is not the reflection of an equilibrium process, as is the actual critical concentration (Figure 13-26), but the result of a complex combination of rate constants producing a steady state, and it should not be confused with a real critical concentration. The steady state is maintained by the continuous hydrolysis of GTP, and as long as GTP is available, equilibrium cannot be reached. When all the GTP has been hydrolyzed, all of the microtubules disappear because the critical concentration for GDP-tubulin is so large.

At concentrations of 10 μM free monomeric tubulin, which is the apparent critical concentration of GTP-tubulin at steady state in the presence of excess concentrations of GTP⁵²⁵ rather than at equilibrium,⁵¹⁰ the rates of depolymerization from uncapped ends containing protomeric GDP-tubulin are at least 10-fold greater than the rates of elongation from ends capped with protomeric GTP-tubulin. As a result, a microtubule that is depolymerizing from an uncapped end will rapidly and catastrophically disappear even if it is elongating at its other end. **Catastrophic depolymerization** of microtubules following dilution proceeds as a zero-order reaction (Figures 13-27 and 13-29)^{505,514} because the rate of depolymerization is defined by the equation

Figure 13-29: Kinetics of the depolymerization of microtubules.⁵⁰⁵ Tubulin (35 μM) was polymerized at 30 $^{\circ}\text{C}$ in 0.1 mM MgCl_2 and 0.5 mM GTP at pH 6.9 to steady state (30 min). When the temperature of a solution of microtubules is dropped, the microtubules depolymerize. When the temperature of this solution was brought to 5 $^{\circ}\text{C}$, the depolymerization could be followed by the decrease in the absorbance at 320 nm. After a lag coinciding with the time necessary to lower the temperature, the depolymerization followed zero-order kinetics (dashed line) until the number of microtubules in the solution began to decrease. Adapted with permission from ref 505. Copyright 1977 Academic Press.

$$\frac{d[\text{polymer}]_b}{dt} = k_{-n,D^+} [+ \text{end}] + k_{-n,D^-} [- \text{end}] \quad (13-52)$$

As long as [end] remains constant, the reaction remains zero-order. As [end] begins to decrease, when more and more microtubules cease to exist, the rate of depolymerization decreases.⁵⁰⁵ From electron micrographs of samples removed at various times from a population of depolymerizing microtubules, the decrease in the observed rate constant of depolymerization at the longer times could be quantitatively correlated to the decrease in the number concentration of microtubules and hence the molar concentration of ends.⁵²⁹

There are a number of observations that support this description of the polymerization of tubulin. Microtubules assembled from tubulin to which guanylyl 5'-(β , γ -methylenediphosphonate), a nonhydrolyzable analogue of GTP, has been bound, rather than GTP itself, exhibit only elongation and no rapid catastrophic depoly-

merization.⁵³⁰ If the concentration of GTP in the solution is suddenly dropped so that GTP dissociates from the protomeric tubulin at the end of a microtubule, the rate at which ends switch to catastrophic depolymerization increases 50-fold. When microtubules are elongating in a mixture of GTP-tubulin and GDP-tubulin, and the concentration of GDP in the solution is increased 100-fold, so that the GTP bound to protomers at the ends of elongating tubules exchanges for GDP, the rate at which ends switch to catastrophic depolymerization increases 10-fold.⁵³¹ When a uniform population of microtubules elongating rapidly at high concentrations of monomeric GTP-tubulin is diluted to a concentration slightly below the apparent critical concentration, the bulk concentration of microtubules, $[\text{microtubule}]_b$, immediately begins to decrease. This decrease, however, is entirely due to a decrease in the number concentration of microtubules rather than the mean length of the remaining microtubules. The microtubules that remain are still slowly elongating.⁵¹⁴ Those that have disappeared have lost the race with the advancing boundary of protomeric GDP-tubulin at one of their ends. When microtubules grown from seeds reach a steady-state bulk concentration, this concentration is maintained by a decrease in the number of microtubules and an elongation of those that remain.⁵¹⁴ Those that are still in the race are staying ahead at the expense of the losers.

Colchicine and podophyllotoxin are inhibitors of tubulin elongation. They bind to free $\alpha\beta$ heterodimers of tubulin, which then have a higher affinity for an elongating end of a microtubule. Once a few of the toxin-tubulin complexes have entered an elongating end, however, it is no longer able either to elongate further or to depolymerize catastrophically when the wave of GDP-tubulin reaches it,^{532,533} because it is capped by those complexes of tubulin and colchicine or podophyllotoxin. When podophyllotoxin is added to microtubules grown to steady state from seeds, the bulk concentration of microtubule, $[\text{microtubule}]_b$, decreases in two phases. One phase has the rate constant ($k_{-n,D+} + k_{-n,D-}$) of normal depolymerization, and the other phase is much slower. The rapid phase is the depolymerization from the ends that lose the race with the boundary of GDP-tubulin and begin to depolymerize before they can be capped by complexes of tubulin and podophyllotoxin. The slow phase is the slow depolymerization of microtubules that have become capped at both ends by podophyllotoxin before either end can begin to depolymerize. If fresh tubulin is added with the podophyllotoxin, the magnitude of the rapid phase is decreased as expected.

The elongation of a microtubule is a **race** between addition of monomeric GTP-tubulin at the end and the spread of the boundary of protomeric GDP-tubulin along the body of the microtubule (Figure 13–28). The race is lost when the GDP-tubulin reaches an end that cannot outdistance it, and the penalty for losing is catastrophic depolymerization. The observed rate constant for

hydrolysis of GTP within an elongating microtubule is slow (0.06 s^{-1}), so there is little chance that it will switch from elongation to catastrophic depolymerization while it is elongating rapidly; and when it has reached a goal, the structure with which it associates at that goal caps its end.

The purpose of this elaborate device seems to be the elimination of microtubules that have failed to find a goal and the maintenance of the origin of the network of microtubules in the cell.⁵¹⁴ In a microtubule that has not been able to find a **goal** and have its elongating end capped in recognition of its success, the boundary of GDP-tubulin will eventually catch up and the uncapped microtubule that has failed in its search will catastrophically depolymerize. Also, when a microtubule breaks into two pieces for any reason, the break will almost always occur in the region where protomeric GDP-tubulin is located. The broken tubule will catastrophically depolymerize from its broken ends, and the fragment attached to the centrosome and the other fragment will disappear. This prevents broken pieces from initiating microtubules unattached to centrosomes. The centrosome has a finite capacity to initiate microtubules, but as sites become empty after the catastrophic depolymerizations of the failures, new microtubules, the elongating ends of which are again outracing their destruction and which are in their turn searching for success, are initiated at those empty sites. As the centrosome can initiate microtubules at concentrations lower than those at which they initiate spontaneously, almost all microtubules end up originating at the centrosome.

The schematic drawings of Figure 13–24B and Figure 13–28 are somewhat misleading. The actual structure of the elongating end is a **flattened sheet of protofilaments** that has not yet been rolled up and joined at the seam of its microtubule. The rolling up of the sheet and zipping of the microtubule along the seam lags behind the elongation of the protofilaments forming the unrolled, flattened sheet at the very end.⁵³⁴

The assembly of **actin** into **thin filaments** (Figure 9–1B) is similar to that of tubulin into microtubules. Thin filaments of actin are polar. As with a microtubule, a thin filament elongates at both ends, but it elongates at one end about 7 times more rapidly than at the other.^{535,536} The end that elongates more rapidly is the plus end or the barbed end of the thin filament when it is decorated with fragments of myosin. This end is the anchored end of a thin filament within the cell, toward which a thick filament of myosin usually slides.

The elongation of actin has all of the characteristic features of the elongation of tubulin, albeit with distinct rate constants, but the nucleotide that controls the polymerization is **ATP** rather than GTP.⁵³⁷ The ATP binds to the actin, the ATP-actin complex is incorporated into the thin filament, and the ATP is then hydrolyzed to ADP slowly enough that the **hydrolysis of the ATP** significantly **lags behind the elongation** of the filament.^{538,539} The elongation of actin filaments displays a critical concentration

for monomeric actin.^{540–542} The ADP·actin complex is unable to elongate actin filaments at concentrations at which ATP·actin can,⁵³⁷ because the critical concentration of ADP·actin is much higher than that of ATP·actin.^{538,540,541} Actin has been crystallized with ATP bound and with ADP bound, and the two crystallographic molecular models have significantly different conformations, an observation that explains their different critical concentrations.⁵⁴³ The rate of depolymerization of filaments of actin with ADP·actin at their ends is about 10-fold greater than the rate of depolymerization of filaments of actin with ATP·actin at their ends,^{540,541,544} so catastrophic depolymerization occurs upon exposure of an end uncapped by ATP·actin.

The **nucleation of the polymerization of actin filaments** in the cell is accomplished by particular proteins or complexes of proteins. One complex of proteins responsible for nucleation of actin filaments is the Arp213 complex, which contains seven different subunits, each present in a single copy, two of which are homologues of actin and may serve as the actual sites of nucleation.⁵⁴⁵ There are also a number of individual, monomeric proteins that are able to initiate the polymerization of actin, such as villin,^{542,546–548} fragmin,⁵⁴⁹ gelsolin,⁵⁵⁰ and F-actin capping protein.⁵⁵¹ They do so by forming complexes with two or three, one, two, or two or three molecules of actin, respectively, and it is these complexes that nucleate polymerization. Consequently, the nuclei required to initiate polymerization of actin are much simpler than those required to initiate polymerization of tubulin. Purified preparations of actin, like purified preparations of tubulin, can spontaneously nucleate polymerization when nucleotide is added, but at least one of the contaminating proteins responsible for this self-nucleation is a covalent dimer of actin produced adventitiously during the purification.⁵⁵²

Reversibly assembled helical polymers such as microtubules and filaments of actin interact with an elaborate set of stabilizing and destabilizing proteins that control, sculpt, and employ the basic polymers according to the needs of the cell. In humans, there are more than 15 **microtubule-associated proteins** that have been identified by their ability to copolymerize with tubulin. The kinetochores of chromosomes bind to the elongating ends of microtubules in such a way that the ends can still elongate and then depolymerize, in the process pushing and then pulling the kinetochores and their attached chromosomes away from and then toward the centrosome.⁵¹³ In this process, it is the significant, favorable free energy of elongation resulting from the fact that the concentration of monomeric GTP·tubulin is well above its critical concentration that provides the free energy to drag the kinetochore along with the elongating end away from the centrosome, and it is the much more favorable free energy of depolymerization resulting from the fact that the concentration of monomeric GDP·tubulin is even more distant from its critical concentration that provides the free

energy to pull the kinetochore even more vigorously toward the centrosome. Dynein is a protein that slides along the outer surfaces of microtubules toward the centrosome while hydrolyzing MgATP, carrying structures to which it in turn is attached in that direction.^{553–555} Kinesins slide along microtubules also while hydrolyzing MgATP.⁵⁵⁶

Thin filaments of actin are often sculpted to precisely regulated lengths and shapes for certain purposes. There are a number of proteins responsible for this function.^{557–561} For example, **F-actin capping protein** is a widely distributed $\alpha\beta$ heterodimer that binds to elongating barbed ends of actin filaments and stably caps them by preventing them from either elongating further or catastrophically depolymerizing.^{551,562–566} Its wide distribution suggests that it is the major capping protein in animal cells. F-Actin capping protein is located in the Z line of skeletal muscle,⁵⁶⁷ a structure in which are embedded the barbed plus ends of the actin filaments that are organized in regular arrays of precise length found in this tissue. The length of these actin filaments in skeletal muscle is defined by the length of a single molecule of the long fibrous protein nebulin,⁵⁶⁸ which acts as a **molecular ruler**^{569,570} that binds tightly along the length of the actin filaments.⁵⁷¹ It is the Z line upon which the actin filament pulls as the thick filament of myosin slides along it in that direction. Capped plus ends of actin filaments are also embedded in structures at the cellular membrane organized around the protein vinculin.^{572,573} The minus ends of the actin filaments in the regular arrays in cardiac muscle are capped by tropomodulin.⁵⁷⁴

Thick filaments of myosin are the oligomeric proteins that slide along thin filaments of actin and pull upon them while hydrolyzing MgATP. Thick filaments are helical polymeric proteins noncovalently assembled from a monomer known as myosin. Myosin is composed from two identical α polypeptides ($n_{aa} = 1940$) and several shorter polypeptides ($n_{aa} = 150–200$). The carboxy-terminal 1100 aa of the two α polypeptides are entwined around each other to form a two-stranded, **α -helical coiled coil** (Figure 6–29) 150 nm in length⁵⁷⁵ that has two globular, detachable domains known as heads, each of which is formed from the amino-terminal 800 aa of one of the α polypeptides, at one of its ends (Figure 13–30A).^{575–578} The shorter polypeptides are incorporated into these **globular heads**.

The individual coiled coils of the myosin molecules are segments of rope that are assembled into a helical cable from which the myosin heads protrude (Figure 13–30B).⁵⁷⁷ The segments of rope add to the elongating cable at each of its two ends with opposite orientation. In each direction along the cable, the molecules of myosin add so that the empty carboxy-terminal ends of their segments of rope point toward the middle of the cable and the amino-terminal ends of the segments of rope to which the myosin heads are attached point away from the middle (Figure 13–30C).⁵⁷⁹ The absence of myosin

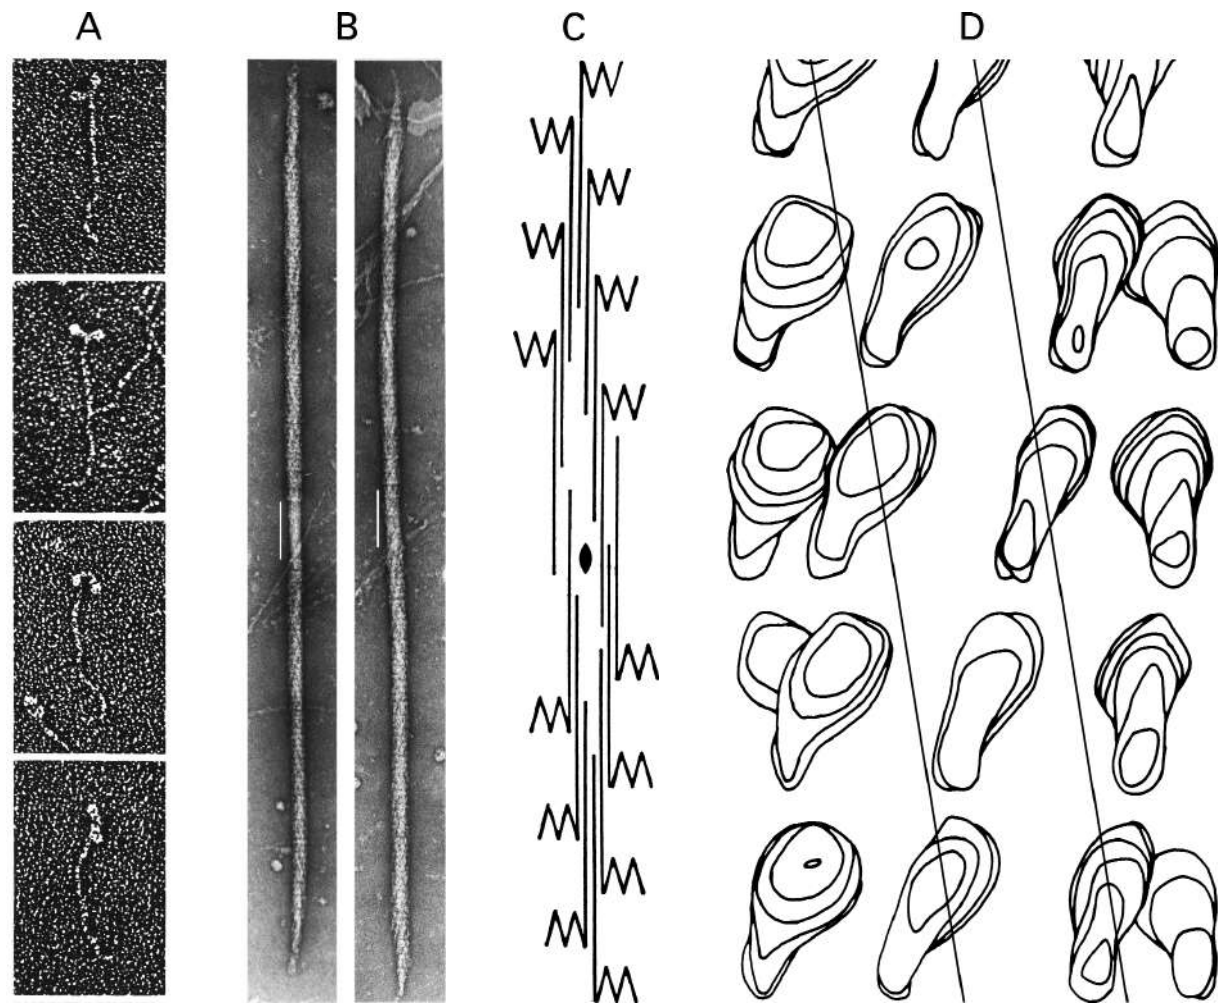

Figure 13-30: Structures of myosin and thick filaments. (A) Gallery of electron micrographs of myosin molecules.⁵⁷⁵ Myosin from thick filaments in rabbit skeletal muscle, which had been disassembled at high ionic strength (0.5 M KCl), was purified by precipitation at low ionic strength, ammonium sulfate precipitation, and anion-exchange chromatography. A solution of purified myosin at $50 \mu\text{g mL}^{-1}$ in 0.6 M ammonium formate was sprayed onto the surface of freshly cleaved mica, and the water and the volatile salt of ammonium formate were evaporated from the surface. The adsorbed molecules of myosin were coated with platinum as the mica was rotated in a beam of platinum vapor. The film of platinum was removed from the mica, transferred to a grid, and viewed in an electron microscope. Magnification 120000 \times . Reprinted with permission from ref 575. Copyright 1978 Academic Press. (B) Thick filaments from muscle of *Placopectin magellanicus*.⁵⁷⁷ Strips of muscle were chopped finely and homogenized in a solution containing MgATP to dissociate thick and thin filaments. A drop of this homogenate was placed on a carbon film and negatively stained with 3% uranyl acetate. Thick filaments were located in the specimen in the electron microscope and photographs were taken. The white bars indicate the bare zones on the thick filaments. Magnification 60000 \times . Adapted with permission from ref 577. Copyright 1983 Academic Press. (C) Diagrammatic representation of the way in which molecules of myosin are assembled to form a thick filament.⁵⁷⁸ Each continuous set of line segments is an individual molecule of myosin; the two globular heads (panel A) are represented by a W and the tail by a line. All of the tails point toward the center of the filament, and at the center the orientation reverses. Because the pairs of heads are directed distally, the bare zone (the smooth central portion of each of the thick filaments indicated by white bars in panel B) has no heads protruding from it. The structure assembled in this way has a 2-fold rotational axis of pseudosymmetry at its center. Reprinted with permission from ref 578. Copyright 1969 American Association for the Advancement of Science. (D) Helical surface lattice of globular myosin heads upon a thick filament.⁵⁷⁷ The optical density of electron micrographs, such as those in panel B, was digitized, and the Fourier transform of the digitized optical density was calculated. Discrete reflections arising from longitudinal spacings of 14.5 and 29.0 nm along the thick filament and helical spacings of 48.0 nm (panel B) were observed in the Fourier transform. Reflections on the reciprocal helical lattice in the Fourier transform were selected and used to calculate a three-dimensional distribution of electron scattering density. The image presented is of the front four helical strands of the seven-start right-handed helical lattice on one thick filament. This helical pattern produces the strong reflections of a 48.0 nm helical repeat. The globular heads are arranged in circular disks 14.5 nm in height and seven heads in circumference that are stacked helically to produce the lattice. The lines drawn in the figure indicate the probable orientation of two thin filaments of actin relative to the surface lattice of the thick filament myosin. Reprinted with permission from ref 577. Copyright 1983 Academic Press.

heads where the segments of rope pointing in opposite directions overlap in the middle of the cable creates a **bare zone** 150 nm in length.⁵⁷⁷ Because of this pattern of assembly, thick filaments (Figure 13–30B),⁵⁷⁷ unlike thin filaments, which have two distinct ends, have two ends that are identical but of opposite orientation. This necessarily produces a 2-fold rotational axis of pseudosymmetry normal to the axis of the thick filament in the center of the bare zone (Figure 13–30C).

Upon the surface of the thick filament distal to the bare zone, the myosin heads are arranged in a **helical surface lattice**, reflecting the underlying helical symmetry of the cable (Figure 13–30D). This helical surface lattice is right-handed and septuply threaded, and myosin heads protrude from each of the seven constituent helices at intervals that are vertically in register⁵⁷⁷ to create horizontal rings, or crowns, each spaced at 14.4-nm intervals.^{577,580} The seven globular protrusions⁵⁸¹ around each crown are each single myosin heads because each crown accounts for the total molecular mass of about 3.5 molecules of myosin.^{580,582} Because seven is an odd number, no two adjacent globular heads in the same crown can be from the same molecule of myosin. The pair of heads from the same molecule of myosin must be consecutive to each other within the same helix. Therefore, along each of the seven threads of the helical lattice, the heads must alternate in the pattern lower head of myosin i , upper head of myosin i , lower head of myosin $i+1$, upper head of myosin $i+1$, and so forth. If upper heads are in register across the seven helices and lower heads are in register, crowns of lower heads and crowns of upper heads would alternate along the thick filament. Such an alternating pattern has been observed.⁵⁷⁷

Thick filaments of myosin assemble spontaneously from monomers of myosin⁵⁷⁹ but do not become helical polymeric proteins of indefinite length such as fibrin, tubulin, or actin. Their **final length** is between 1000 and 3000 nm when they are polymerized under experimental situations⁵⁸³ or between 1600 and 2000 nm when they are polymerized within a contractile tissue such as skeletal muscle (Figure 13–30B).^{577,584}

Myosin from *Acanthamoeba castellanii* spontaneously assembles into minifilaments that are bipolar thick filaments composed of only eight myosin monomers. During the assembly of these minifilaments, monomers first form antiparallel dimers, antiparallel dimers form antiparallel tetramers, and tetramers then form octamers.⁵⁸⁵ The formation of such an antiparallel dimer may also be the initial step in the formation of the larger types of thick filaments.^{586,587}

When monomeric actin is induced to polymerize in the presence of thick filaments of myosin, thin filaments of actin form around each thick filament of myosin.⁵⁸³ The thin filaments are positioned around the thick filaments at seven evenly spaced intervals. Presumably, the assembly of this 7-fold array is dictated by the underlying seven helices of the myosin heads. The pitch of the seven

thin filaments of this actin, however, is much steeper than that of the seven primary helices on the surface of the thick filament, the assembled thin filaments of actin are almost parallel to the axis of the thick filament, and the pitch of the septuply threaded helical array of actin filaments is left-handed instead of right-handed. This alignment could be explained if the thin filaments of actin were in contact only with every other crown or every fourth crown along the thick filament and stepped up one helix for each contact (Figure 13–30D).

The measured rise for each subunit in a thin filament of actin is 2.8 nm and the measured rotation for each subunit is 166°. For a thin filament to span two crowns and step up one helix (Figure 13–30D) would require 29.7 nm, the distance covered by 11 subunits of actin if the rise for each subunit in a thin filament were actually 2.7 nm rather than 2.8 nm. The eleventh protomer further along a thin filament would be pointed in exactly the same direction toward the thick filament as a subunit of actin already attached to a myosin head in that thick filament if the rotation for each subunit of actin in a thin filament were 164° instead of 166°. A similarly successful but not so remarkable fit of the dimensions can be made if the thin filament of actin makes contact only with every fourth crown and steps up one helix. The **coincidences between the dimensions of the thin filament and the thick filament** are reminders that the more primordial of the two served as the template for the evolution of the other.

With the assembly of helical polymeric proteins such as microtubules, thick filaments of myosin, and sculpted thin filaments of actin and the assembly of oligomeric proteins such as ribosomes, protein chemistry enters the microscopic realm and becomes cell biology. Another set of striking microscopic cellular features that are of importance in cell biology are membranes.

Problem 13–8: Make a xerographic copy of Figure 13–24B. Cut out the surface lattice and roll the paper into a cylinder. Follow the various helices over the cylinder and identify how many individual strands each of them has.

Problem 13–9: The observed rate constants for microtubule assembly listed in this table were obtained from the data in Figure 13–27.

rate constant	value	rate constant	value
$k_{n,T+}$	$3.8 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$	$k_{-n,T+}$	0.4 s^{-1}
$k_{n,T-}$	$1.2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$	$k_{-n,T-}$	1.1 s^{-1}
$k_{-n,D+}$	340 s^{-1}	$k_{-n,D-}$	210 s^{-1}

- (A) Describe which rate constant was derived from which aspect of this figure. Which rate constants are in error and why?
- (B) If the concentration of monomeric tubulin were 10 μM , the steady-state apparent critical concentration, at what rate (second^{-1}) would a tubule capped with GTP-tubulin be elongating at its minus end?
- (C) If the plus end of this tubule were capped with GDP-tubulin, at what rate (second^{-1}) would it be depolymerizing?

Chapter 14

Membranes

Implicit in the cellular theory is the existence of a boundary between the cytoplasm of a cell and its surroundings, be they seawater or the extracellular fluid in a highly organized tissue. The boundary is a defined physical structure known as the **plasma membrane**, and it is a thin, continuous, closed bag marking the boundary of the cell. In electron micrographs of thin sections through a cell, the plasma membrane appears as a continuous closed curve that designates the perimeter of the cytoplasm.

In many microorganisms, such as algae, fungi, and bacteria, the plasma membrane is surrounded on its outer surface by an **outer membrane** or a **cell wall**. The cells of higher plants are also surrounded by a thick cell wall. Usually, the cells of animals, when they are located in organized tissues, are surrounded by networks of collagen and mucopolysaccharide. All of these integuments encasing these various cells are tough polymeric materials that provide support and security for the plasma membrane, which is the formal boundary between the cytoplasm and the environment, between the living and the inert.

When a thin section of a eukaryotic cell is examined in the electron microscope, the most striking feature of the image is the collection of closed curves that represent systems of **intracellular membranes** cut in cross section. These intracellular membranes are the endoplasmic reticulum, the Golgi membranes, and the membranes of the mitochondria, the nucleus, the lysosomes, the peroxisomes, the chloroplasts, the endosomes, and the vacuoles of the cell. Each of these structures at any instant is a closed, continuous, often highly irregular bag enclosing its respective volume of fluid, which is isolated by its membrane from the cytoplasm of the cell. The aqueous solution of proteins found within any one of these bags is unique from that in the cytoplasm surrounding it and is characteristic of the particular organelle. The membranes creating each of these organelles have the same structure as the plasma membrane, although each is distinct in its chemical composition. Because almost every membrane in the cell separates the cytoplasm from another space, the two sides of a membrane are defined relative to the cytoplasm, and they are referred to as **cytoplasmic** and **extracytoplasmic**, respectively. Among the more interesting ambiguities in this situation are the inner membranes of the mitochondria and the thylakoids of chloroplasts, which are the descendants of smaller cells that were incorporated into larger cells.

Consequently, their extracytoplasmic volumes were at one time cytoplasm, of which vestiges remain.

Each of the membranes composing a cell can be purified from the homogenate of a eukaryotic tissue by **cell fractionation**.¹ Originally these purifications were performed in water,¹ but it was subsequently noted that the organelles retained their appearance more successfully in concentrated solutions of sucrose.² Tissues are usually homogenized in a solution of 0.25 M sucrose, and the membranes are isolated by centrifugation on gradients composed of solutions of increasing concentrations of sucrose, which is a solute that stabilizes proteins by salting in, or of other solutes that change the density or osmolarity of the solution. During homogenization, the mitochondria, lysosomes, peroxisomes, chloroplasts, nuclei, and Golgi membranes remain intact and can be identified by their characteristic morphology.^{3,4} Plasma membranes and endoplasmic reticulum are disintegrated by the homogenization and become rounded fragments, often goblet-shaped or vesicular in morphology, and these fragments are known as **microsomes**.⁵ Microsomes of rough endoplasmic reticulum are readily identified by their adherent ribosomes.³

The various membranes and intact organelles suspended in the homogenate of a eukaryotic cell differ in their size and shape, their ratio of protein, lipid, and carbohydrate, and their composition of fixed acid-bases. Therefore, they can be separated from each other by differences in their **sedimentation coefficients** and their **buoyant densities** (Figure 14-1)⁶ or their net charges at a particular pH. Homogenates are often submitted to sequential centrifugations at different centrifugal forces for different durations. Such **differential centrifugations**¹ separate only crudely on the basis of sedimentation coefficient because large differences in sedimentation coefficient between any two organelles are necessary if one of the organelles is to form a pellet exclusively at one centrifugal force and duration while the other forms a pellet exclusively at a higher force or longer duration. **Rate sedimentation**⁷ is a technique in which a narrow band of sample is layered onto a gradient that changes only gradually in sucrose concentration, and the components are separated owing to their differences in sedimentation coefficient as they move through the gradient under the influence of a centrifugal field. Rate sedimentation provides much higher resolution than differential centrifugation.

Figure 14-1: Buoyant density and sedimentation coefficient of the organelles and fragments of membrane found in a homogenate of a eukaryotic cell.⁶ Each of the boundaries surrounds the distribution of buoyant densities (grams centimeter⁻³) and sedimentation coefficients of the particular organelle or fragment of membrane. Uniform organelles such as mitochondria, lysosomes, nuclei, and peroxisomes have relatively tight distributions of buoyant density and sedimentation coefficient. Smooth endoplasmic reticulum and plasma membrane become microsomes upon homogenization. Microsomes and rough endoplasmic reticulum, because they are heterogeneous fragments of membrane broken from much larger continuous structures, have fairly uniform buoyant densities but a wide range of sedimentation coefficients. The diagram illustrates that each of these classes of particles occupies a unique region in the two-dimensional space, and this allows each class of membranes to be isolated by a method exploiting differences in sedimentation coefficient in combination with a method exploiting differences in buoyant density. Usually, the boundaries for microsomes of plasma membrane and smooth endoplasmic reticulum coincide, so these two types of membrane fragments are difficult to separate. Adapted with permission from ref 6. Copyright 1974 Academic Press.

Unfortunately, the population of a given organelle in a tissue usually has a significant variation (Figure 14-1)⁶ in its sedimentation coefficient, and additional steps that separate membranes by other independent properties are often required for complete purification. During **isopycnic centrifugation**⁴ the sample is layered onto a much steeper gradient of density formed usually either by varying sucrose concentration or by varying Ficoll concentration.⁸ Ficoll is a polysaccharide that does not have the high osmolarity of sucrose. The gradients are submitted to centrifugation until all of the components have traveled to their respective buoyant densities, at which point they cease to move. The various membranes suspended in a homogenate can also be separated on the basis of their charge by **free-flow electrophoresis**.⁹ In certain instances, where the fixed anionic functional groups on a particular type of membrane are properly oriented, these membranes can be precipitated exclusively with divalent cations such as magnesium or calcium.¹⁰ Such a **precipitation** has been used to separate microsomes derived from endoplasmic reticulum from microsomes derived from plasma membrane.¹¹

During purification, the various classes of membranes can be followed by assaying for particular **marker enzymes**. Each type of organelle has at least one enzymatic activity that is almost exclusively confined to it and can be used as a measure of its concentration.^{3,4,12,13} The ability of certain membranes to bind very specific ligands has also been used to follow their purification. For example, the plasma membranes of animal cells bind the protein wheat germ agglutinin, the peptide hormone insulin, and the toxin from *Vibrio cholerae* with high specificity; the binding of any one of these three ligands can be used to identify plasma membranes.¹⁴ The final identification of the purified suspension of membranes as the organelle of interest, however, must always be made by examining thin sections of pellets of the purified material by **electron microscopy**.

All of these procedures have been used to develop methods for the purification of **mitochondria**,⁴ **peroxisomes**,⁴ **lysosomes**,⁴ **Golgi membranes**,¹³ **rough endoplasmic reticulum**,¹⁵ and **chloroplasts**.¹⁶ Ironically, it is the plasma membrane of most cells that is the most difficult membrane to purify because upon homogenization it fragments and becomes very similar to the much more abundant fragments of smooth endoplasmic reticulum. For this reason, the plasma membrane of the erythrocyte, a cell lacking any other membranes, has often been used as a model for an animal plasma membrane. Plasma membranes, however, have been purified from a number of animal tissues, including liver,¹⁷ kidney,⁹ adipose tissue,⁸ and brain,¹⁸ and from cells grown in tissue culture, such as murine fibroblasts (L-cells),¹⁹ A431 cells,¹¹ and HeLa cells.²⁰ Plasma membranes from fungi²¹ or bacteria, such as *Escherichia coli*,²² are prepared from spheroplasts, which are individual cells that have been enzymatically stripped of their outer membranes or cell walls. The spheroplasts are ruptured and the smooth plasma membranes are isolated from the homogenate.

Any of the membranes comprising an organelle or derived from a larger cellular structure can be freed from the soluble proteins it encloses by lysis and sedimentation. Such a membrane is constituted from lipids, carbohydrate, and proteins. All of the carbohydrate is covalently attached to protein in the form of glycoprotein or to lipid in the form of glycolipid. The component lipids, glycolipids, proteins, and glycoproteins are both heterogeneous mixtures, and the fraction of the mass that is protein can vary up to 75%. The basic structure upon which biological membranes are based is a bilayer of amphipathic lipids in which some neutral lipid is dissolved.

The Bilayer

The basic structural element of a biological membrane is a bilayer of **phospholipids** (Figure 14-2). Bilayers can be formed from a wide variety of lipids, but the plasma membrane of the typical eukaryotic cell is formed from phospholipids and cholesterol. The most prevalent phospholipids are **phosphatidylcholine** (Figure 14-2A) and **phosphatidylethanolamine** (Figure 14-2B). Phosphatidylcholine and phosphatidylethanolamine are **glycerophospholipids** constructed from a molecule of *sn*-glycerol 3-phosphate

in which carbon 2 has the *R* configuration. Either trimethylethanolammonium (choline; Figure 14-2A) or ethanolamine (Figure 14-2B), respectively, is esterified to the phosphate, forming a phosphate diester. The two remaining hydroxyls of the glycerol 3-phosphate are acylated with a pair of fatty acids.

Phosphatidylcholine and phosphatidylethanolamine are amphipathic lipids. An **amphipathic lipid** is an elongated molecule, usually of biological origin, that is composed of a substantial portion of unadulterated hydrocarbon at one of its ends and a portion of hydrophilic functional groups at its other end. One end of each molecule of phosphatidylcholine or phosphatidylethanolamine, the end containing the phosphate diester and the choline or ethanolamine, is hydrophilic. The other end, the end containing the linear hydrocarbon of the fatty acids, is hydrophobic. Linear hydrocarbons are the most hydrophobic functional groups among biological molecules (Table 5-9).²³

Most glycerophospholipids have two fatty acids attached to the glycerol in **ester linkages**. The fatty acids found in naturally occurring phospholipids seem to be chosen almost at random from the mixture of fatty *S*-acylcoenzymes A produced by the particular organism in which the membrane is located. Saturated fatty acids are esterified mainly to carbon 1 of the *sn*-glycerol 3-phosphate, and unsaturated fatty acids are esterified mainly to carbon 2 (Figure 14-2), so that the naturally occurring phospholipids end up with a roughly equal ratio of saturated and unsaturated hydrocarbons, inescapably intermixed.

The **saturated fatty acids** are mainly linear carboxylic acids that vary in length from 12 to 24 carbons. The most frequently encountered saturated fatty acids in biological membranes are palmitic acid (*n*-hexadecanoic acid; Figure 14-2C,F) and stearic acid (*n*-octadecanoic acid; Figure 14-2B). The most stable conformation of a

linear hydrocarbon is all-*trans* (14-2), but the introduction of a *gauche* (14-3) conformation at one of the carbon-carbon bonds requires only about 5 kJ mol⁻¹ if the hydrocarbon is unhindered. Therefore, at 25 °C about 10% of the unhindered carbon-carbon single bonds in a saturated fatty acid should be *gauche*. The *gauche* conformation transiently introduces an elbow with an angle of about 109° into the chain:

A second *gauche* conformation can reorient the chain to its original direction.

Unsaturated fatty acids contain one or more carbon-carbon double bonds. A *trans* double bond would not put an elbow in the hydrocarbon, but almost every carbon-carbon double bond in naturally occurring fatty acids is *cis*. One *cis* double bond introduces a permanent elbow with an angle of about 120-130° into an otherwise unsaturated linear hydrocarbon:

In the most stable conformation, one of the hydrogens on one of the two methylenes adjacent to the double bond fits between the two hydrogens of the other. The most common unsaturated fatty acids with only one carbon-carbon double bond are palmitoleic acid (*cis*-hexadec-9-enoic acid; Figure 14-2F) and oleic acid (*cis*-

octadec-9-enoic acid; Figure 14-2A,E), and the latter predominates.

When an unsaturated fatty acid contains two or three double bonds, they are spaced three carbons apart with a saturated carbon between them. This prevents the double bonds from conjugating with each other and becoming a rigid planar structure. Two *cis* double bonds spaced in this way produce a sinuous curve in the alkyl chain but do not change its ultimate direction:

They do, however, shorten its ultimate length by the equivalent of two carbon atoms, and the volume lost at the end is expressed as a bulge at the location of the unsaturation. The most common unsaturated fatty acid with two double bonds is linoleic acid (*cis,cis*-octadeca-9,12-dienoic acid; Figure 14-2C). Three *cis* double bonds produce an even longer sinuous curve that does place a permanent elbow in the alkyl chain:

The most common **polyunsaturated fatty acid** with three carbon-carbon double bonds is linolenic acid in its two geometric isomers, α -linolenic acid (*cis,cis,cis*-octadeca-9,12,15-trienoic acid; Figure 14-2B,G,H) and γ -linolenic acid (*cis,cis,cis*-octadeca-6,9,12-trienoic acid). Arachidonic acid (*cis,cis,cis,cis*-icosa-5,8,11,14-tetraenoic acid; Figure 14-2D) is a less common polyunsaturated fatty acid that serves as the precursor to prostaglandins, and its frequency is regulated for that purpose. Almost all of the unsaturation commences at carbon 9 in the usual naturally occurring mixture of the various fatty acids, so the portion of the hydrocarbon closest to the glyceryl group in a phospholipid is fully saturated and that farthest away contains unsaturated positions and is more geometrically disordered (Figure 14-2).

The **head groups** are the polar alcohols esterified to the phosphoric acid in naturally occurring phospholipids. The majority of the head groups are based on ethanolamine:

In phosphatidylethanolamine (Figure 14-2B), the ethanolamine is unaltered. In phosphatidylcholine (Figure 14-2A), the ethanolamine is triply methylated on nitrogen. In **phosphatidylserine** (Figure 14-2C), the ethanolamine is carboxylated. Two glycerophospholipids not based on ethanolamine are **phosphatidic acid** (Figure 14-2D), which lacks a second ester on the phosphoric acid, and **phosphatidylinositol**, in which the alcohol is *myo*-inositol (Figure 14-2F). Phosphatidylinositol is a minor phospholipid present at less than 5% in membranes. It provides the covalently attached anchor for phosphatidylinositol-linked proteins (Figure 3-17). Because it is also an intermediate in the biosynthesis of the second messenger *myo*-inositol 1,4,5-trisphosphate, its levels are independently regulated.

There are several other phospholipids that are variations on the theme developed by the glycerophospholipids. The **plasmalogens** (Figure 14-2E,H) have an enol ether at carbon 1 of the *sn*-glycerol 3-phosphate rather than an acylated oxygen. Upon treatment with BF_3 in methanol, the enol ether is released as the dimethyl acetal of a fatty aldehyde.²⁴ The enol ethers are usually derived from *n*-hexadecanal (Figure 14-2H) or *n*-octadecanal (Figure 14-2E), but minor amounts of the derivatives of unsaturated fatty aldehydes are also present.¹⁹ Either ethanolamine (Figure 14-2H) or choline (Figure 14-2E) is esterified, respectively, to the *sn*-glycerol 3-phosphate of plasmalogens.

There are a number of phospholipids and glycolipids in the membranes of archaebacteria that have tetraisoprenyl alcohols, such as 3,7,11,15-tetramethylhexadecanol, in **ether linkage** to two of the oxygens of glycerol.²⁵ The head group attached to the third oxygen can be a monosaccharide, such as glucose, in direct acetal linkage; a disaccharide, such as glucosyl (β 1-6) glucose, in acetal linkage; or a 1-phospho-*myo*-inositol, a phosphoserine, or a phosphoethanolamine in a phosphodiester linkage.²⁶⁻²⁸ One of these glycolipids and one of these phosphoinositides can also be fused at both of the terminal methyls of their tetraisoprenyl alkanes to produce a two-headed phosphoglycolipid.²⁷

14-8

At its two ends **14-8** is a paradigm for the types of head groups in archaeobacterial isopranylether lipids. In the membranes of the protist *Leishmania donovani* there is a different type of glycoposphoetherlipid in which either tetracosanol or hexacosanol forms an alkylether at carbon 1 of glycerol, the 2-hydroxy group of the glycerol is unsubstituted, and the head group on the 3-hydroxy group is a 1-phospho-*myo*-inositol to which a branched heptasaccharide is attached, and a (-6Gal β 1-4Man- α 1-phosphate)₁₆ is attached to the heptasaccharide.^{29,30}

A **sphingomyelin** has a primary alkene of 15 carbons replacing one of the hydrogens on carbon 1 of *sn*-glycerol 3-phosphate, the oxygen on carbon 1 is not acylated, and a nitrogen replaces the oxygen on carbon 2 and forms an amide rather than an ester with a fatty acid (Figure 14-2G). Upon saponification, **sphingosine** [(2*S*,3*R*)2-amino-3-hydroxyoctadec-4-en-1-ol], the fundamental skeleton on which sphingomyelin is constructed, is released. Sphingomyelins have choline for their head group.

Glycosphingolipids are also derived from sphingosine. As in sphingomyelin, the amino group on carbon 2 of the sphingosine in a glycosphingolipid is acylated. An acylated, unglycosylated sphingosine is a **ceramide**. A **cerebroside** is a glycosphingolipid in which either a glucose or a galactose is attached to the 1-hydroxyl of the ceramide in acetal linkage. Glycosphingolipids, however, can also have oligosaccharides attached to the 1-hydroxyl of the ceramide. Depending on the sequence of the immediately attached core oligosaccharide, the resulting glycosphingolipid is a ganglioside, a globoside, a lactoside, or of some other name (Table 14-1). As in the oligosaccharides on glycoproteins, the core of the oligosaccharide defining each type of glycosphingolipid can be incompletely finished, but the core oligosaccharides are usually further elaborated by adding *N*-acetylgalactosamine, galactoses, and as many as four or five sialic acids, and these modifications produce a dizzying array of microheterogeneous oligosaccharides more complex than that of the oligosaccharides on glycoproteins.

The composition (Table 14-2) of the lipids in plasma membranes from human erythrocytes³² or from murine fibroblasts (L-cells) grown in tissue culture¹⁹ are typical of **plasma membranes from animal cells**. The distribution of fatty acids among the various phospholipids from

^aData represent the composition of fatty acids (percent) present in total neutral lipid and the several types of phospholipid. Each of the compositions is the average of those from two membrane preparations. Neutral lipid and phospholipid from the plasma membranes were separated by silicic acid chromatography. Phospholipids were further separated by two-dimensional thin-layer chromatography, and the lipids were visualized by spraying with bromthymol blue. Iodine was not used in order to avoid possible losses of unsaturated fatty acids. Fatty acid methyl esters were prepared from the fatty acids in each preparation and analyzed by gas-liquid chromatography. ^bFatty acids are designated by the number of carbons and the number of double bonds. ^cLong-chain fatty acids are defined as fatty acids containing 20 or more carbon atoms.

phosphatidylinositol and phosphatidylserine. Fungi lack plasmalogens and sphingolipids.³³

The composition of the lipids varies among the various types of membranes in an animal cell: plasma membrane, endoplasmic reticulum, and mitochondria.³⁴ Mitochondria have less neutral lipid, sphingomyelin, and phosphatidylserine and more phosphatidylethanolamine than plasma membranes but about the same amount of phosphatidylcholine and plasmalogen.

The **plasma membranes of eubacteria**, such as the bacterium *E. coli*,^{35,36} are composed mainly of phosphatidylethanolamine (70%) but also contain small amounts of phosphatidic acid and phosphatidylserine as well as two unusual phospholipids, phosphatidylglycerol, where a glycerol is esterified to the phosphate of phosphatidic acid, and diphosphatidylglycerol, where a single molecule of glycerol is esterified at its two ends with two respective phosphatidic acids. These latter two phospholipids are found exclusively in prokaryotes and mitochondria, which are the direct descendants of prokaryotes. The lipids of the plasma membranes from the bacterium *Mycoplasma laidlawii*, however, have high percentages (45%) of the glycolipids 3-[*O*- α -D-glucopyranosyl]-1,2-diacyl-*sn*-glycerol and 3-[*O*- α -D-glucopyranosyl-(1,2)-*O*- α -D-glucopyranosyl]-1,2-diacyl-*sn*-glycerol.³⁷ This bacterium also contains phosphatidylglucose, a homologue of phosphatidylinositol.

In Gram-negative bacteria,* the plasma membrane

is surrounded by an **outer membrane**. The outer surface of this outer membrane, the surface exposed to the hostility of the environment, is formed mostly of a glycolipid called **lipopolysaccharide**. Instead of glycerol, the central element of lipopolysaccharide is a repeating polymer, (-phosphate-4-glucosamine(β 1,6)-glucosamine-1-)_n. 3-Keto fatty acids and 3-hydroxy fatty acids are linked to the 3-hydroxy and the 2-amino positions of each glucosamine.³⁸ To the glucosamines are also attached long oligosaccharides composed of mannose, glucose, galactose, *N*-acetylglucosamine, abequose, L-rhamnose, L-glycero-D-manno-heptose, 3-deoxy-D-manno octulosonic acid, and ethanolamine.³⁹ The inner surface of this outer membrane, however, is formed from normal glycerophospholipids.

Phosphatidylcholine, purified from a natural source such as eggs of *Gallus gallus*, spontaneously forms bilayers when it is suspended in water.⁴⁰ Initially, these bilayers are gathered in sets of nested spherical shells known as **multibilayer vesicles** (Figure 14–3).⁴⁰ Each of the shells in a multibilayer vesicle is a thin, closed, continuous bag. If such a suspension is submitted to sonication, the multibilayers eventually fragment and become small, unilamellar spherical vesicles.⁴¹ These vesicles are so small that they are not representative of the bilayer in biological membranes because of their excessive curvature. Larger, sealed, spherical unilamellar vesicles with uniform diameters of around 100 nm⁴² or with heterogeneous diameters as large as 50 μ m⁴³ can also be prepared from glycerophospholipids suspended in aqueous solution. A flat planar membrane, which is a single bilayer of phospholipid, can be formed

* Gram-negative bacteria are bacteria that do not stain with a particular dye because the dye cannot penetrate their outer membranes.

Figure 14-3: Spherical multibilayers of phosphatidylcholine.⁴⁰ Phosphatidylcholine was purified from the yolks of eggs from *G. gallus* by chromatography on alumina and then silicic acid with solvents of chloroform in methanol. The pure solid phosphatidylcholine was suspended in 0.15 M sodium chloride, and the resulting suspensions were examined in a polarizing microscope. The structures observed are small hollow spheres of phospholipid. The pattern of alternating dark and light sectors around the wall of the sphere within the plane of the page results from the fact that each sphere is formed from many concentric spherical shells, nested each within the other. Each of these spherical shells is a single bilayer of phosphatidylcholine. Reprinted with permission from ref 40. Copyright 1965 Academic Press.

across a small circular hole separating two aqueous compartments.^{44,45} Oriented bilayers of phosphatidylcholine can also be produced by evaporating a solution of the phospholipid in chloroform-methanol onto a flat surface such as mica and hydrating it with moist helium.⁴⁶ In each of these forms it is believed that the basic structural element, the bilayer of phospholipids, is the same and that the bilayer is a thin (4–5 nm) fluid film of phospholipid that can assume all of these different forms.

When bilayers of phosphatidylcholine are stacked upon mica as flat, planar, parallel sheets and this stack is placed in a beam of X-radiation, it produces a **diffraction pattern** (Figure 14-4A)⁴⁶ that is characterized by a set of sharp meridional arcs and two broad symmetrical equatorial reflections.⁴⁶ The equatorial reflections arise from the diffraction of the array of the linear hydrocarbons of the phospholipids oriented normal to the plane of the specimen. The meridional arcs arise from diffraction by the planes stacked one upon the other parallel to the orienting surface. The diffraction pattern of the meridional arcs can be transformed into a distribution of electron density along an axis normal to the orienting surface of the mica (Figure 14-4B). Because the stack of flat bilayers is a regularly repeating structure, the recurring variation of **electron density** in this dimension produces the diffraction pattern.

The repeating pattern in the properly phased Fourier transform of the meridional diffraction pattern consists of two regions of high electron density symmetrically sandwiching a region of low electron density (Figure 14-4B). This sandwich is the bilayer of phosphatidylcholine. The two regions with the highest electron density on either surface of the bilayer have been assigned to the glycerol, the phosphate, and the choline of the phosphatidylcholine (Figure 14-2). These functional groups, because they contain oxygen, nitrogen, and, in particular, phosphorus, have high electron density. The central region of the bilayer has been assigned to the hydrocarbon of the fatty acids.

A more recent calculation of the distribution of electron density in oriented bilayers of synthetic 1,2-dioleoylphosphatidylcholine, based on more extensive phasing of the meridional reflections, gave the same profile as that in Figure 14-4B.⁴⁷ The analysis of the profile of electron density, however, could be extended significantly in these later studies, because profiles of scattering density for both X-radiation and neutrons were calculated from the diffraction of X-radiation and the diffraction of neutrons, respectively, by the same sample of 1,2-dioleoylphosphatidylcholine. The scattering lengths for hydrogen, carbon, nitrogen, oxygen, and phosphorus differ dramatically relative to each other when these atoms are scattering X-radiation as opposed to when they are scattering neutrons. In particular, there are large differences in the relative scattering lengths for hydrogen. Because the different functional groups within a molecule of the phospholipid have different atomic compositions, the differences in scattering length and the significant differences between the profiles for the scattering of X-radiation and for the scattering of neutrons could be used to dissect the profile of electron density into the components that produce it. This dissection defines the **mean locations of choline, phosphate, glycerol, ester, carbon-carbon double bond, and hydrocarbon**.⁴⁷ These functional groups were calculated to be situated symmetrically at 2.2, 2.0, 1.9, 1.6, 0.8, and 0–1.6 nm, respectively, from the center of the bilayer. The width of this particular synthetic bilayer from choline to choline is 4.4 nm.

As the widths of the layers of water between each bilayer in such a stack is decreased by decreasing the vapor pressure of the water in the chamber (Figure 14-4B), greater and greater decreases in vapor pressure are required to elicit the same change in width once the separation between the maxima of electron density goes below about 0.5 nm.⁴⁸ In the dissection of the map of electron density into its components, it was estimated that the choline head groups extend 0.2 nm beyond

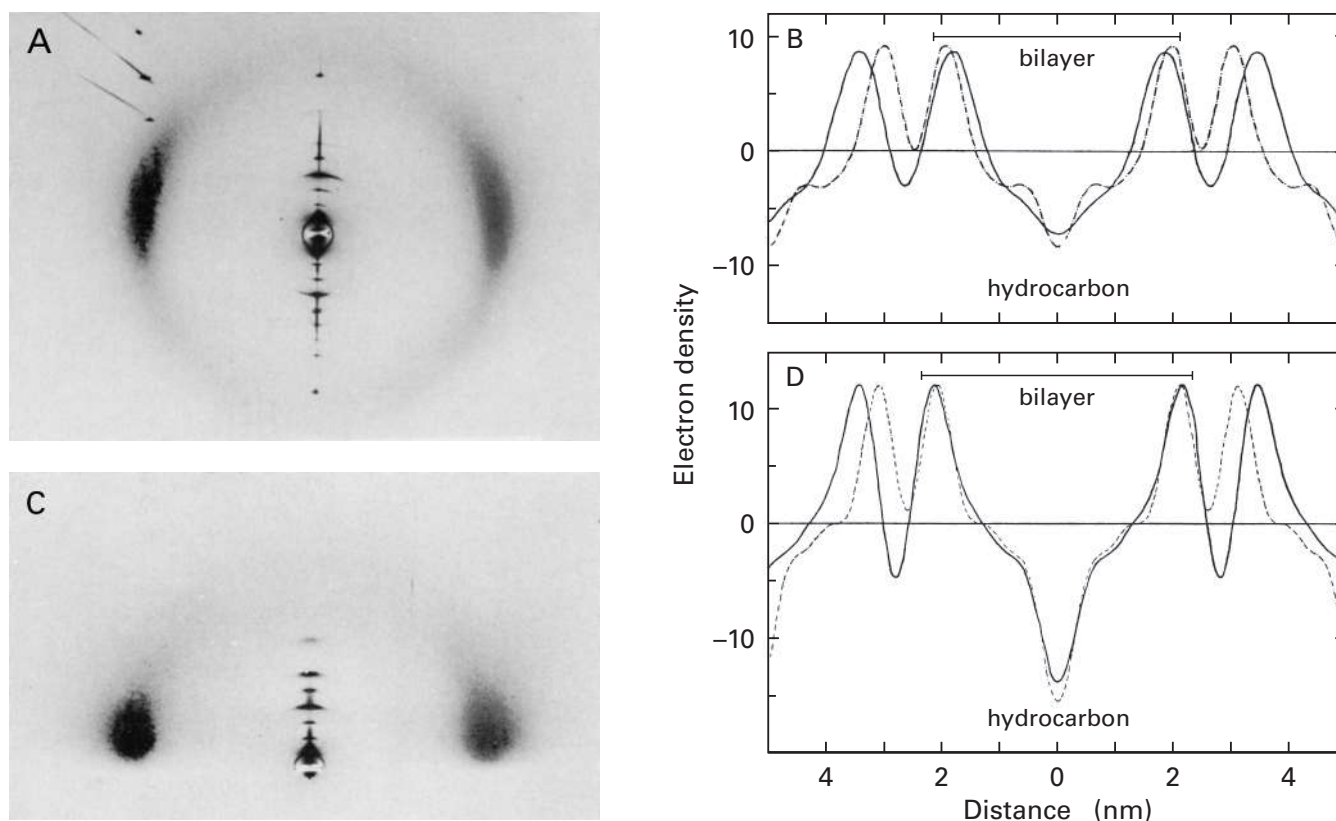

Figure 14-4: Diffraction patterns (A and C) and their respective computed Fourier transforms (B and D) for multilayers of pure phosphatidylcholine (A and B) from yolks of eggs from *G. gallus* or an equimolar mixture of the same phosphatidylcholine and cholesterol (C and D).⁴⁶ Lipids dissolved in chloroform in methanol were smeared on mica sheets, and the solvent was evaporated under a stream of moist helium. The multilayers that resulted were submitted to diffraction in a beam of X-radiation (A and C). The two symmetrically displayed, diffuse but intense diffractions on the equators (0.46 nm) in panels A and C are from the spacings of the linear hydrocarbons of the phospholipids oriented normal to the plane of the specimen. The sharp reflections on the meridian (the vertical axis of the pattern) are the reflections arising from the set of planes produced by the stacking of the bilayers. With the appropriate choice of phase, the amplitudes of the meridional reflections can be submitted to Fourier transform to obtain profiles of electron density (B and D) along an axis normal to the plane of the specimen. Presumably this axis is normal to the flat sheets producing the multilayer. The electron density in arbitrary units is presented as a function of the distance (nanometers) from the center of the bilayer. In panel B, the profile of electron density is given for lipids equilibrated with moist helium of 57% relative humidity (dashed lines; 14% water), or 100% relative humidity (solid line; 21% water), and in panel D, the profile of electron density is given for lipids equilibrated with moist helium of 57% relative humidity (dashed lines; 13% water) or 100% humidity (solid line; 22% water). It was the expectation of the investigators that the width and structure of the bilayer (within the double arrow) would remain constant while the distance between bilayers would increase as the water content increased. This expectation was used to assign the phases so its fulfillment is inconsequential. Adapted with permission from *Nature*, ref 46. Copyright 1971 Macmillan Magazines Limited.

maxima of electron density on the two sides of the aqueous space.⁴⁷ It has been proposed that the cause of the resistance to decreasing the separation between the bilayers is **steric repulsion** between these cholines on the apposed surfaces.⁴⁸ The observed distance at which repulsion sets in is consistent with the calculated location of the cholines. That the repulsion at these short distances arises from the collision of the head groups is supported by the fact that incorporation of cholesterol into the bilayers, which spreads apart the head groups and permits them to interdigitate significantly, decreases the repulsion.⁴⁹

When the amount of water in a sample of hydrated natural phosphatidylcholine from eggs is systematically increased from 10% to 45%, changes in the structure of the bilayers occur.^{50,51} The width of the bilayers decrease from 4.5 to 3.8 nm,⁵⁰ and the cross-sectional area for

each phospholipid in one of the two monolayers increases^{50,51} from 0.55 to 0.68 nm². It is thought that these changes are responses to the steric effects coincident to the **hydration** of the hydrophilic functional groups on the external surfaces. As hydration increases, it pushes apart the adjacent molecules of phosphatidylcholine in each monolayer of the bilayer and produces the observed changes. Above a certain level of hydration (>40% water), when all hydrophilic groups are fully hydrated, the thickness of the bilayer no longer decreases.

Because it is heterogeneous, naturally occurring phosphatidylcholine will not crystallize. Synthetically prepared dimyristoylphosphatidylcholine, however, has been crystallized, and a **crystallographic molecular model** has been constructed (Figure 14-5).⁵² The crystalline material consists of stacks of bilayers whose dis-

tribution of electron density along an axis normal to the planes of the bilayers (vertical axis in Figure 14-5) would resemble the distribution seen in Figure 14-4B. The molecules of phospholipid are distributed symmetrically about the center of the bilayer just as they are in a bilayer of fluid natural phospholipids. In fact, in the crystal, there are crystallographic screw axes of symmetry between the methyl groups at the ends of the hydrocarbons. Each plane of adjacent phospholipid molecules oriented in the same direction forms one of the two **monolayers** of one of the bilayers. As in the fluid, uncrys-

Figure 14-5: Arrangement of the molecules of phosphatidylcholine in the crystallographic molecular model of dimyristoylphosphatidylcholine dihydrate.⁵² The asymmetric unit in the unit cell of the $P2_1$ space group is formed from two molecules of dimyristoylphosphatidylcholine (1 and 2). The unit cell is outlined, and the 2-fold screw axes of symmetry normal to the plane of the page are designated. Because the crystal is the dihydrate, grown from a mixture of ether, ethanol, and water, each asymmetric unit has four water molecules (●) associated with it in the hydrophilic region between the bilayers. This corresponds to a water content of 5%. Reprinted with permission from *Nature*, ref 52. Copyright 1979 Macmillan Magazines Limited.

talline bilayer, the functional groups of the phospholipid are encountered in the order choline, phosphate, glycerol, ester, hydrocarbon from the outermost surface to the interior. Because the fatty acids are homogenous, their hydrocarbon has solidified into a crystalline array that is hexagonally packed. Dilauroylphosphatidylethanolamine crystallizes from acetic acid in bilayers, and the vertical hexagonal packing of the fatty acids in its crystallographic molecular model is readily discerned from a view normal to the plane of one of the bilayers (Figure 14-6).⁵³ Such crystallographic models provide a starting point for a discussion of the structure of a bilayer of amphipathic lipids. It must be remembered, however, that they represent homogeneous lipids in which the alkane is fully saturated and solid.

Four types of **conformation at the glyceryl backbone** of phospholipids have been observed in crystallographic molecular models (Figure 14-7), and there is evidence from nuclear magnetic resonance spectra that, in the liquid state, the phospholipids fluctuate among these conformations.⁵⁴ One interesting aspect of these structures is that in the conformations represented by dimyristoylphosphatidylcholine (DMPC) and dilauroyl-*N,N*-dimethylphosphatidylethanolamine (DLPEM₂), the acyl carbon of the fatty acid on carbon 3 of the glyceryl group is buried more deeply in the bilayer than the acyl carbon of the fatty acid on carbon 2, while in the two conformations represented by dilauroylphosphatidic acid (DLPA) and dimyristoylphosphatidylglycerol (DMPG), it is the acyl carbon of the fatty acid on carbon 2 that is buried more deeply. This means that, in the rapid transitions among these conformations that occur in bilayers of liquid phospholipid, the linear hydrocarbons slide back and forth past each other in a direction normal to the plane of the bilayer. As these sliding movements occur, each of the acyl oxygens on the two fatty acids comes in turn to the surface of the bilayer (Figure 14-7). Because of the sliding movements, the equilibrium among these conformations can be shifted by changing the structure of the surroundings in which the far ends of the fatty acids are located.⁵⁵

In these **sliding fluctuations**, the positions of the charged phosphate and the charged nitrogen on phosphatidylcholine must average to about the same mean location relative to the surface of the bilayer. This follows from the fact that vesicles of phosphatidylcholine have zero electrophoretic mobility, which demonstrates that on the average the negative charges on their phosphates must reside in the same plane parallel to the surface of the bilayer as the positive charges on their cholines.⁵⁶ The dielectric properties of bilayers of phosphatidylcholine are also consistent with this disposition. In the crystallographic molecular model of dilauroylphosphatidylethanolamine (Figure 14-6), the ammoniums of the ethanolamines form hydrogen bonds to the oxygens of the phosphates, bringing the two opposite charges into the same plane parallel to the surface of the bilayer.

Figure 14-6: View of the crystallographic molecular model of dilauroylphosphatidylethanolamine looking down on the hydrophilic surface of the bilayer.⁵³ Only one monolayer of the bilayer of phospholipid is shown in the drawing. One of the oxygens of each phosphate forms a hydrogen bond with the ammonium group of an adjacent ethanolamine. The dilauroylphosphatidylethanolamine was crystallized from glacial acetic acid, and in the crystals there was one molecule of acetic acid (not shown) for each molecule of phospholipid. The fact that the linear hydrocarbons are all normal to the surface of the monolayer is apparent, and the drawing gives a representation of the view from above the surface of a bilayer of phospholipid. Figure 14-7: Four conformations available to a phospholipid in a bilayer.⁵⁴ These four drawings are taken from the crystallographic molecular models of crystalline dimyristoylphosphatidylcholine (DMPC), dilauroyl-*N,N*-dimethylphosphatidylethanolamine (DLPEM₂), dilauroylphosphatidic acid (DLPA), and dimyristoylphosphatidylglycerol (DMPG). Within each structure the two fatty acids are the same length, so the relative positions of the two fatty acids are most readily ascertained by looking at their ends. Within each structure the fatty acid to the right is the one on carbon 2 of the glycerol, and the fatty acid to the left is the one on carbon 3. In the upper two conformations, the fatty acid on carbon 3 of the glycerol is deeper in the bilayer of phospholipid than that on carbon 2, and in the lower two conformations the fatty acid on carbon 2 is deeper in the bilayer of phospholipid than that on carbon 3. In the upper two structures the acyl oxygen of the fatty acid on carbon 2 of the glycerol is at the surface of the bilayer; in the lower two structures the acyl oxygen of the fatty acid on carbon 3 is at the surface of the bilayer. Reprinted with permission from ref 54. Copyright 1988 American Chemical Society.

Phosphatidylcholine and phosphatidylethanolamine are zwitterionic and neutral, but phosphatidylserine, phosphatidylglycerol, phosphatidylinositol, and half a molecule of diphosphatidylglycerol each have a net charge number of -1 . Consequently, natural bilayers have a net **negative surface potential**. In a bilayer of pure phosphatidylserine, the potential at the surface is about -80 mV and falls off as a function of the distance from the surface as predicted by the Gouy-Chapman equation for an ionic double layer.^{57,58} At a distance of 1 nm from the surface in a solution of ionic strength of 0.1 M, the potential has dropped to -30 mV. The magnitude of the surface potential varies with the mole fraction of negatively charged lipid in a bilayer and the ionic strength of the solution⁵⁹ and affects the adsorption of small charged molecules⁵⁹⁻⁶¹ and proteins⁶² to the bilayer in a predictable manner.

The **electrostatic repulsion** of the negatively charged phospholipids decreases the stability of a bilayer. In fact, at low ionic strength, bilayers of pure dimyristoylphosphatidylglycerol are unstable enough that the monomer has a measurable solubility in aqueous solution (10^{-15} – 10^{-16} mole fraction),⁶³ which is almost unheard of. The **solubilities** of neutral phospholipids or monoanionic phospholipids with longer fatty acyl groups are so small that they cannot be measured. Bilayers of entirely monoanionic phospholipid are unstable enough that they do not occur naturally. There is, however, a mutant of *E. coli* in which the synthesis of phosphatidylethanolamine has been deleted; and this curiosity, the phospholipids of which are almost entirely phosphatidylglycerol and diphosphatidylglycerol, will grow as long as the concentration of Mg^{2+} in the medium is high enough to decrease significantly the surface potential of its plasma membrane.⁶⁴

The bilayers observed in crystallographic molecular models are solids in which the hydrocarbon is frozen; the bilayers of the mixture of phospholipids purified from a natural source or the bilayer present in a biological membrane is liquid. The **transition between solid and liquid** resembles the melting of paraffin, and it can be observed by cooling a bilayer to solidify it and then raising the temperature gradually to melt it. As phospholipids from most natural sources remain fluid even at low temperatures, the transition is usually followed either in homogeneous, synthetic phospholipids or in biological membranes the composition of which is highly enriched in one particular fatty acid. For example, when the bacterium *M. laidlawii* is grown on medium supplemented with a chosen fatty acid, up to 70% of the fatty acids in its membranes are the supplemented fatty acid.⁶⁵

The transition between solid and liquid can be observed by diffraction of X-radiation. In a solid bilayer the hydrocarbon of the phospholipids is in a **hexagonal array** (Figure 14-6), and the spacing between the linear, all-*trans* alkanes produces a strong sharp equatorial

reflection (see Figure 14-4A) at $(0.415 \text{ nm})^{-1}$ characteristic of crystalline paraffins.⁶⁶ The cross-sectional area of such a hexagonal array of solid paraffin hydrocarbons is 0.40 nm^2 for every two alkyl chains,⁶⁶ and this agrees closely with the cross-sectional areas of 0.39 – 0.41 nm^2 for one complete molecule of phospholipid in each monolayer of the crystallographic molecular models.^{52,53,67} The width of a solid bilayer of phospholipid with only saturated fatty acids is consistent⁶⁶ with the width of two layers of slightly tilted ($\leq 20^\circ$) alkanes of the appropriate length in the all-*trans* configuration (Figure 14-5).

When a solid bilayer is melted to a liquid bilayer by raising the temperature, its width decreases by 0.5 – 1.0 nm .^{66,68-70} If at the same time the hydrocarbon is expanding to the extent that paraffins expand as they become liquid, the **cross-sectional area for each phospholipid** in one of the monolayers of the bilayer must increase^{66,68} to 0.55 – 0.70 nm^2 . This expansion of the cross-sectional area of the bilayer, among other factors, reflects the establishment of the normal disorder of the liquid state of a paraffin. In this state, *gauche* conformations, which necessarily shorten the distance that can be covered by a hydrocarbon, become common features that lead to the narrowing of the bilayer.

In such molten bilayers of fully saturated phospholipid, the hydrocarbons remain oriented preferentially with their long axis aligned with an axis normal to the plane of the bilayer. This conformation has been demonstrated by neutron diffraction of oriented bilayers of dipalmitoylphosphatidylcholine in which different carbons along the palmitates have been labeled with deuterium, an atom that scatters neutrons strongly. In the solid phase at low hydration, where all of the hydrocarbons are in hexagonal array normal to the plane of the membrane, the location of the deuteriums in the distribution of scattering density is easily distinguished (Figure 14-8).⁶⁹ In such solid bilayers, the deuteriums appear at the expected distances from the center (Table 14-4). When bilayers of the various dipalmitoylphosphatidylcholines are melted, the deuteriums in the fluid

^aDetermined by neutron diffraction of bilayers of dipalmitoylphosphatidylcholine selectively deuterated at the noted positions.

Figure 14-8: Distribution of neutron scattering density across bilayers of phospholipid in which hydrogen has been replaced by deuterium at specific locations along the linear alkyl groups of the phospholipid.⁶⁹ Stacked, parallel bilayers of the di-(15,15-dideuteriopalmityl)phosphatidylcholine (A), di-(5,5-dideuteriopalmityl)phosphatidylcholine (B), or dipalmitoylphosphatidylcholine hydrated with $^2\text{H}_2\text{O}$ (C) were prepared on quartz slides. Each of these multilayers was brought to 20 °C, which is below the melting point of dipalmitoylphosphatidylcholine under these circumstances, and allowed to diffract neutrons. From the meridional reflections and appropriate phases, a distribution of neutron scattering density (relative units) normal to the plane of the membranes as a function of distance from the center (nanometers) could be calculated by Fourier transformation. The positions of the deuterated carbons in the first two samples are clearly observed (arrows). The position of the $^2\text{H}_2\text{O}$ in the third sample was defined by a difference map of neutron scattering density (C) between a specimen hydrated with H_2O and one hydrated with $^2\text{H}_2\text{O}$. hydrocarbon remain similarly distributed (Table 14-4), but each moves closer to the center. This rearrangement is consistent with the narrowing of the bilayer that occurs upon melting. In fluid bilayers of phospholipids in which all of the fatty acids are the same length, the methyl groups at the ends of the fatty acids from the two monolayers end up adjacent to each other (Figure 14-5), but in bilayers in which the two fatty acids on the phospholipids are of significantly different length, the longer

fatty acids interdigitate so that the methyl groups of the longer fatty acids on one monolayer end up adjacent to the methyl groups of the shorter fatty acids on the other.⁷⁰

The transition between solid and liquid in a bilayer composed of mixtures of various homogeneous, synthetic phospholipids has also been studied. When a suspension of bilayers composed of only one phospholipid such as dipalmitoylphosphatidylcholine is melted, a single sharp transition that occurs completely over 2–3 °C is observed. It can be monitored in a **calorimeter** as the absorption of heat resulting from the **heat of fusion**.⁷¹ When two phospholipids are mixed, the transition occurs over a broader range of temperatures somewhere between the temperatures of the transitions of the separated components.^{72–74} At temperatures in the range over which the transition is occurring, regions of fluid phase are in equilibrium with regions of solid phase laterally separated from each other in the plane of the bilayer.⁷² In many instances, the two component phospholipids are not miscible with each other as solids and a separate solid phase of one or the other remains laterally isolated in the bilayer.⁷² For example, mixtures of up to 40% dipalmitoylphosphatidylethanolamine in dimyristoylphosphatidylcholine contain significant regions of unmixed dimyristoylphosphatidylcholine in the solid phase.⁷² These results suggest that **regions of immiscible, unmelted phospholipid** might form in natural bilayers under certain circumstances. The heterogeneous mixtures of phospholipids normally found in natural circumstances, however, appear to form bilayers that are fully liquid and fully miscible at all physiological temperatures.

The fluid bilayers in normal biological membranes and in bilayers formed spontaneously from the amphipathic lipids extracted from normal biological membranes have been studied by following the **electron spin resonance** of probes incorporated into them. **Nitroxyl fatty acid 14-9**⁷⁵ is an example of such a probe:

The nitroxyl radical is in a five-membered ring similar to that of the 1-oxyl-2,2,5,5-tetramethylpyrrolin-3-yl radical (**12-11**). The unpaired electron in the nitroxyl radical is located in a π molecular orbital the principal axis of which is aligned parallel to the axis of the all-*trans* linear hydrocarbon:⁷⁶

The spectrum of 3-carbamoyl-1-oxyl-2,2,5,5-tetramethylpyrroline freely tumbling in aqueous solution displays three sharp peaks of equal intensity (Figure 12-35),^{77,78} reflecting the rapid isotropic motion of the molecule and the full coupling of the unpaired electron and the nitrogen nucleus. When nitroxyl fatty acid **14-9**, however, is incorporated into an oriented multibilayer of phosphatidylcholine from eggs of *G. gallus*, the absorbances of the unpaired electron in the spin-labeled fatty acid within the multibilayer are much broader because the motions reorienting its nitroxyl radical are much less rapid (Figure 14-9).^{77,78} The decrease in the intensity of the symmetrically displayed hyperfine peaks resulting from the change in bonding of the nitroxyl radical (**12-12**) that occurs within the nonpolar environment of the interior of the bilayer is also apparent.

The spectra also have become anisotropic because the motion of the nitroxyl radical has become **anisotropic**. The easiest way to demonstrate this is to take two spectra from the specimen oriented so that the magnetic field is either normal to the planes of the multibilayers (Figure 14-9B) or parallel to the planes of the multibilayers (Figure 14-9C). In the one case the splitting of the peaks is larger than that of the isotropic spectrum, and in the other it is smaller. From theoretical simulations of these spectra, it could be concluded that, in the bilayers of phosphatidylcholine, nitroxyl fatty acid **14-9** is oriented with the axis of its hydrocarbon perpendicular to the planes of the multibilayers and rotates exclusively or almost exclusively about this axis. These conclusions are consistent with expectations based on the structure of a bilayer of phospholipid (Figure 14-2) and the amphipathic structure of nitroxyl fatty acid **14-9**. When such nitroxyl radicals are incorporated into multilamellar vesicles of phosphatidylcholine suspended in water (Figure 14-3), the spectrum that results is a composite of the perpendicular and parallel spectra seen in Figure 14-9, panels B and C, respectively.⁷⁹

That **molecular motions of the linear alkane** in a fluid bilayer of phospholipid increase in proceeding from the acyl carbon to the center can be demonstrated with spin-labeled phospholipids.⁷⁹ A series of phosphatidyl-

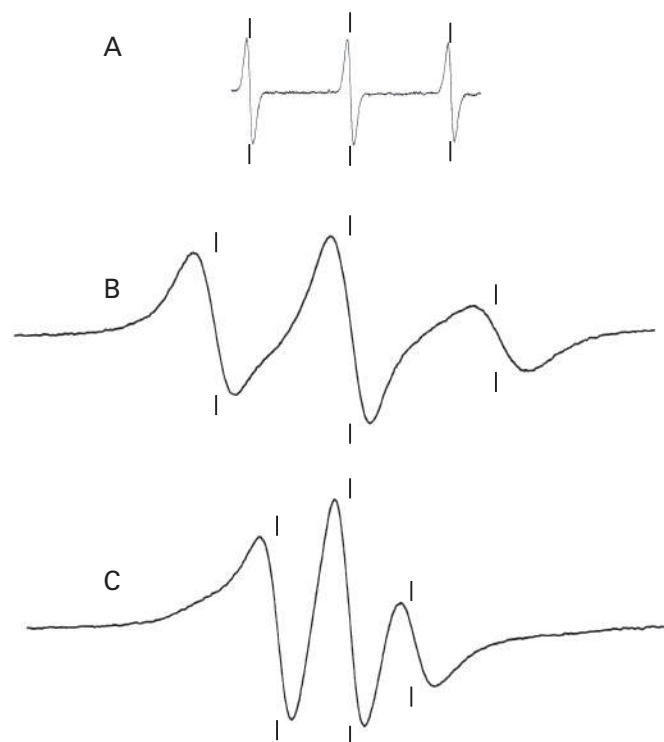

Figure 14-9: Electron spin resonance spectra of azacyclic *N*-oxides. (A) 2,2,5,5-Tetramethyl-3-(aminocarbonyl)azacyclopentane *N*-oxide (see **12-11**) dissolved in water.⁷⁷ (B, C) 2-(10-Carboxydecyl)-2-hexyl-5,5-dimethyl-3-azetidine *N*-oxide (**14-9**) incorporated into multibilayers of phosphatidylcholine from eggs of *G. gallus*. The magnetic field of the spectrometer was oriented perpendicular (B) or parallel (C) to the plane of the cover slip.⁷⁸ Nitroxyl fatty acid **14-9** and phosphatidylcholine were dissolved in chloroform and the mixture was evaporated to dryness. Water was added and a portion of the opalescent suspension that resulted was spread on a cover slip. The water was evaporated at 39 °C to produce the multibilayers oriented by the plane of the cover slip. In all of the spectra, the derivative of the absorbance is presented on the vertical axis. The microwave frequency was held at a constant value while the strength of the magnetic field was varied continuously. The magnetic flux density (tesla) is the variable on the horizontal axis. The distance between the two absorbances at the ends of the spectrum in panel A is 0.0028 T. The vertical lines mark the positions of maximum absorption (zero slope) of microwave energy. Reprinted with permission from refs 77 and 78. Copyright 1965 and 1969 National Academy of Sciences.

cholines were synthesized in which the acyl groups on carbon 1 of the *sn*-glycerol 3-phosphate were derived from either palmitic acid or stearic acid, and the acyl groups on carbon 2 were derivatives of palmitic acid or stearic acid, respectively, on which the cyclic dimethyl nitroxyl radical was positioned at the 5th, 8th, 12th, and 16th carbon.⁷⁹ An **order parameter**, *S*, can be defined, which is a number that quantifies the confinement of the rotational motion of these cyclic nitroxyl radicals to one particular axis. When *S* = 1, the ring rotates about a fixed axis in space; and when *S* = 0, its rotational motion is isotropic (Figure 14-9A).

When the various labeled phospholipids were

incorporated into multibilayers of natural phosphatidylcholine, the order parameter S was observed to decrease as the cyclic nitroxyl radical was situated farther from the acyl carbon. For cyclic nitroxyl radicals at the 5th, 8th, 12th, and 16th carbon of the labeled fatty acid, the order parameters S were 0.68, 0.50, 0.33, and 0.16, respectively.⁸⁰ In experiments of this type, caution must be taken that the probe does not affect the behavior of the alkane to which it is attached. For example, when a similar experiment was performed with the fluorescent probe 7-nitro-2,1,3-benzoxadiazol-4-yl covalently attached to the phospholipid, the hydrophilicity of the probe drew the end of the fatty acyl group to which it was attached to the surface of the membrane, pulling it away from the center of the core.⁸¹ The order parameters observed with the much less hydrophilic nitroxyl group, however, have been confirmed by using deuterium as a probe, which produces the least possible perturbation of the fatty acyl group.

Measurements of the order parameter as a function of the position along the linear alkane of the fatty acyl groups in a phospholipid have been made by **deuterium nuclear magnetic resonance**.⁸² A series of synthetic phospholipids were prepared that contained either palmitic acid at both carbon 1 and carbon 2 or palmitic acid at carbon 1 and oleic acid at carbon 2 of the *sn*-glycerol 3-phosphate. In each member of the series, deuterium atoms were placed synthetically on a specific carbon in the palmitic acids. Because a deuteron, like a nucleus of ¹⁴nitrogen, is quadripolar, a deuterium nuclear magnetic resonance spectrum can also be used to estimate an order parameter S for the degree of anisotropy experienced by the carbon to which it is attached.^{67,83} Order parameters S for dipalmitoylphosphatidylcholine, 1-palmitoyl-2-oleoylphosphatidylcholine, and dipalmitoylphosphatidylserine, gathered from bilayers of these phospholipids held at temperatures an equivalent distance above each of their melting points, have been presented as a function of the carbon on which the deuteriums were located (Figure 14-10).⁸⁴ The confinement experienced by a carbon in the liquid hydrocarbon of the bilayer decreases as the distance from the acyl carbon increases. Carbons at the very core of the bilayer are able to assume almost every orientation, while carbons near the periphery are confined in their orientations. These observations relate to an apparent **stereochemical paradox** in the structure of a bilayer of phospholipids from natural sources.

Beyond the eighth carbons of the fatty acids attached to carbon 2 of either the *sn*-glycerol 3-phosphates or the sphingosines in a natural bilayer, within the **core of the hydrocarbon**, the carbon-carbon double bonds begin (Figure 14-2). This fact has two consequences. First, permanent elbows incompatible with straight linear alkanes necessarily disrupt the alignments of the hydrocarbons of the fatty acids. Second, the average length for each carbon is decreased by the multiple

double bonds. Both the disorder introduced by single and triple *cis* double bonds and the shortening of the chains caused by all of the double bonds necessarily increase the mean cross-sectional area parallel to the plane of the bilayer for each chain of hydrocarbon in this region distal to the glyceryl groups located on the two sides of the bilayer. Added to this effect is the disorder that naturally occurs farther away from the surfaces of the bilayer even in saturated phospholipids (Figure 14-10).

Before the ninth carbons of the acyl groups on carbon 2 of the *sn*-glycerol 3-phosphates and sphingosines, however, essentially all of the hydrocarbon is

Figure 14-10: Variation of the molecular order parameter, S_{mol} , estimated from deuterium nuclear magnetic resonance spectra as a function of the position of the deuterium along the hydrocarbon of 1,2-di(dideuteriopalmityl)phosphatidylcholine (○), 1,2-di(dideuteriopalmityl)phosphatidylserine (□), or 1-(dideuteriopalmityl)-2-oleoylphosphatidylcholine (△).⁸⁴ A series of selectively deuterated palmitic acids were synthesized, each with two deuteriums at a different carbon along the chain. From these dideuteriopalmic acids a series of dipalmitoylphosphatidylcholines was synthesized, each with two palmitic acids in which deuterium occupied the same position. These lipids were separately suspended in water at a temperature 19 °C above their melting points (41 °C) and deuterium nuclear magnetic resonance spectra were recorded, from which order parameters, S_{mol} , were calculated (○). A similar series of dipalmitoylphosphatidylserines was also prepared and a similar analysis performed at 51 °C (□). Samples of each of the dipalmitoylphosphatidylcholines were digested with phospholipase A, and the resulting 2-lysophosphatidylcholines were esterified with oleic acid to produce a series of 1-(dideuteriopalmityl)-2-oleoylphosphatidylcholines in each of which two deuteriums occupied a different position, respectively, in the palmitic acid. Deuterium nuclear magnetic resonance spectra were taken of suspensions of these phospholipids at a temperature 16 °C above their melting points (−5 °C). From these spectra, order parameters, S_{mol} , were calculated (△). A series of palmitic acids selectively deuterated at specific positions were separately fed to *M. laidlawii* bacteria to enrich (70%) the membranes of these cells in the added fatty acid, and the order parameters for samples of each of these selectively deuterated membranes were also determined (×). Order parameters are plotted as a function of the position of the labelled carbon in the respective fatty acids. Reprinted with permission from ref 84. Copyright 1978 Elsevier Science Publishers.

linear, saturated alkane, and more ordered (Figure 14–10). In a bilayer composed only of phospholipids and sphingomyelins, these regions of **alkane proximal to the glyceryl groups** are nevertheless necessarily required to have the same mean cross-sectional area for each phospholipid as exists in the distal regions at the core. All of these considerations require that the solution to this paradox incorporate a large cross-sectional area, low density, and high disorder in the regions distal to the glyceryl groups at the core of the hydrocarbon and a large cross-sectional area, high density, and low disorder in the two symmetrical regions of alkane proximal to the glyceryl groups in a bilayer.

One solution to this paradox would be that the linear alkanes in the two proximal regions are tilted.⁸⁰ Tilting the alkane increases its cross-sectional area parallel to the plane of the bilayer while retaining the density of the condensed, hexagonal array. This possibility has been examined with a series of synthetic phosphatidylcholines that each had a dimethyl cyclic nitroxyl radical attached at a different carbon in the saturated fatty acyl group on carbon 2 of their *sn*-glycerol 3-phosphates. These labeled phosphatidylcholines were incorporated into bilayers of phosphatidylcholine from eggs of *G. gallus*. When the dimethyl cyclic nitroxyl radical was on the 5th or the 8th carbon, its principal axis was tilted 30° relative to the plane of the bilayer, but when it was on the 12th or the 16th carbon, its principal axis was oriented on average normal to the plane of the bilayer.⁸⁰ Tilted hydrocarbon chains have been directly observed in crystallographic molecular models of bilayers of phospholipids.⁶⁷ A tilting of the alkyl chains in the two regions on the two sides of the bilayer proximal to the glyceryl groups would also explain the increase in cross-sectional area and decrease in width that occurs upon the melting of bilayers of homogeneous phospholipids.⁶⁶ The implausible feature of this explanation is that all of the alkyl chains in a fluid bilayer would have to tilt in the same direction within one of these regions for it to be correct.

Such a **coordinated tilting of the hydrocarbon** over large areas of a solid bilayer has been observed by diffraction of X-radiation. In bilayers of dipalmitoylphosphatidylcholine and distearoylphosphatidylcholine below the temperature at which they melt, the equatorial reflection in the X-ray diffraction pattern that arises from the aligned chains of alkane displays the fine structure of a sharp reflection superimposed upon a broader reflection.⁸⁵ This distribution of reflected intensity has been shown to arise from hydrocarbons tilted relative to the axis normal to the bilayer, and the degree of tilt can be calculated from the diffraction pattern. As the degree of hydration in these solids was increased from 6% to 30%, the tilt of the hydrocarbons increased from 17° to 40°. Presumably the **steric effects of the hydration** force the hydrophilic functional groups of the phospholipids to take up a greater surface area for each molecule of phos-

pholipid, and the linear hydrocarbons adjust to the required increase in their cross-sectional area by tilting. It has also been observed that a dimethyl cyclic nitroxyl radical, attached at the fifth carbon of a fatty acid on carbon 2 of the *sn*-glycerol 3-phosphate of dipalmitoylphosphatidylcholine, appeared to be in a more polar environment in bilayers of natural phospholipids than nitroxyl radicals attached farther down the fatty acid.⁸⁶ If the hydrocarbons were tilted in this region, their surfaces should be more exposed to the aqueous phase.

These observations, however, illustrate a difficulty in interpreting many of the physical studies on bilayers. The bilayers used in these experiments were vesicles prepared by **sonication**. It has been shown by nuclear magnetic resonance spectroscopy that vesicles of small diameter (30–90 nm) prepared by sonication display anomalous physical properties because of their high curvature.⁸⁷ It has been pointed out that these anomalies arise from the fact that the high curvature unavoidably forces a portion of the hydrocarbon adjacent to the hydrophilic functional groups of the phospholipids to occupy locations on the outer surface of the vesicle in contact with the water,⁸⁸ and this would explain why the environment of the nitroxyl radical in this situation appears to be so polar. Naturally occurring bilayers, however, rarely have such high curvature. The tension within such small vesicles produced by sonication seems to be significant. When the kinetic barrier is overcome by adding appropriate catalysts, small vesicles of phospholipid spontaneously fuse among themselves to produce much larger single-walled structures.⁸⁹

The **paradox of the cross-sectional areas** has been phrased in terms of the structure of bilayers of phospholipids from natural sources because this is the most critical situation. Natural phospholipids have unsaturated fatty acids that necessarily disrupt the hydrocarbon in the core of their bilayers (Figure 14–2). Consistent with the stereochemical consequences of the *cis* double bonds, the most obvious discontinuity in the plot of the order parameter *S* against position (Figure 14–10) occurs after the sixth carbon of the palmitate on 1-palmitoyl-2-oleoylphosphatidylcholine (see Figure 14–2A). A similar, although a much less abrupt, discontinuity, however, also seems to be present in the plot for bilayers formed from fully saturated phospholipids such as dipalmitoylphosphatidylcholine. Even in this case, the disorder increases most precipitously beyond the eighth carbon.

It has been argued that there is no stereochemical paradox associated with the first seven saturated carbons of the fatty acyl groups in a bilayer of phospholipid in which there is the normal complement of unsaturated fatty acyl groups if the carbon–carbon bonds connecting these carbons can support enough *gauche* configurations to make this region fluid enough to fill the volume allotted to it.⁹⁰ At first glance, this would seem difficult to accomplish. The difference in standard free energy between a *trans* and a *gauche* configuration in a linear

At the maximum, the width of the bilayer has increased by 19%.⁹⁸ At the same time, however, the **cross-sectional area** for each molecule of phosphatidylcholine in a monolayer of the bilayer decreases from 0.62 to 0.48 nm², if it is assumed that each molecule of cholesterol contributes 0.37 nm² to the surface area.⁹⁸ These are the changes expected if cholesterol straightens the posture of the alkane in the regions of the bilayer proximal to the glyceryl groups. The minimum value of 0.48 nm² for the cross-sectional area is not far from the value of 0.40 nm² for the cross-sectional area of a pair of hexagonally arrayed all-*trans* linear alkanes in a solid paraffin. Because the molecules of cholesterol are spacing the molecules of phosphatidylcholine, the phosphocholine head groups are more widely separated, and the steric effects of their hydration are no longer significant. If the distance between the esters in a bilayer of dioleoylphosphatidylcholine is 3.2 nm, the width of the hydrocarbon should be 3.0 nm.⁴⁷ If this bilayer is representative of one composed of only phospholipid and if the addition of the normal amount of cholesterol increases the width of the hydrocarbon in such a membrane of phospholipids by 20%, the width of the hydrocarbon in a membrane of phospholipids and cholesterol in a cell should be about 3.6 nm.

There is evidence from calorimetric studies,⁷¹ X-ray diffraction,⁹⁹ deuterium nuclear magnetic resonance,¹⁰⁰ and pressure-area functions of monolayers^{101,102} that complementary interactions occur between cholesterol and phospholipids, causing them to segregate into **distinct phases**. For example, between mole fractions of 0.08 and 0.28 mole % cholesterol at 30 °C, the lipids in a bilayer of dimyristoylphosphatidylcholine and cholesterol separate into a phase enriched in cholesterol and a phase depleted in cholesterol. Above 0.28 mole %, the cholesterol and the dimyristoylphosphatidylcholine are miscible and form a single phase.¹⁰³ Below the melting point of pure dimyristoylphosphatidylcholine, the phase enriched in cholesterol remains fluid while the phase depleted in cholesterol with which it coexists solidifies. The phases enriched in cholesterol that separate from mixtures of cholesterol and phospholipid have volumes that are smaller than the sum of the volumes of the separate components¹⁰¹ and have much broader phase transitions.⁷¹ In these distinct phases, the alkane of the phospholipid is more ordered than it is in the absence of cholesterol but reorients more rapidly,¹⁰⁰ results consistent with a decrease in the frequency of *gauche* conformations and the elimination of any tilting of that alkane.

These separate phases enriched in cholesterol usually have distinct molar ratios between the two components. The **stoichiometry between cholesterol and phospholipid** in these phases varies depending on the type of phospholipid with which the cholesterol is mixed.¹⁰² In mixtures between synthetic phospholipids and cholesterol the mole fraction of cholesterol in one of these separate phases is usually between 0.25 and

0.4,^{99,100} but with mixtures of natural phospholipids it may be higher, judging from the normal ranges in the cholesterol composition in biological membranes.

One possibility is that the stoichiometry between cholesterol and phospholipid established in one of these phases for a particular phospholipid or mixture of phospholipids is determined by the adjustment of volumes within the bilayer that is accomplished upon the dissolution of the cholesterol.¹⁰¹ The difference in cross-sectional area between the fused rings and the isoprenoid of the cholesterol cancels the imbalance between the cross-sectional area for the regions of alkane proximal to the glyceryl groups and the cross-sectional area for the hydrocarbon in the distal region beyond the eighth carbons of the fatty acyl groups. To effect this cancellation completely, there should be an optimal molar ratio between cholesterol and phospholipid. The fact that, within these separate phases formed between phospholipid and cholesterol, the molecules of cholesterol are evenly spaced, with each molecule of cholesterol surrounded by about four molecules of phospholipid,¹⁰⁴ is consistent with the adjustment of the volumes being the force establishing the stoichiometry and the very existence of these phases.

The distribution of electron density across a bilayer of amphipathic lipids in a membrane from a eukaryotic cell, represented by an equimolar mixture of cholesterol and phosphatidylcholine (Figure 14-4D), displays three regions.

First, the two symmetrical boundaries of high electron density, formed by the hydrophilic head groups, the glyceryl group, and the esters, sandwich the hydrocarbon and provide interfaces compatible with the water on either side. The distance between the two maxima of electron density that designate these two interfaces in a bilayer of phospholipid and cholesterol is 5.0–5.4 nm.^{47,98} In a natural membrane, these surfaces are irregular (Figure 14-5) and are formed by the phosphocholines, phosphoethanolamines, phosphoserines, phosphoinositols, and oligosaccharides. These surfaces are constantly changing in appearance owing to the fluid state of the bilayer.

Second, the two symmetric regions of hydrocarbon proximal to the glyceryl groups, formed by the first seven saturated carbons of the fatty acyl chains (Figure 14-2) and the fused rings of the cholesterol (**14-11**), have a lower electron density (Figure 14-4D) only because they are hydrocarbon. They are densely packed, with the alkane of the fatty acyl groups predominantly in its fully extended, all-*trans* configuration aligned normal to the plane of the bilayer, supported by the fused rings of the cholesterol and in turn spacing the molecules of cholesterol in a fairly uniform distribution. In one of the monolayers of a bilayer formed from an equimolar mixture of cholesterol and natural phosphatidylcholine, the cross-sectional area for each phospholipid is 0.48 nm², if the cross-sectional area for each cholesterol is 0.37 nm². The

width of each of the two symmetrically displayed proximal regions of hydrocarbon is about 1 nm. They commence at the level of the two acyl carbons attached to the glycerol and extend into the bilayer to the level at which the unsaturation of the fatty acids and the isoprenoid tail of the cholesterol commence.

Third, within these two symmetric boundaries, the central core of the bilayer contains the unsaturated hydrocarbon of the fatty acids and the disordered alkane of the fatty acids and the isoprenoid tail of the cholesterol. It has the lowest electron density (Figure 14-4D) because the disorder of the hydrocarbon in this region increases the frequency at which vacant space is encountered. It is believed that the hydrocarbon in the central core of the bilayer has most of the properties of liquid paraffin. The width of the central core, about 1.5 nm, brings the width of the entire sheet of hydrocarbon to about 3.6 nm.

When an amphipathic lipid, such as natural phosphatidylcholine from eggs of *G. gallus*, is spread at an **interface between air and water**, it forms a **monolayer** with its hydrophilic functional groups directed toward the water and its hydrophobic hydrocarbon directed toward the air. The area for each phospholipid in this monolayer is a function of the **surface pressure**. This pressure is exerted mechanically by changing systematically the area of the surface, and it is measured with a torsion balance. Above a certain pressure, or in other words below a certain area, the monolayer becomes so compressed that phospholipid molecules leave it and form small patches of bilayer adhering to the monolayer.

Before this breakdown, however, the area for each molecule of phospholipid at the interface is a monotonic inverse function of the surface pressure (Figure 14-11).^{105,106} The explanation for this behavior is that, at low pressure, the tendency of the hydrocarbon to be maximally disordered causes the monolayer to have a large surface area, which is about 3-fold greater than that of hexagonally packed linear alkane oriented normal to the interface. The molecules of phospholipid, at zero pressure, do not lie flat upon the surface, presumably because this would bring all of their hydrophobic hydrocarbon into contact with water. The observed **surface area at zero pressure** is a balance between the entropy that would spread the lipids and the hydrophobic effect that would contract them. As the surface is compressed and its free energy is thereby increased, the hydrocarbons become more and more aligned, and of lower and lower entropy. The surface area of a molecule of phosphatidylcholine in a normal fluid bilayer of natural phosphatidylcholine is about 0.7 nm^2 , which corresponds to a surface pressure of about 37 dyn cm^{-1} in a monolayer at an air-water interface.

The same measurements can be made on a monolayer of natural phosphatidylcholine at an interface between an alkane, such as *n*-hexadecane, and water (Figure 14-11).¹⁰⁶ At each surface pressure, the mono-

Figure 14-11: Relationship of surface pressure (dynes centimeter⁻¹) and area [nanometers² (mole of phosphatidylcholine)⁻¹] for monolayers of phosphatidylcholine purified from eggs of *G. gallus* at an interface between air and water (○)¹⁰⁵ or between *n*-hexadecane and water (△).¹⁰⁶ Phospholipid was spread at the interfaces from a solution in *n*-hexane; and, in the case of the interface with air, the hexane evaporated immediately, leaving behind the monolayer of lipid. In each case, a monolayer of phosphatidylcholine was produced. The area of the interface could be varied by movable boundaries, and the interfacial pressure could be measured directly by a torsion balance. Areas for a molecule of phospholipid were calculated on the assumption that all of the phospholipid added to the system had been incorporated into the monolayer. Arrows mark areas of $0.7 \text{ nm}^2 \text{ mol}^{-1}$. Adapted with permission from refs 105 and 106. Copyright 1960 Biochemical Society and 1971 Springer-Verlag.

layer in this situation has a greater surface area than when it is backed by air. The reason for this is that, because of van der Waals forces, liquid alkane is more compatible with the hydrocarbon side of the monolayer than is air; and when the monolayer is backed by alkane, there is not an interfacial free energy causing it to contract spontaneously and minimize its surface area at the interface between hydrocarbon and air as well as at the interface between phospholipid and water. Consequently, the pressure needed to compress this monolayer to 0.7 nm^2 (molecule of phosphatidylcholine)⁻¹ is 44 dyn cm^{-1} .

A droplet of alkane in water has a surface tension of about 50 dyn cm^{-1} , which reflects the free energy of the hydrophobic effect. As amphipathic lipid is added to a droplet of alkane, its surface tension rapidly decreases and reaches zero before the mole fraction of the amphipathic lipid reaches 1.¹⁰⁷ When its surface tension reaches zero, the surface area of the droplet will begin to

expand indefinitely, and at a mole fraction of amphipathic lipid equal to 1, it will be a bilayer.¹⁰⁸ That the **surface tension of a bilayer of amphipathic lipid** is zero has been verified experimentally.¹⁰⁶ The initial surface tension of the droplet of alkane is a direct measurement of the cohesive force of the hydrophobic effect. In the bilayer, this cohesive force is still in operation, trying to minimize its surface area, but it is counterbalanced by the hydration of the head groups.

From these various considerations, it follows that a bilayer of amphipathic lipids immersed in an aqueous solution represents a **compromise among a number of forces**. The hydrocarbon of the fatty acyl groups is hydrophobic and is withdrawn as successfully as possible from contact with the water by the cohesive force of the **hydrophobic effect**. The most successful stereochemical solution to this problem would be all-*trans* alkane in the regions proximal to the water oriented normal to the surface in hexagonal array. The presence of *cis* double bonds, the **steric effects of hydration**, and the **entropy of the liquid state** defeat this solution (Figures 14-10 and 14-11) and cause the cross-sectional area for each amphipathic lipid to be greater than the value of 0.40 nm² for hexagonal packing. This stereochemically enforced spreading of the bilayer must expose some of the hydrocarbon in the regions proximal to the water.⁸⁸ The hydrophilic head groups of the amphipathic lipids are facing the aqueous phase. If they were buried or sterically excluded from contact with water, their **free energies of hydration** would be lost, which would be unfavorable (Figures 5-8 and 5-18). In the compromise among the various forces, a bilayer of unadulterated natural phosphatidylcholine ends up with about half the surface area (0.7 nm²) for each molecule in one of its two monolayers as that for a molecule in a monolayer of phosphatidylcholine at an air-water interface (Figure 14-11) at zero surface pressure. Presumably, this difference between a bilayer and a monolayer arises from the greater cohesion, due to van der Waals forces, that can be established within an interior of liquid hydrocarbon as opposed to a thin layer of hydrocarbon at an interface with air and from the fact that there are two interfaces with the water, one on each side of the bilayer.

A bilayer represents one example from a spectrum of different **structures that can be formed by amphipathic compounds** such as amphipathic lipids, soaps, and detergents. An amphipathic compound usually contains one or more hydrocarbons that are each covalently attached at one of their ends to the others and to one or more hydrophilic functional groups. When an amphipathic compound is added to an aqueous solution, it forms noncovalent, multimolecular complexes referred to as either micelles or bilayers. In these complexes, all of the hydrophilic functional groups of the constituent molecules reside on the surface at the interface or interfaces with the aqueous phase so that they can be hydrated by the water. The hydrocarbon occupies the interior of the

complex sequestered from the aqueous phase by the hydrophobic effect. The **molar volume of the hydrocarbon** in the complex is determined simply by the partial molar volume of the hydrocarbon from which it is composed.

The final **molar surface area** at an interface of the complex with the aqueous phase, however, is determined by the balance between two opposing forces.^{23,109} The hydrophilic functional groups have an inescapable atomic cross-sectional area for their covalent structure that forces them to be spaced at least a minimum distance apart on the surface of the complex. This spacing is increased by the layers of hydration that are noncovalently associated with each hydrophilic functional group and any mutual electrostatic repulsion driving them apart. The farther apart the hydrophilic functional groups are spaced to relieve these repulsive forces, the more of the hydrocarbon to which they are covalently attached is drawn out to the surface to come in contact with water. This exposure of the hydrocarbon to water is resisted by the hydrophobic effect. The balance between the intermolecular repulsion among the hydrophilic functional groups and the hydrophobic effect determines the ultimate molar surface area of the complex.

There is a third geometric constraint on the complex. Because every hydrocarbon is covalently attached to one or more hydrophilic functional groups, and every hydrophilic functional group must remain in contact with the aqueous phase, no carbon in the interior of the complex can be located more than a **maximum distance from the aqueous phase**. If the hydrocarbon were fully extended linear alkane with all of its carbon-carbon bonds in the all-*trans* conformation, that maximum distance would be the maximum length of the amphipathic molecule. A certain amount of the hydrocarbon, however, having been dragged out of the interior by the repulsive forces among the hydrophilic functional groups, is required to occupy the surface of the complex, and the hydrocarbon in the interior is rarely fully extended because it is fluid and because it must mix to fill the interior. Therefore, the maximum distance any carbon can be from the aqueous phase is significantly less than the maximum length of the fully extended hydrocarbon found in the amphipathic molecule. One dimension of the complex formed from molecules of the amphipathic compound must always be less than or equal to twice this maximum distance. If it were not, the complex would contain a region farther from the aqueous phase than any matter can be located.

The dimensions of the complex that an amphipathic compound can form are dictated by this maximum dimension. The **shapes** available are a sphere the radius of which is less than or equal to the maximum dimension; an ellipsoid of revolution, prolate or oblate, the minor axis of which is less than or equal to the maximum dimension; a cylindrical rod of indefinite length the diameter of which is less than or equal to the maxi-

mum dimension; a bilayer of indefinite area the width of which is less than or equal to the maximum dimension; or cylindrical rods, ellipsoids of revolution, or spheres of water embedded uniformly in a volume otherwise filled with the amphipathic compound and spaced such that no distance between two adjacent surfaces of these aqueous inclusions is greater than the maximum dimension.

The choice among these different geometric alternatives in a given situation is determined by the ratio between the molar surface area, which is determined independently by the repulsion among the hydrophilic functional groups and the hydrophobic effect, and the molar volume, which is determined by the molecular structure of the particular amphipathic compound. The hydrocarbon of the compound must also be able sterically to fill the volume allotted to it by a particular shape;⁸⁸ certain volumes are too anisotropic to be filled by real hydrocarbon, which is made from atoms of carbon and hydrogen joined by covalent bonds of precise bond angle and bond length and around which only particular rotations are permitted, even though these same volumes can be filled with imaginary hydrocarbon, which is a uniform continuum that can fill any shape drawn on a sheet of paper.

Several examples will illustrate the outcome of the competition among the various free energies. When one of the fatty acyl chains is removed from phosphatidylcholine to form **lysophosphatidylcholine**, the product forms **ellipsoidal micelles**²³ rather than bilayers because the internal volume of a bilayer about half the width of that formed by phosphatidylcholine that would be dictated by the appropriate molar surface area and molar volume cannot be filled uniformly by the hydrocarbon available, but an ellipsoidal micelle, with its smaller and more isotropic volume for each unit of surface area, can be filled readily. When suspended in 6% ethanol in water at 40 °C, distearoylphosphatidylcholine forms a phase in which the alkyl chains of its fatty acids interdigitate, rather than butting up against each other, to produce a narrower bilayer.^{110,111} The ethanol promotes the increased exposure of the hydrocarbon to the water required by the increased cross-sectional area for each phospholipid. Dodecyl sulfate in 0.3 M lithium chloride forms spherical micelles because the electrostatic repulsion among the sulfates is sufficient to produce the largest possible ratio of molar surface area to molar volume and the linear, fully saturated hydrocarbon is flexible enough to fill the appropriate spherical volume uniformly.¹¹²

A heterogeneous mixture of phospholipids extracted from mammalian brain, when hydrated at 37 °C to a low content of water ($\leq 20\%$), forms a **reversed hexagonal phase**¹¹³ in which parallel cylinders of water spaced 4.5 nm apart are embedded in a volume otherwise filled with phospholipid.^{114,115} In this case, the poorly hydrated hydrophilic functional groups of the

phospholipids produce such a small molar surface area that when combined with the unavoidable molar volume of the acyl groups, it would produce a bilayer wider than the maximum dimension permitted these phospholipids. Pure phosphatidylethanolamine, presumably because its head group is more compact than that of phosphatidylcholine, forms bilayers under certain circumstances and reversed hexagonal phases under other circumstances. The reverse hexagonal phase of phosphatidylethanolamine becomes more stable relative to the bilayer as the temperature is raised, the length of the fatty acyl groups is increased, the unsaturation of the fatty acyl groups is increased, or when the fatty acyl groups are branched.¹¹⁶ All of these alterations increase the cross-sectional area of the hydrocarbon and favor the reversed hexagonal phase with its lower ratio of surface area in contact with water to mean cross-sectional area for hydrocarbon.

The fact that the particular phospholipids synthesized by living organisms form bilayers spontaneously rather than one of these other structures is as much a result of evolution by natural selection as the fact that the polypeptides synthesized by living organisms happen to fold.

The Proteins

Even a homogeneous suspension of biological membranes, highly purified by a series of centrifugations so that only identical membranes from the same source within the cells are present, contains a diverse collection of proteins. These proteins fall into several categories. All membranes when they are present in the cell are closed continuous sacs, containing solutions of soluble proteins. Even if the final suspension of purified membranes has been submitted to lysis and centrifugation, **entrapped soluble proteins** may still be enclosed in small vesicles of membrane and contaminate the preparation. For example, it is difficult to obtain from erythrocytes a suspension of plasma membranes completely devoid of hemoglobin.

Peripheral membrane-bound proteins¹¹⁷ are proteins that are not physically embedded in the bilayer of phospholipid but are associated with the membrane either through interfaces with proteins that are embedded in the bilayer or through superficial interactions with the bilayer of phospholipid of the membrane. Peripheral

membrane-bound proteins can be dissociated by treatments that do not dissolve the bilayer of the membrane. If they are associated with more firmly attached proteins, they can often be removed from the membrane by mild treatments that are normally used to dissociate the subunits of multimeric proteins. Examples of such treatments are increasing or decreasing either the pH or the ionic strength, removing divalent cations, using mild denaturants, or some combination of these treatments.^{118–120} For example, the cytoskeletal proteins spectrin and actin can be released from the plasma membranes of erythrocytes by chelating divalent cations.¹²¹

Some peripheral membrane-bound proteins **associate directly with the head groups** of the phospholipids in a bilayer. For example, in the presence of Ca^{2+} , isoform V of annexin associates at diffusion-controlled rates ($1 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$) with large unilamellar vesicles of phospholipid¹²² and releases from these vesicles rapidly upon chelation of the Ca^{2+} . In contrast to annexin, which displays no preference for the head group of the phospholipid,¹²² the peripheral association of protein kinase C with vesicles of phospholipid requires that they contain significant concentrations of phosphatidylserine,¹²³ and the dissociation constant between the enzyme and the phospholipid bilayer decreases as the concentration of 1,2-diacylglycerol in the membranes is increased.^{124,125} That the interaction of protein kinase C is mainly with the hydrophilic surface of the bilayer is suggested by the fact that the interaction requires the naturally occurring enantiomers of both the phosphatidylserine and the diacylglycerol.¹²⁶ That no association occurs with bilayers formed from the unnatural enantiomers demonstrates that it is not the surface charge of the bilayer that is being recognized by protein kinase C but the head groups themselves. The pleckstrin domain of phospholipase C binds specifically to one molecule of phosphatidylinositol 4,5-bisphosphate within a bilayer of phospholipid,¹²⁷ and prothrombin and protein Z both also seem to bind to the head group of only one of the phospholipids in a bilayer.¹²⁸

In contrast to these proteins that recognize the head groups of the phospholipids specifically, the peripheral association of choline-phosphate cytidylyltransferase with a bilayer of phospholipid requires only that its **surface charge** be negative because any negative phospholipid promotes its binding.¹²⁹

An **anchored membrane-bound protein** is a protein a portion of whose primary covalent structure, uninvolved in its function, is immersed within the hydrocarbon of the bilayer of phospholipid and serves only to anchor the protein to the membrane. The portion of the protein embedded in the bilayer is not engaged in the native structure of the globular domain or globular domains to which it is covalently joined and can often be removed endopeptidolytically or by genetic manipulation to produce a protein that is soluble and that still displays all of the functions of the membrane-bound form.

Often the embedded portion in an anchored membrane-bound protein is a short segment of polypeptide at its **amino terminus or carboxy terminus** that appears to have been tacked on to an otherwise soluble protein to confine it to the surface of the membrane. Carboxypeptidase E is attached to the membranes of secretory granules from the adrenal medulla through an **amphipathic α helix** (see Figure 6–8) about 20 aa in length at its carboxy terminus.¹³⁰ The hydrophobic surface of this α helix is submerged in the hydrocarbon of the bilayer of phospholipid. A more common type of anchor, however, is a segment of polypeptide at one of the termini that spans the bilayer of the membrane. For example, bovine polypeptide *N*-acetylgalactosaminyltransferase has the amino-terminal sequence MRKFAYCKVVLATSLIWVLLDMFLLLYFSECNKCDEKKER–.¹³¹ The segment from Valine 9 to Phenylalanine 28 spans the bilayer of phospholipid that forms one of the Golgi membranes to which the protein is anchored, and the rest of the protein is a normal water-soluble, globular structure.¹³² This enzyme is a member of a large group of glycosyltransferases, each of which is anchored to the Golgi membranes.¹³³ Cytochrome c_1 is a cytochrome that is anchored in the mitochondrial membrane by a **membrane-spanning segment** at its carboxy terminus. When this segment is removed, a completely soluble form of the cytochrome is produced that is functionally intact.¹³⁴ Cytochrome c_1 , however, in addition to possessing the carboxy-terminal anchor, is also, under normal circumstances, a subunit of ubiquinol-cytochrome-*c* reductase, a large, heterooligomeric, membrane-spanning complex.

Many proteins are directed to certain organelles in the cell by amino-terminal **signal sequences**. The signal sequence directing bovine dopamine- β -monooxygenase to secretory granules of the adrenal medulla is a hydrophobic segment 20 aa in length, and if the signal sequence is not removed as it normally is, it becomes a membrane-spanning segment anchoring this protein in the bilayer of phospholipid.¹³⁵

Sometimes a **separate domain** at one of the termini of a protein is responsible for anchoring it within the bilayer of phospholipid. For example, the domain of 60 aa at the amino terminus of the receptor Tom 20 is an anchor embedded in the outer mitochondrial membrane,^{136,137} and the domain of 103 aa at the carboxy terminus of 3-hydroxybutyrate dehydrogenase¹³⁸ is an anchor embedded in the inner mitochondrial membrane; each of these domains anchors the otherwise soluble protein into its respective membrane. Hydroxymethylglutaryl-CoA reductase, which is an anchored membrane-bound protein by virtue of the fact that a detachable domain with full catalytic activity can be removed from the membrane by endopeptidolytic cleavage, has an embedded anchor almost 400 amino acids in length containing seven hydrophobic segments of greater than 20 aa each.¹³⁹

The segment of the polypeptide anchoring a protein in a bilayer of phospholipid can also be in its interior.¹⁴⁰ The amino acid sequence between Methionine 177 and Alanine 229 in (S)-mandelate dehydrogenase from *Pseudomonas putida*, a protein 393 aa in length, anchors it in the plasma membrane of the bacterium. When this segment is replaced by sequence 20 aa in length that occupies the homologous location in (S)-2-hydroxy-acid oxidase, a closely related but completely soluble protein, the resulting chimera no longer associates with the membrane, is fully active, and can be readily crystallized.^{141,142} The three respective **interior segments** of coagulation factor VIII¹⁴³ and coagulation factor V¹⁴⁴ responsible for anchoring each of them in a bilayer of phospholipid form loops directing hydrophobic side chains into the hydrocarbon of the membrane.

Proteins that have been posttranslationally modified with glycosylphosphatidylinositol (Figure 3-17) are anchored in their respective membranes by the covalently attached phosphatidylinositol, which spontaneously takes its place within the bilayer of phospholipid.^{145,146} The set of **glycosylphosphatidylinositol-linked (GPI-linked) proteins** is a heterogeneous collection. Their respective functions are unrelated to each other, so their common mode of attachment is probably fortuitous. They are, however, all inserted into the extracytoplasmic surfaces of the plasma membranes of the respective cells in which they are found. Immediately after they have been synthesized, these proteins are anchored temporarily in the membrane by a carboxy-terminal segment of their polypeptide that is rich in hydrophobic amino acids. The ultimate carboxy terminus of the posttranslationally modified protein is a glycine, alanine, cysteine, serine, or asparagine 15-30 amino acids in from the initial carboxy terminus. Through an enzymatically catalyzed transamidation, the carboxy terminus of this amino acid is transferred from the carboxy-terminal segment of 15-30 amino acids to which it was originally attached to the amine of the ethanolamine phosphate connected through the oligosaccharide to the phosphatidylinositol (Figure 3-17).¹⁴⁷

A glycosylphosphatidylinositol-linked protein can be identified by its ability to be released from the surface of the cell by glycosylphosphatidylinositol diacylglycerol-lyase¹⁴⁸ or by site-directed mutation.¹⁴⁹ Once released, the resulting globular, soluble protein can be purified and crystallized.^{149,150} In fact, glycosylphosphatidylinositol-linked proteins are often isoforms from species of proteins the other members of which are water-soluble and make no contact with membranes. Examples of such glycosylphosphatidylinositol-linked proteins are the variant surface glycoprotein on the exterior of cells of *Trypanosoma brucei*,¹⁵¹ the receptor for the F_c domain of immunoglobulin G on the exterior surface of neutrophilic lymphocytes,^{152,153} one isoform of acetylcholinesterase on the exterior surfaces of several types of animal cells,¹⁵⁴⁻¹⁵⁶ isoform IV of carbonate dehydratase on the exterior surfaces of cells from lung and

kidney,^{157,158} and the cell surface glycoprotein a-2 on the exterior surfaces of hematopoietic cells.^{159,160} Sometimes two isoforms of one of these proteins, the glycosylphosphatidylinositol-linked isoform and an isoform anchored to the membrane by a carboxy-terminal membrane-spanning segment of polypeptide, are produced in the same tissue.^{160,161}

Each of the various types of anchor is **more or less firmly embedded** in the bilayer of phospholipid. The segments of polypeptide at the amino or carboxy termini that span the bilayer, either once or several times, are permanently affixed to it. Amphipathic α helices, either at one of the termini¹³⁰ or in the middle of the protein,¹⁴² are much less firmly embedded and can be dissociated under appropriate circumstances.¹³⁰ Proteins that dip loops of their polypeptide in the bilayer of phospholipid are also less firmly embedded, display requirements such as negative surface charge for competent association, and have measurable dissociation constants.¹⁶² A protein with an anchor of glycosylphosphatidylinositol is permanently embedded in the membrane because its covalently attached phosphatidylinositol, with two fatty acids of the normal length, is so hydrophobic that its dissociation constant from the bilayer of phospholipid is immeasurably small.⁶³ Proteins posttranslationally modified by isoprenylation, however, because they have only one covalently attached hydrocarbon (Figure 3-16), are less firmly anchored in the membrane. Those with a geranylgeranyl modification ($C_{20}H_{33}$) have dissociation constants^{163,164} for a bilayer of phospholipid of 0.1-40 μ M; and those with a farnesyl modification ($C_{15}H_{25}$), 1-150 μ M. The particular value of the dissociation constant depends on the number of basic amino acids in the carboxy-terminal sequence of the protein and the surface potential of the bilayer of phospholipid.

Proteins that have been posttranslationally modified by **acylation with fatty acids** such as palmitic acid, oleic acid, and stearic acid (Table 3-1)¹⁶⁵ are usually bound to the cytoplasmic surface of the plasma membrane.¹⁶⁶ They are bound tightly because these proteins usually have several sites of fatty acylation. In some cases, however, it is unclear whether such fatty acylation is directed almost exclusively to an otherwise membrane-bound protein after it has associated irreversibly with the membrane or the fatty acylation itself promotes the association of the protein with the membrane. For example, proteolipid protein from myelin is a membrane-bound protein with six cysteines in its amino acid sequence that are fatty acylated, but it also has several membrane-spanning segments.¹⁶⁷ The cytochrome subunit of the photosynthetic reaction center from *Rhodospseudomonas viridis*, however, has a diglyceride in ether linkage with its amino-terminal cysteine that does seem to be the only portion of the protein anchoring it in the membrane.¹⁶⁸

Proteins that are posttranslationally modified by **myristoylation** of their amino termini (tetradecanoyl in

Figure 3–16) may or may not associate with membranes. Whether or not they do seems to depend on their amino-terminal sequence and the accessibility of the myristate. The amino-terminal segments of several normally *N*-myristoylated proteins associate with bilayers of phospholipids even when they are not myristoylated^{169,170} either by forming an amphipathic α helix or by accumulating at membranes with negative surface potential.¹⁷¹ Other *N*-myristoylated proteins, however, lose their ability to associate with the membrane when they are not myristoylated.¹⁷² Yet other proteins either associate with membranes or fail to associate depending on whether or not their myristoyl groups are fully exposed on their surface or buried in their interior.¹⁷³ The variability in behavior is probably the result of the fact that the dissociation constant for just a myristoylated amino terminus from a bilayer of phospholipid is only about 0.1 μ M.¹⁷⁴

Many **enzymes** catalyze reactions in which phospholipids, steroids, other membrane-bound proteins, or other molecules embedded in a membrane are substrates. To find their substrates, these enzymes must associate with the membrane in which those substrates are located. Such enzymes often bind tightly to those membranes and process their substrates by **scooting** across their surfaces.^{175–177} They can be firmly anchored in the membranes with which they associate by embedding one or more segments of their polypeptides in the bilayer of phospholipid.¹⁷⁸ For example, the polypeptide between Isoleucine 50 and Asparagine 98 of prostaglandin-endoperoxide synthase forms four short α helices that are embedded in one of the monolayers of the bilayer of amphipathic lipids¹⁴⁰ forming the membrane. The membrane to which it is anchored contains the phospholipids to which are acylated the arachidonoyl groups that are the substrates for this enzyme. Enzymes that must move from one membrane to another to perform their function, however, are only loosely associated with the respective bilayers of phospholipids. For example, isoform 2 of sterol carrier protein associates desultorily with membranes by an amino-terminal segment forming two amphipathic α helices.¹⁷⁹ Enzymes that catalyze reactions with membrane-bound substrates are often anchored in the membrane only by a portion of their structure uninvolved in the actual catalysis. Unlike anchored membrane-bound proteins, however, they would be unable to perform their function were the anchor to be removed and they were no longer able to associate with a membrane, because they would be unable to find their substrates.

An **integral membrane-bound protein** is a protein a portion of the polypeptide of which is permanently embedded in the bilayer of phospholipid constituting its membrane, and that portion of its polypeptide within that membrane is essential for its function. There is a family of proteins, exemplified by the receptor for epidermal growth factor,^{180,181} the members of which contain only one short hydrophobic segment of their

polypeptide embedded within membrane. This segment is in the middle of the amino acid sequence^{182–184} and spans the bilayer of phospholipid once. On the two ends of this membrane-spanning segment, there are globular domains on the cytoplasmic and extracytoplasmic sides of the membrane. The role of these proteins is to transmit across the membrane to their cytoplasmic domains the information that a circulating hormone is bound to their extracytoplasmic domains. Upon receipt of the information, a protein tyrosine kinase, catalyzed by the cytoplasmic domain, is activated. Neither domain by itself is capable of displaying hormone-dependent protein tyrosine kinase activity,¹⁸³ so in this case, the single membrane-spanning segment performs a much greater role than merely anchoring the protein in the membrane.

Usually, however, a significant portion of the native structure of the polypeptide or polypeptides of an integral membrane-bound protein¹¹⁷ is **within the hydrocarbon of the bilayer** of amphipathic lipids forming the membrane. Integral membrane-bound proteins can never be detached in a functional form from the bilayer by endopeptidolytic cleavage or site-directed mutation and often lose their native structure or precipitate from solution or both when the bilayer is completely dissolved by detergents. As with any protein, the native structure of the portion of an integral membrane-bound protein that is within the membrane is determined by the solvent in which it is dissolved. This solvent is a sheet of liquid paraffin about 3.6 nm wide possessing covalently attached oligosaccharides, anions, and zwitterions at both of its surfaces and in contact on each of its surfaces with an aqueous solution.

Examples of integral membrane-bound proteins that are required by their function to have significant portions of their mass within the hydrocarbon itself are proteins that form **channels** through the membrane for the transport of polar, water-soluble metabolites across the membrane, proteins that catalyze the **active transport** of metallic cations and metabolites against their gradients of concentration across the membrane, large complexes of subunits that catalyze **electron transport** and the concomitant active transport of protons across the membrane, and proteins that change their conformation or oligomeric state upon the **reception of information** to transfer that information across the membrane. Integral membrane-bound proteins can also be enzymes the substrates for which are dissolved in and confined to the membrane.¹⁸⁵

Integral membrane-bound proteins vary in **size** from diacylglycerol kinase of *E. coli*, with a single folded polypeptide 121 aa in length,¹⁸⁵ to the ryanodine receptor of animal sarcoplasmic reticulum, with a single folded polypeptide about 5000 aa in length,¹⁸⁶ or NADH dehydrogenase (ubiquinone), a complex of 45 different subunits for a total of about 9000 aa.¹⁸⁷

The distinction between an anchored membrane-bound protein and an integral membrane-bound protein

is not a clean one. For example, a membrane-bound protein known as glycophorin is found in the plasma membrane of erythrocytes. The protein is 131 amino acids long, and its embedded anchor¹⁸⁸ is located to the carboxy-terminal side of Glutamate 72. This embedded anchor spans the plasma membrane.¹⁸⁹ The 35 carboxy-terminal amino acids on the cytoplasmic side of the membrane are rich in proline and seem to be structureless and functionless, simply acting as a barb that cannot be pulled across the membrane. The protein is about 60% carbohydrate by weight,¹⁸⁸ and this carbohydrate is entirely linked as oligosaccharides¹⁹⁰ to the extracytoplasmic amino-terminal portion of the protein through 15 *O*-glycosidic linkages to threonines and serines and one *N*-glycosidic linkage.¹⁸⁸ The function of glycophorin is to serve as the source of most of the oligosaccharide on the extracytoplasmic surface of the erythrocyte, so its function would be lost if its anchor were removed.

Membrane-bound proteins are inserted into natural membranes such that every copy of the same protein is oriented in the same direction relative to the cytoplasm. The earliest observations addressing this point explicitly confirmed this assumption of **vectorial insertion**.^{117,191,192} For example, nucleophilic amino acids in 10 of the thermolytic peptides on the peptide map of a digest of band 3 anion transport protein from human erythrocytes could not be modified with *N*-formyl-[³⁵S]sulfinylmethionyl methylphosphate, a polar reagent that cannot pass through an intact membrane, when the native protein was in sealed, intact erythrocytes, even though they could be readily modified when the erythrocytes were broken open.¹⁹¹ The explanation of this observation is that every copy of anion carrier is oriented the same way in the membrane, each presenting the same unique surface to the cytoplasmic space of the cell as well as a different, also unique face to the extracytoplasmic space, and that the cytoplasmic surface is inaccessible to the impermeant reagent in an intact cell. Since these early studies, many examples of vectorial insertion have been verified, and no example of a membrane-bound protein the copies of which are oriented at random in a natural membrane has been verified.

A property related to the vectorial insertion of every protein in a biological membrane is the asymmetric distribution of the oligosaccharides on the **glycoproteins** and glycolipids embedded in the plasma membranes of cells. Almost all¹⁹³ of the oligosaccharide bound to the plasma membrane of an animal cell is located upon its extracytoplasmic surface.^{194,195} This feature is a corollary of the fact that almost no¹⁹⁶ glycoproteins are found in the cytoplasm, only in extracytoplasmic spaces, and a direct result of the fact that the glycosyltransferases that synthesize the oligosaccharides on these glycoproteins are in the extracytoplasmic lumens of the Golgi membranes. Membrane-bound proteins are synthesized on ribosomes bound to the endoplasmic reticulum and incorporated in their proper orientation by the machin-

ery responsible for their insertion into the membranes of the endoplasmic reticulum. The membrane in which they have been incorporated is then sent to the Golgi membranes where the oligosaccharides are added. Then vesicles, which bud off the Golgi membranes and which maintain the vectorial orientation of the membrane-bound proteins and their attached oligosaccharide, transport them to the plasma membrane. These vesicles then fuse with the plasma membrane so that their extracytoplasmic surfaces, on which the membrane-bound oligosaccharides reside, and their extracytoplasmic lumens, in which the soluble glycoproteins are located, remain extracytoplasmic.

In addition to glycosylation, membrane-bound proteins are posttranslationally modified as often as are water-soluble proteins. For example, they can be modified to contain covalently attached coenzymes or they can be phosphorylated.

When a suspension of purified membranes is examined by electrophoresis in solutions of dodecyl sulfate, a large collection of different polypeptides, each present at its own characteristic concentration, is observed (Figure 14-12).¹⁹⁷ Each of these polypeptides is a component of one of the many native proteins bound to the membranes, and the protein it constitutes is responsible for a particular biochemical function. Therefore, a biological membrane, although often much less complex, resembles cytoplasm in being a **heterogeneous solution of a large number of different proteins**, each present at a different concentration and each with a specific function. Many of the functions performed by membrane-bound proteins have been identified, and biochemical assays have been developed for determining their presence and their concentration. In many instances, the protein responsible for one of these functions has been identified and purified, and its cDNA has been cloned and sequenced.

Because membrane-bound proteins are often more difficult to purify than soluble proteins, indirect procedures are often used to **identify the gene** encoding them to assist in their purification. Classical genetics can be used with bacteria and fungi to identify the gene encoding a membrane-bound protein responsible for a particular function.¹⁹⁸⁻²⁰¹ It is also possible to select a cDNA encoding a membrane-bound protein that is responsible for a particular function, such as the transport of a particular metabolite²⁰² or a change in the conductance of the membrane in response to a neurotransmitter,²⁰³ by screening the expression of a library of cDNA in oocytes of *Xenopus laevis*. If a cDNA has been identified before a membrane-bound protein has been purified, that cDNA can be modified to assist in its purification. For example, the protein can be expressed with a sequence of histidines at its carboxy terminus to permit its purification by affinity adsorption.²⁰⁴ If the protein is an anchored membrane-bound protein, a site for endopeptidolytic cleavage can be inserted to ensure that the protein can be

Figure 14-12: Polyacrylamide gels displaying the collection of polypeptides found in the plasma membranes of erythrocytes from *R. norvegicus* (A), the plasma membranes of cells from liver of *R. norvegicus* (B), and the portion of the plasma membrane of kidney cells from *R. norvegicus* referred to as the brush border (C).¹⁹⁷ Purified membranes from these various tissues were dissolved in a solution of sodium dodecyl sulfate, which unfolded and coated each polypeptide with a layer of dodecyl sulfate. The polypeptides were then separated by electrophoresis on gels of polyacrylamide cast in a solution of sodium dodecyl sulfate. Each band represents a different polypeptide. The dashes indicate polypeptides that are glycosylated. Reprinted with permission from ref 197. Copyright 1971 *Journal of Biological Chemistry*.

released from the membrane by digestion.²⁰⁵ In most cases, however, a membrane-bound protein of interest is purified before the cDNA for it is available.

The purification of the particular membrane-bound protein identified by a biochemical assay proceeds in two stages. In the first stage, a biological source is chosen that contains the highest possible concentration of the protein. This involves assaying the biochemical activity in different tissues from different species or trying to increase the concentration of the protein in its active form by genetic manipulation of a microorganism or cultured eukaryotic cells. Membranes that contain the protein in high concentration are then separated by the procedures of **cell fractionation** from other membranes in the biological source that contain little or none of the protein. These purified membranes are lysed to release the entrapped soluble proteins and submitted to treatments that release peripheral membrane-bound proteins without inactivating or releasing the protein of

interest. The product of these manipulations is a suspension of membranes in which are embedded the protein of interest in the highest possible concentration. At the completion of this first stage, the membrane-bound protein being purified may be essentially homogeneous. For example, fragments of membrane the only protein of which (90%)²⁰⁶ is Na^+/K^+ -exchanging ATPase can be purified²⁰⁷ from a region of the mammalian kidney, the only function of which is to transport sodium and potassium. In the kidney these membranes are paved with this protein. Many of the membrane-bound proteins that have been purified to homogeneity are those that are already present at high density in such suspensions of appropriately purified and extracted membranes.

Once **membranes enriched in a particular protein** have been obtained, the next step in its purification is to release that protein from them. The few proteins that are linked to the membrane by glycosylphosphatidylinositol can be released by glycosylphosphatidylinositol diacylglycerol-lyase and then purified as water-soluble proteins. Anchored membrane-bound proteins can often be released from a membrane by mild endopeptidolytic digestion while retaining their full biological activity. The majority of membrane-bound proteins, however, cannot be released from the membrane so easily, and the second stage in their purification is usually to dissolve the membranes without unfolding the protein and then purify the dissolved protein as if it were a soluble protein. A non-ionic or zwitterionic detergent is used to **dissolve the membranes**, because nonionic or zwitterionic detergents bind only to the hydrophobic membrane-spanning portions of integral membrane-bound proteins and are unable to bind tightly all along a polypeptide and unfold it as does dodecyl sulfate.^{208,209} Ionic detergents, such as those used to wash laundry, are much harsher than non-ionic detergents, which are used for washing dishes by hand or for shampoos.

Nonionic or zwitterionic detergents are amphipathic compounds that have neutral or zwitterionic hydrophilic functional groups attached to one end of their hydrocarbon. A common class of **nonionic detergents**, the **alkyl oligo(ethylene oxide) ethers** (Brij series), is synthesized from linear, saturated primary alcohols produced commercially by the reduction of linear fatty acids 12–20 carbons in length. Because these fatty acids are usually from biological sources, the alcohols usually have an even number of carbons. Ethylene oxide is polymerized at random to the hydroxyl of one of these alcohols to form the detergent $\text{CH}_3(\text{CH}_2)_m\text{CH}_2\text{O}(\text{CH}_2\text{CH}_2\text{O})_n\text{H}$. The length of the alcohol ($m + 2$) is defined by the synthesis, but when the detergent is prepared for commercial use, the ethylene oxide is simply polymerized at random to produce a random mixture of hydrophilic extensions of different lengths within the same batch of synthetic detergent. As demand grew for structurally homogeneous detergents, the mixtures of these random polymers were separated chromatograph-

ically into their pure components to produce detergents such as $n\text{-C}_{12}\text{H}_{25}\text{O}(\text{CH}_2\text{CH}_2\text{O})_8\text{H}$ (abbreviated C_{12}E_8) and $n\text{-C}_8\text{H}_{17}\text{O}(\text{CH}_2\text{CH}_2\text{O})_4\text{H}$ (abbreviated C_8E_4). Another series of structurally heterogeneous oligo(ethyleneoxide) detergents are the **Tritons**:

14-12

A broad class of nonionic detergents each member of which can be synthesized directly in pure form are the **alkyl glycosides**. A pure saccharide such as glucose or maltose is coupled synthetically to a pure long-chain alcohol such as octanol, decanol, or dodecanol in a glycosidic linkage at the carbonyl carbon of the saccharide. An example of such a structurally homogeneous detergent would be decyl $\beta\text{-D}$ -maltoside:

14-13

The exclusive coupling of the alcohol to the only carbonyl carbon of the saccharide in acetal linkage permits the direct synthesis of a detergent that is structurally homogeneous except at the anomeric carbon, and the two anomers can then be separated chromatographically. Either glucose or maltose can be chosen as the hydrophilic group and an alcohol of length between 8 and 14 carbons can be chosen as the hydrophobic group to generate a wide selection of different detergents. A set of related, naturally occurring detergents are the **saponins**, which are glycosides of triterpenes such as oleanolic acid. In the saponins, monosaccharides, disaccharides, and trisaccharides are coupled in acetal linkage to hydroxyls and carboxylates on the triterpene to produce biosynthetically a dramatically heterogeneous mixture.²¹⁰

A structurally homogeneous class of **zwitterionic detergents** that can be synthesized directly are the N -oxides of linear dimethylalkyl amines such as N,N -dimethyldodecylamine N -oxide:

14-14

3-[(3-Cholamidopropyl)dimethylammonio]-1-propane-sulfonate (CHAPS)

14-15

is a zwitterionic detergent that is synthesized from cholic acid, which itself is a mild ionic detergent, as is 7-deoxycholic acid.

Each of these detergents, the pure and the impure, because it contains only a single amphipathic compound or is a mixture of several related amphipathic compounds, forms elliptical micelles when it is dissolved in water. If the detergent is pure, however, the micelles that it forms in aqueous solution are of a uniform size (Table 14-5). Each detergent has a **critical micelle concentration** (Table 14-5). When its concentration is below the critical micelle concentration, the detergent is present in solution as free, independent molecules; and when its concentration is above the critical micelle concentration, there is a mixture of free molecules of detergent at the critical micelle concentration and micelles of detergent accounting for the excess over the critical micelle concentration. As the concentration of detergent is increased above the critical micelle concentration, the concentration of free detergent remains constant while the concentration of micelles increases.

At high enough concentrations, a nonionic detergent in aqueous solution is able to form **mixed micelles with phospholipids and cholesterol** and thereby dissolve membranes.²¹²⁻²¹⁴ There are several stages in this dissolution of a bilayer of phospholipid by a nonionic detergent.²¹⁵⁻²¹⁷ At low concentrations of free detergent, below its critical micelle concentration, there is a partition coefficient governing the distribution of detergent between the bilayer of phospholipid and the water, the membranes remain intact, and the detergent incorporates into the bilayer just as if it were an amphipathic lipid.²¹⁸ As the concentration of detergent is increased, its incorporation into the intact membrane begins to saturate, the apparent partition coefficient begins to drop, and the permeability of the membranes abruptly increases, as if fissures or pores were opening, but the bilayer of phospholipid still remains intact.^{217,218} As the concentration of the detergent is increased even further, the amount of bound detergent suddenly increases dramatically and the membranes dissolve and are replaced by mixed micelles of detergent and phospholipid.

These mixed micelles are completely formed before the free concentration of detergent reaches its critical micelle concentration in the absence of phospholipid

Table 14-5: Micelles of Nonionic and Zwitterionic Detergents²¹¹

detergent	mean aggregation number ^a	molar mass of micelle (g ⁻¹ mol ⁻¹)	critical micelle concentration (mM)

^aMean aggregation number is the average number of molecules of detergent in a micelle.

(Table 14-5), an observation suggesting that the critical micelle concentration of the mixed micelles is lower than that of pure micelles of detergent. The **abrupt dissolution of the bilayer** of phospholipid to form these mixed micelles occurs at a fixed ratio of detergent to lipid rather than at a particular concentration of detergent,²¹⁶ an observation suggesting that there is an optimal ratio of detergent to phospholipid for the formation of these mixed micelles. An intermediate stage in some instances between a suspension of bilayers and a solution of elliptical mixed micelles seems to be the formation of long tubular micelles.²¹⁹

When natural membranes containing membrane-bound proteins are dissolved with a nonionic detergent, the same stages are passed through, and ideally, if the removal of the bilayer of phospholipid by this process does not unfold the protein being purified, the nonionic detergent forms a **toroidal micelle** surrounding the segments of the protein formerly embedded in the membrane and replacing the hydrocarbon of the bilayer of phospholipid with the hydrocarbon of the detergent. This toroidal micelle presents the hydrophilic functional groups of the detergent to the aqueous phase while its hydrocarbon surrounds and supports the hydrophobic portions of the protein formerly embedded in the membrane. The previously membrane-spanning segment or segments of polypeptide end up in the center of the toroid; the inner surface of the toroid is formed from the hydrocarbon of the detergent flush against the membrane-spanning segments of the protein, and the outer surface of the toroid is the hydrophilic portion of the detergent directed outward into the water (Figure 14-13). Such toroidal micelles have been crystallographically

observed surrounding molecules of integral membrane-bound proteins crystallized from solutions of the protein produced with detergent.²²⁰

As with phospholipids, there seems to be a required **ratio between the detergent and the protein and lipid** present in the original membrane for the protein to be dissolved completely.²²¹ This minimum ratio of concentrations is that required for there to be at least one

Figure 14-13: Diagrammatic representations of the mechanism by which a nonionic detergent dissolves an integral membrane-bound protein. A toroidal micelle is formed within which the bilayer of phospholipids is replaced by the hydrocarbon of the detergent. micelle of detergent, as measured in the absence of the membranes (Table 14-5), for each molecule of protein.²¹¹ Furthermore, there must be sufficient detergent in the solution to maintain its free concentration at a level equal to its critical micelle concentration in the absence of membranes (Table 14-5).

One peculiarity of these mixed micelles of protein and detergent is that at ratios of detergent where the protein is not completely dissolved and the solution contains micelles with one molecule of protein, micelles with two molecules of protein, micelles with three molecules of protein and so forth, these micelles neither fuse with each other nor dissociate into smaller aggregates.²²²⁻²²⁴ Once the ratio of these states of aggregation is established in the initial rapid dissolution, it remains fixed as long as the total concentration of detergent remains fixed.

There are several drawbacks to the necessity of dissolving the membranes in detergent to dissolve the proteins within them. The actual dissolution of the membrane occurs over a narrow range of free concentration of detergent,²¹⁷ so it is not possible to control the process very successfully. For reasons that are unknown, when ratios of detergent to protein increase beyond those needed to dissolve the membranes, the biological function of the protein is often impaired or disappears entirely.²²¹ Consequently, changes in the concentration of detergent or the ratio of detergent to protein that automatically occur during chromatography often lead to loss of activity. For this reason, it is often necessary to **screen a large number of different detergents** to discover by trial and error the one that preserves the biological activity of the protein over the broadest possible range of concentrations of both protein and detergent. Fortunately, there are a large set of homogeneous non-ionic detergents to explore with a wide range of critical micelle concentrations (Table 14-5).

Often it is difficult to find a detergent and the proper conditions to produce a monodisperse solution of the membrane-bound protein of interest without producing its inactivation,²²⁵ yet a **monodisperse solution of the protein** is essential if chromatography by molecular exclusion is to be used to purify it.²²¹ The large sizes of the micelles of the detergents limit the range of molecular sizes that can be separated by chromatography by molecular exclusion because no complex between a micelle and a molecule of protein can be smaller than the micelle itself. Many membrane-bound proteins are sialoglycoproteins so their charge is microheterogeneous, a situation causing difficulties for chromatography by ion exchange. For all of these reasons, the purification of a membrane-bound protein is more difficult than that of a soluble protein.

As with a soluble protein, a **biochemical assay** is used to follow the purification of a membrane-bound protein. If the protein is an enzyme, its enzymatic activity can be measured in a standard assay.²²⁶⁻²²⁸ If one of the sub-

strates for the enzyme is a phospholipid or another lipid incorporated in a membrane, the enzyme is reassociated with vesicles of phospholipid containing that substrate before assay.²²⁹ If the membrane-bound protein is responsible for transmitting across the membrane the information that a hormone is bound at its extracytoplasmic surface, the binding of that hormone or of a synthetic agonist or antagonist that binds tightly to the site at which the hormone binds can be used as an assay for that protein.²³⁰ If the membrane-bound protein is responsible for transporting a metabolite across the membrane, the binding of an inhibitor of that transport with high affinity for the protein can be used as an assay.²³¹

If a membrane-bound protein catalyzes the transport of a particular metabolite across its native membrane, it is also possible to reconstitute that protein into sealed vesicles of phospholipid and then assay the accumulation of that metabolite into the vesicles.²³²⁻²³⁴ The membrane-bound protein, detergent, and phospholipid are mixed together at concentrations necessary to produce a disperse solution. The detergent is then removed from that solution; and if the **reconstitution** has been successfully performed, sealed vesicles of phospholipid will form in the bilayers of which the protein of interest is inserted in a functional state. The ability of that protein to transport its specific substrate across the membrane into the vesicles is then assayed. Rapid methods for performing the separate reconstitutions of multiple samples can be used to assay the fractions from chromatographic separations for the protein responsible for the particular transport of interest. For example, proteins responsible for the transport of citrate,²³⁵ oxalate,²³⁶ and ornithine,²³⁷ respectively, could be purified to homogeneity by assaying them with reconstitution. There is even one instance in which an integral membrane-bound protein can be renatured and then reconstituted from a completely denatured state.^{238,239}

When the membranes have been dissolved in a solution of detergent in such a way that the activity of the membrane-bound protein of interest is preserved and an assay for that protein has been developed, the protein can often be purified chromatographically. For example, (*R*)-pantolactone dehydrogenase (flavin) was purified 80-fold from membranes of *Nocardia asteroides* by ammonium sulfate precipitation and six **chromatographic steps** after it was dissolved in a solution of 0.5% Brij 35.²⁴⁰ Both chromatography by molecular exclusion and chromatography by ion-exchange run in solutions of nonionic detergent, are used to purify membrane-bound proteins dissolved with detergent,^{241,242} as well as chromatography on hydroxyapatite^{243,244} and chromatography by adsorption on solid phases modified with specific functional groups (Table 1-2) such as phenylboronate²⁴⁵ or particular dyes.^{246,247} If one has been able to produce immunoglobulins specific for a particular membrane-bound protein before that protein has been purified, those immunoglobulins can be used to purify a mem-

^aTotal number of amino acids and total number of membrane-spanning segments of the noted secondary structure in each protomer of the protein unless otherwise noted. ^bComposition of subunits in complete oligomer. ^cAll β barrels are antiparallel. ^dNumber of α helices in the continuous cylinder of α helices formed by the complete oligomer. ^eOne of the membrane-spanning α helices is formed from two smaller α helices that butt against each other, each of which passes only halfway through the membrane. ^fNumber of strands in the continuous β barrel formed by each subunit. ^gNumber of strands in the continuous β barrel formed by the complete oligomer.

brane-bound protein by **immunoadsorption**²⁴⁸⁻²⁵⁰ because nonionic detergents usually cannot denature immunoglobulins.

After a membrane-bound protein has been purified to homogeneity so that only one protein remains in the sample, reconstitution is often used to prove that the purified protein is responsible for the biological activity of interest. Examples of some of the purified proteins that have been shown by reconstitution to be responsible for a specific function are ones that catalyze respectively the passive transport of water,²⁵¹⁻²⁵³ the passive transport of glucose,²⁴² the passive transport of melibiose,²⁵⁴ the passive transport of halide ions,²⁵⁵ the voltage-activated passive transport of sodium ions,²⁵⁶ the calcium-activated passive transport of potassium ions,²⁵⁷ the inositol 1,4,5-triphosphate-activated passive transport of calcium ions,²⁵⁸ the ATP-driven active transport of sodium and potassium ions,²³³ and the ATP-driven active transport of covalent conjugates between glutathione and other molecules²⁵⁹ across the membrane, as well as ones that form large, nonspecific pores.²⁶⁰ It is also possible to demonstrate that a particular protein is responsible for a particular type of transport by expressing mRNA encoding that protein in oocytes of *X. laevis* and then demonstrating that the oocytes have become able to display the particular type of transport.^{261,262}

In addition to reconstitution into sealed vesicles of phospholipid, purified membrane-bound proteins can be transferred into **bicelles**.²⁶³ Bicelles are small flat disks, each a bilayer of dimyristoylphosphatidylcholine. The rim of each disk is a continuous ring of detergent, either 3-[(3-cholamidopropyl)dimethylammonio]-2-hydroxy-1-propanesulfonate or dihexanoylphosphatidylcholine.^{264,265} The diameter of these circular disks can be varied by changing the ratio of detergent to phospholipid.²⁶⁵ It is also possible to replace the micelle of detergent surrounding the membrane-spanning portion of a purified membrane-bound protein with a copolymer of acrylate, *N*-octylacrylamide, and *N*-isopropylacrylamide, which is an amphipathic, polymeric detergent.²⁶⁶

Once an integral membrane-bound protein has been purified, amino acid sequences from peptides can be used to design probes for screening libraries of **cDNA**. Once their cDNAs are available, integral membrane-bound proteins are often expressed from their cDNA so that, even though they are produced at low levels, they can be modified by **site-directed mutation** and other genetic manipulations to identify amino acids critical for one of their functions²⁶⁷⁻²⁷⁰ or for other studies.²⁷¹ The cDNA for a membrane-bound glycoprotein from an animal must be expressed in animal cells to produce the properly glycosylated protein.²⁰⁵ The expression of a particular cDNA that has been identified indirectly with a particular function is often used to prove that the protein for which it encodes actually is responsible for that function.^{272,273}

Many anchored membrane-bound proteins have been released from the membrane endopeptidolytically or have been dissolved with nonionic detergents as biologically active proteins and purified to homogeneity by the normal methods of chromatography or affinity adsorption. A few examples of such purified anchored membrane-bound proteins are cytochrome *b*₅,^{274,275} HLA histocompatibility antigens,²⁷⁶ HLA-linked B-cell antigen,²⁷⁷ dipeptidyl-peptidase IV,^{278,279} membrane alanine aminopeptidase,²⁸⁰ sucrose α -glucosidase/oligo-1,6-glucosidase,²⁸¹ dolichyl-phosphate β -D-mannosyltransferase,²⁸² unspecific monooxygenase,²⁸³⁻²⁸⁵ ATP diphosphatase,²⁸⁶ and the hemagglutinin of influenza virus.²⁸⁷

When anchored membrane-bound proteins are purified intact in the presence of nonionic detergent, they will recombine with bilayers of phospholipid when the detergent is removed^{275,281,288} and become anchored again, but when they are removed from the membrane by endopeptidolytic cleavage, the detached biochemically active, globular domains have no affinity for bilayers of phospholipids. Many of the **endopeptidolytically released detachable domains** have been crystallized, and crystallographic molecular models have been constructed from the maps of electron density.²⁸⁹⁻²⁹¹ The portions of anchored membrane-bound proteins that reside outside the membrane have also been expressed by themselves, after being genetically detached from their anchors, and crystallized, and crystallographic molecular models have been constructed for these **genetically released detachable domains**.^{292,293}

The **crystallographic molecular models of the detached domains** of anchored membrane-bound proteins are indistinguishable from those of normal water-soluble proteins. The terminal region of the polypeptide at which the cleavage releasing the detachable domain from the membrane occurred is usually disordered and featureless in the map of electron density. From all of these observations, it can be concluded that such an anchored membrane-bound protein is simply a water-soluble protein that is leashed to the bilayer of phospholipid by a flexible segment of its polypeptide attached in turn to the embedded anchor. An anchored membrane-bound protein may be attached to the membrane not only by a transmembrane anchor at one of its termini but also by adsorption to the bilayer through additional interactions on its surface. In such an instance the anchor must be removed and site-directed mutations within this region on its surface must be performed to produce a fully water-soluble protein capable of being crystallized.²⁹⁴

The **embedded anchor** left behind in the bilayer of phospholipid when a membrane-bound protein anchored at one of its termini is released by endopeptidolytic digestion almost always has at least one segment of sequence composed almost exclusively of the most hydrophobic amino acids. The entire stretch of polypep-

tide left behind in the membrane may be quite long, but the length of each of the hydrophobic segments is usually only about 20–25 aa long. The amino acid sequence of the hydrophobic segment from equine cytochrome *b*₅ is –WWTNWVIPAISAVVVALMY–,²⁹⁵ that from one of the human HLA histocompatibility antigens is –VPIVGI VAGLVLLVAVVTGAVVAVMW–,²⁹⁶ that from sucrose α -glucosidase/oligo-1,6-glucosidase from *O. cuniculus* is –LIVLFVIVFIIAIALI AVL A–,²⁹⁷ that from the hemagglutinin of an influenza virus is –WILWISFAISCFLLCVVL GFIMWAS–,²⁹⁸ and that from human glycophorin A is –ITLIIFGVMAGVIGTILLISYGI–.²⁹⁹ Such hydrophobic segments from anchored membrane-bound proteins are the most hydrophobic sequences of their length found in any protein.³⁰⁰ These sequences are usually flanked at both ends by regions containing normal or above-normal frequencies of polar and charged hydrophilic amino acids.

It is these hydrophobic segments of anchored membrane-bound proteins that span the hydrocarbon of the bilayer of phospholipid. That each of these **single, isolated membrane-spanning segments** of amino acid sequence is completely surrounded by liquid hydrocarbon explains their extreme hydrophobicity. The short hydrophilic segments that end up in most of these proteins on the opposite side of the membrane from the large globular, detachable domains probably act simply as barbs that cannot be pulled through the bilayer of phospholipid, but other roles, such as the relay of information across the membrane, have been proposed for some of them.

The hydrophobic segment of polypeptide that spans the membrane and serves to attach an anchored membrane-bound protein to the bilayer of phospholipid will spontaneously assume an α helix over most or all of its length, as judged by circular dichroic spectra, when it is incorporated into micelles of detergent^{301,302} or bilayers of phospholipid.³⁰³ It is believed that these hydrophobic anchors when they are attached to the native protein are also uninterrupted α helices spanning the hydrocarbon of the biological membranes in which they are normally found. An α helix is the logical structure for a segment of polypeptide to assume when it is immersed in liquid hydrocarbon in the total absence of water or any other donor or acceptor of hydrogen bonds. Within itself, an α helix satisfies all of the hydrogen-bond donors on the polypeptide (Figure 4–16A). The width of the hydrocarbon in a bilayer of naturally occurring amphipathic lipids and cholesterol is about 3.6 nm (Figure 14–4D).^{47,98} As the rise for each amino acid in an α helix is 0.15 nm, it should require about 24 aa to span the hydrocarbon. The fact that the lengths of the hydrophobic segments of anchored membrane-bound proteins are usually greater than 20 aa is further support for the proposal that these hydrophobic segments are α -helical in their normal situation.

The **distribution of amino acids** in the hydropho-

bic segments of the naturally occurring anchors that span the membrane in one isolated α helix elucidate the hydrophobic imperatives of a bilayer of phospholipid.³⁰⁴

As one might expect, isoleucines, leucines, valines, alanines, and phenylalanines represent 74% of the amino acids in these segments, a percentage 2.5 times greater than their percentage in water-soluble proteins. Cysteine, glycine, and methionine have frequencies equal to those for these amino acids in water-soluble proteins. Serines and threonines, although they occur half as frequently as they do in water-soluble proteins, are present within these fully engulfed membrane-spanning segments, but the donors on their hydroxyls can be automatically satisfied by the intramolecular hydrogen bonds in which these two amino acids often participate with the empty lone pairs on the acyl oxygens of the amino acids three or four positions ahead of them in an α helix (Figure 6–7).

Tryptophans and tyrosines are present in these membrane-spanning segments at about two-thirds the frequency with which they are present in water-soluble proteins, but they occur exclusively at the **ends of the segments** where their lone hydrogen-bond donors can remain in contact with water as they do almost always in a crystallographic molecular model of a soluble protein. If, however, a membrane-spanning segment is hydrophobic enough, it can drag a tryptophan into the middle of a bilayer of phospholipid.^{305,306} Prolines are also confined to the ends of such membrane-spanning segments, usually at the amino-terminal end, so that the α helix can cross the bilayer unbroken. The remaining polar amino acids, histidine, lysine, glutamine, aspartate, asparagine, glutamine, and arginine, constitute less than 1% of the amino acids in these segments and are always found at the ends, so that the hydrophilic portions of their side chains can remain in contact with the water or the polar headgroups of the phospholipids.

A number of peptides incorporating such hydrophobic sequences have been synthesized. For example, the peptide acetyl-KK(LA)₁₂KK- α -amide forms a stable α helix that spans the bilayers of phospholipid in vesicles of dipalmitoylphosphatidylcholine.³⁰⁷ The central portion of such a **synthetic hydrophobic peptide** is a rigid α helix from which the α -amido protons cannot exchange with protons in the water on the two sides of the bilayer, but the α -amido protons in the portions of the peptide exposed on the two sides of the bilayer exchange rapidly.³⁰⁸ There is a symbiotic relationship between the length of the hydrophobic sequence and the width of the bilayer. The peptide forms a fully miscible solution with the bilayer only when the length of the hydrophobic α helix matches the width of the bilayer,^{306,307} and the hydrophobic α helix can, to a certain extent, adjust the width of the bilayer to match its length.³⁰⁹ Cholesterol exerts an influence on this symbiosis to the extent that it increases the width of the bilayer.³⁰⁶

If a single lysine, aspartate, asparagine, glutamate, glutamine, or histidine is positioned during the synthesis in the center of an α -helical, polyleucyl, membrane-spanning peptide, the leucines will drag that side chain into the center of the bilayer^{310,311} because there is more than enough standard free energy in the hydrophobic effect to do so. The side chain of the lone lysine, the lone histidine, the lone aspartate, or the lone glutamate, however, enters the hydrocarbon as the neutral unprotonated or protonated form, respectively, so that the debit of standard free energy is only for its neutralization (Equation 5-66). That each enters as the neutral form, which is the only form of its acid-base that contains both a donor and an acceptor for hydrogen bonding, is supported by the fact that the peptides containing a single histidine, aspartic acid, or glutamic acid, as well as those containing a single asparagine or glutamine, readily form dimers and higher oligomers when they are incorporated into micelles or bilayers.³¹¹⁻³¹⁴ These oligomers result from hydrogen bonding within the hydrocarbon between the polar side chains.

These results clearly demonstrate that **hydrogen bonds**, which will not form in water because of competition from donors and acceptors on the molecules of water, are as stable within a phase of hydrocarbon, removed from contact with water, as they are in organic solvents (Table 5-3). When a hydrogen-bond donor and acceptor enter a hydrogen bond during the folding of a polypeptide in aqueous solution, the standard enthalpy change for the reaction is zero because the reaction proceeds with no net change in the number of hydrogen bonds (Equation 5-40) and little change in their net intrinsic stability (Equation 5-48). A hydrogen-bond donor or acceptor in the middle of an otherwise hydrophobic segment spanning a membrane, however, is held within the hydrocarbon by the hydrophobic α helix that was formed by the segment when it entered the membrane. The price of withdrawing the hydrogen-bond donors and acceptors from the water and stripping them of their hydration has already been paid by the hydrophobic effect that immersed the membrane-spanning segment in the first place. When a hydrogen-bond donor and acceptor form a hydrogen bond between these α helices within the hydrocarbon, the standard enthalpy change for the reaction is -12 to -20 kJ mol⁻¹ (Table 5-2).

When a single tryptophan is positioned in a sequence of leucines longer than is necessary to span a membrane, that tryptophan shifts the membrane-spanning polyleucyl α helix across the membrane until that tryptophan ends up close enough to the surface of the bilayer of phospholipid to thrust the hydrogen-bond donor in its side chain out of the hydrocarbon,³¹⁵ but a tyrosine does not display the same compulsion.

Many integral membrane-bound proteins have also been purified,^{221,242,316-320} some of these have been crystallized, and those crystals have provided crystallographic molecular models (Table 14-6).

It is generally assumed that, as for its purification, the most effective strategy for **crystallizing an integral membrane-bound protein** is to begin with the protein dissolved in a solution of a nonionic or zwitterionic detergent that is structurally homogeneous, such as one of the alkyl glycosides, one of the alkyl oligo(ethylene oxide) ethers, or *N,N*-dimethyldodecylamine *N*-oxide (Table 14-6). There are examples, however, of integral membrane-bound proteins crystallizing from solutions of structurally heterogeneous mixtures of detergents, such as the crystallization of mammalian cytochrome-*c* oxidase from a random mixture of dodecyl poly(ethylene oxide) ethers (Brij 35; average number of ethylene oxides equals 23)³³⁴ or the outer membrane protein F from *E. coli* from a random mixture of octyl poly(ethylene oxide) ethers.³⁵⁵ Sometimes a mixture of several structurally homogeneous nonionic detergents is intentionally prepared, as for the crystallization of the bacterial outer membrane protein TolC.³⁶⁰ Mammalian ubiquinol-cytochrome-*c* reductase will crystallize from a solution of methyl 6-*O*-(*N*-heptylcarbamoyl)- α -D-glucopyranoside, octyl β -D-glycoside, octanoyl-*N*-methylglucamide, octanoylsucrose, or octyl β -D-maltoside³³⁶ but also from a solution of dodecyl β -D-maltoside, decanoyl-*N*-methylglucamide, or diheptanoylphosphatidylcholine (Table 14-6). All of these observations seem to suggest that any one of several detergents could be used to obtain readily crystals of a particular integral membrane protein, but the efforts of many investigators over many years that have been expended to produce crystals of only a few integral membrane-bound proteins belie this suggestion.

Molecules of a particular protein must be dissolved in a **continuous isotropic phase** so that they can diffuse over the full extent of that phase to associate with each other and form a macroscopic crystal. Molecules of an integral membrane-bound protein dissolved in a solution of nonionic detergent are in an isotropic solution and each can encounter all of the others. A **bicontinuous cubic phase** of lipid and water is an isotropic phase that forms from particular aqueous suspensions of lipid.³⁶² In such a phase, a three-dimensional network formed from a single, continuous bilayer of amphipathic lipid encloses a single continuous three-dimensional network of aqueous channels. Such a bicontinuous cubic phase forms spontaneously under the proper conditions from a mixture of water and 1-oleoylglycerol.³²⁹ If bacteriorhodopsin from *Halobacterium salinarium* is incorporated into the lipid of such a bicontinuous cubic phase, the molecules of protein can diffuse over the full extent of the lipid phase to find each other and crystallize.³²⁹

When integral membrane-bound proteins are in vesicles of phospholipid that are suspended in an aqueous solution, each molecule of protein can associate productively only with other molecules of protein within that vesicle. Under certain circumstances, however, it is possible to produce stacked planar bilayers by fusion of

vesicles containing a particular integral membrane-bound protein, and the molecules of protein may be able to crystallize within each bilayer, and these two-dimensional arrays may then be able to stack regularly upon each other to produce a macroscopic crystal. Macroscopic crystals of bacteriorhodopsin suitable for crystallography have also been prepared in this way.^{363,364}

The membrane-bound proteins from bacteria that have been crystallized successfully are often purified from bacteria that have been genetically altered to overexpress that one particular protein.^{340,342,343,353,357,359,365} For example, succinate dehydrogenase from *E. coli* was produced by the **overexpression** of a gene that had been introduced on a plasmid; and in the resulting bacteria, 50% of the protein in the plasma membranes was succinate dehydrogenase.³⁶⁶ The protein responsible for glycerol transport in *E. coli* was overexpressed with a sequence of six consecutive histidines on its carboxy terminus so that it could be purified by affinity adsorption.³⁴⁹ In order to discover a large-conductance mechanosensitive channel that would crystallize, the proteins from nine different prokaryotes were each overexpressed and purified.³⁴⁷ To obtain a bacterial outer membrane containing only one porin, the gene for outer membrane protein F was expressed from a plasmid in a strain of *E. coli* lacking all of its porins.³⁵⁵

So far, however, integral membrane-bound proteins from **plants and animals** can seldom²⁰⁴ be expressed in a functional form at high levels. For example, when isoform 4A4 of unspecific monooxygenase from lung of *Oryctolagus cuniculus* was expressed in *E. coli*, less than 0.1 mg of the monooxygenase that had been incorporated into the bacterial plasma membrane could be purified from each liter of culture.²⁸³ When human glucose transporter was expressed in *E. coli*, the most sensitive methods of immunoblotting were used to detect its presence in membranes isolated from the cells.³⁶⁷ When bovine opsin was expressed in the mammalian cell line HEK293, only about 2 mg of the protein that had been incorporated into the plasma membrane of the cells could be isolated from each liter of culture.³⁶⁸ And when porcine Na⁺/K⁺-exchanging ATPase was expressed in the yeast *Pichia pastoris*, only about 1 mg of the protein was present in the unfractionated plasma membranes obtained from each liter of culture.³⁶⁹ It seems that bacteria are unable to insert animal proteins into their plasma membranes efficiently and that eukaryotic expression systems such as yeast or animal cells have trouble inserting extra protein into their membranes, perhaps because they are already crowded or perhaps because the systems for inserting them have only limited capacity. Consequently, most of the integral membrane-bound proteins from animals that have been crystallized have been purified from naturally occurring membranes that normally contain high concentrations of those proteins and can be obtained in large quantities from whole tissues.

From an examination of the crystallographic molecular models of integral membrane-bound proteins, there seem to be only two successful strategies that have been discovered by evolution through natural selection for immersing a protein in a membrane so completely that a major portion of its structure spans the bilayer of phospholipid, exposing respective portions of its surface to each side. Either the portion of the protein within the hydrocarbon of the bilayer is a **bundle of α helices** or it is a **β barrel**. The reason that these two arrangements are exclusive is that they seem to be the only two ways to provide acceptors for most if not all of the amido nitrogen-hydrogens in the backbone of those segments of polypeptide spanning the hydrocarbon of the bilayer. This conclusion is reinforced by the fact that bacterial outer membrane protein A spans the membrane with an eight-stranded β barrel that is almost a perfect cylinder so that every amido nitrogen-hydrogen participates in a hydrogen bond. Eight-stranded β barrels in soluble proteins are usually flattened so that the hydrogen bonds of the backbone in the two flattened regions can be straighter, but the α -amido nitrogen-hydrogens in the creases at the two edges of the flattened cylinder are able to form hydrogen bonds with water. Such an arrangement would be impossible within a bilayer of phospholipid, so the cylinder cannot be flattened.

At the moment, it appears that the integral membrane-bound proteins spanning the membrane with bundles of α helices are confined exclusively to the plasma membranes and intracellular membranes of cells, be they eukaryotic or bacterial, and the integral membrane-bound proteins spanning the membrane with β barrels are confined almost exclusively to the **bacterial outer membrane**, which is a bilayer formed from an outer monolayer of lipopolysaccharide and an inner monolayer of phospholipid. One of the few exceptions to this rule is bacterial α -hemolysin (Table 14-6), which is a toxin excreted from *Staphylococcus aureus* that forms a β barrel of 14 strands, two from each of its seven subunits, within the plasma membrane of a foreign cell to punch a hole in it and kill that cell.

Bacteriorhodopsin from *H. salinarium* (Figure 14-14),³⁷⁰ Ca²⁺-transporting ATPase from endoplasmic reticulum of *O. cuniculus* (Figure 14-15),³⁵¹ the membrane-spanning domain of potassium channel KcsA from *Streptomyces lividans* (Figure 14-16),^{343,344} photosynthetic reaction center from *R. viridis* (Figure 14-17),³²¹ and ubiquinol-cytochrome-*c* reductase from mitochondria of *S. cerevisiae* (Figure 14-18)^{371,372} are paradigms of the α -helical class of integral membrane-bound proteins; and porin OmpF from *E. coli* (Figure 14-19)³⁵⁵ and ferrichrome-iron receptor from *E. coli* (Figure 14-20)³⁵⁷ are paradigms of the β -barrel class of bacterial integral membrane-bound proteins. These crystallographic molecular models illustrate the variety of the structures assumed by integral membrane-bound proteins.

The extant **crystallographic molecular models of**

integral membrane-bound proteins demonstrate nicely the range of structures that are possible (Table 14-6). They vary in size from the monomer of mammalian rhodopsin (350 aa) to the dimer of heteroundecamers of mammalian ubiquinol-cytochrome-*c* reductase (4400 aa). In some of these proteins, such as the bacteriorhodopsin (Figure 14-14), the bacterial porins (Figure 14-19), or the aquaporins, most of the protein is within the membrane; in others, such as bacterial succinate dehydrogenase, mitochondrial ubiquinol-cytochrome-*c* reductase (Figure 14-18), or bacterial α -hemolysin, less than 15% of the protein is within the membrane. Some of the proteins are monomers (Figures 14-15 and 14-20), some are rotationally symmetric homooligomers (Figures 14-16 and 14-19), some are heterooligomers (Figures 14-17 and 14-18), and some are homooligomers of heterooligomers. The heterooligomeric protomer of mammalian cytochrome-*c* oxidase, with 13 different unrelated subunits with lengths ranging from 45 to 510 aa, is one of the most complex heterooligomeric proteins in existence, if matrices of polymeric proteins are not counted.

In some of the heterooligomers, such as, ironically, cytochrome-*c* oxidase, every one of the subunits has at least one membrane-spanning segment; in others, such as ubiquinol-cytochrome-*c* reductase (Figure 14-18) and bacterial succinate dehydrogenase, only about half the subunits have **membrane-spanning segments**. In these latter proteins, the subunits without membrane-spanning segments are globular structures associated by typical heterologous protein-protein interfaces with the subunits that do have them. When dissociated from such a complex, these subunits with no contact to the bilayer can sometimes be crystallized as water-soluble proteins.³⁷³ Two of the four nonidentical subunits of heterooligomeric photosynthetic reaction center from *R. viridis* (Figure 14-17) are homologous in sequence and have superposable arrangements of their five membrane-spanning α helices arranged around a 2-fold rotational axis of pseudosymmetry; the third subunit has a single membrane-spanning anchor; and the fourth subunit has no membrane-associated segments of polypeptide but does have a 1,2-diacyl-3-deoxyglyceryl group that is attached by a thioether linkage to its amino-terminal cysteine¹⁶⁸ and that is embedded in the membrane.

The eukaryotic complexes for electron transport often contain one or more short subunits that each contain one membrane-spanning segment and that appear to perform only a structural role in the complex. For example, ubiquinol-cytochrome-*c* reductase from *S. cerevisiae* (Figure 14-18) has two such membrane-spanning subunits of 94 and 65 aa, while bovine cytochrome-*c* oxidase (Table 14-6) has six of 84, 73, 56, 56, 47, and 46 aa, respectively. Beyond the 30 aa needed to span the membrane, the smaller of these subunits have little else left.

Figure 14-14: Skeletal drawing of the crystallographic molecular model of an individual subunit of the α_3 homotrimer of bacteriorhodopsin from *H. salinarum*.³⁷⁰ The protein used for the crystallography was overexpressed in *H. salinarum*. Membranes were dissolved in octyl β -glucoside, and the protein was purified chromatographically. The purified protein in a solution of octyl β -glucoside was mixed with 1-monooleoyl-*rac*-glycerol (monoolein) and a concentrated aqueous solution of sodium phosphate at pH 5.6 to incorporate the protein into a bicontinuous cubic phase of monoolein and water in which it crystallized.³²⁹ The complete crystallographic molecular model is drawn with the polypeptide backbone in thick line segments and side chains in thin line segments. The numbering is that of the mature posttranslationally modified protein. The crystallographic molecular model is oriented so that the plane of the membrane is horizontal and the cytoplasmic surface of the protein is at the bottom. A bar 3.6 nm high is placed next to the protein to represent the hydrocarbon of the bilayer. The exact location of the membrane is unknown because the protein was crystallized from monoolein.⁷⁷⁸ This drawing was produced with MolScript.⁷⁷⁸

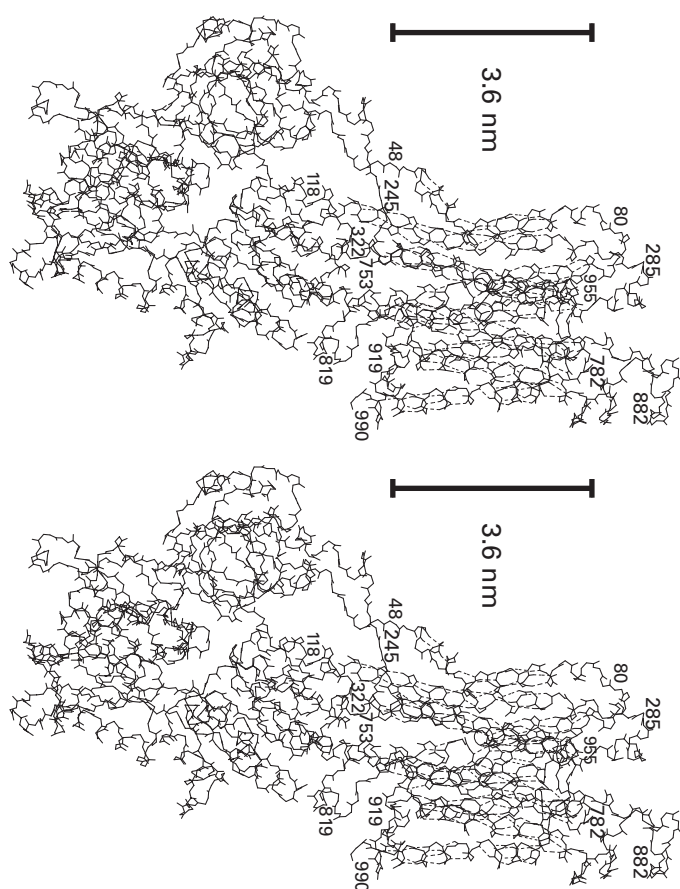

Figure 14-15: Skeletal drawing of the polypeptide backbone of the crystallographic molecular model of Ca^{2+} -transporting ATPase from *O. cuniculus*.³⁵¹ Purified endoplasmic reticulum from skeletal muscle was dissolved in a solution of $n\text{-C}_{12}\text{H}_{25}\text{O}(\text{CH}_2\text{CH}_2\text{O})_8\text{H}$, and the Ca^{2+} -transporting ATPase in this solution was purified by affinity adsorption. Crystals were grown by dialyzing the final purified protein dissolved in detergent against 0.8 M sodium butyrate, 2.75 M glycerol, 10 mM CaCl_2 , 3 mM MgCl_2 , 2.5 mM sodium azide, 0.2 mM dithiothreitol, and 20 mM *N*-(2-sulfoethyl)morpholine, pH 6.1. There are 10 membrane-spanning α -helices in the molecular model, and at one or the other end of each, an amino acid is numbered with its position in the amino acid sequence of the protein. The plane of the membrane is horizontal, and the cytoplasmic surface of the protein is at the bottom. The protein has a large globular cytoplasmic domain formed almost entirely by two long segments of polypeptide located between the second and the third membrane-spanning α -helices (from Alanine 118 to Aspartate 245) and between the fourth and the fifth membrane-spanning α -helices (from Glycine 322 to Isoleucine 753). Only the hydrogen bonds in the membrane-spanning α -helices are drawn. The exact location of the membrane is unknown because the protein was crystallized from a solution of detergent. The two cations of Ca^{2+} that are transported across the membrane by the protein were trapped in the crystals on their way across and were observed in the map of electron density. They are the open circles in the drawing, each drawn with a radius equal to the ionic radius of a Ca^{2+} cation. Many of the membrane-spanning α -helices in the structure are broken. This drawing was produced with MolScript.⁷⁷⁸

The membrane-spanning portion of the integral membrane-bound proteins represented by the crystallographic molecular models can be formed entirely by segments of secondary structure from one polypeptide, such as those in Ca^{2+} -transporting ATPase (Figure 14-15) mammalian rhodopsin, or bacterial outer membrane protein A; from segments of secondary structure from several different subunits, both heterologous and homologous, as in photosynthetic reaction center (Figure 14-17); from segments of secondary structure from many different heterologous subunits, as in mammalian cytochrome-*c* oxidase; or from identical segments of secondary structure from the identical subunits in a homooligomer, as in the membrane-spanning domain of potassium channel KcsA (Figure 14-16). In the homooligomers responsible for transport of specific molecules or inorganic ions across the membrane, each subunit can form within the membrane its own channel for the substrate, as in the bacterial porins and the aquaporins; or each subunit in the oligomer can contribute an identical set of secondary structures that are arrayed around an *n*-fold rotational axis of symmetry normal to the membrane to form together the sole channel in the complete oligomer, as in the membrane-spanning domain of potassium channel KcsA (Figure 14-16), the bacterial outer membrane protein TolC, and bacterial α -hemolysin.

Many of the integral membrane-bound proteins are responsible for transporting metabolites or inorganic ions, either actively or passively, or for transporting information across the membrane. Those responsible for passively transporting metabolites nonspecifically, such as the porin OmpF (Figure 14-19),³⁵⁵ have a fairly wide **hydrophilic water-filled channel** passing through their center; in the porin OmpF the channel at its narrowest is only 0.7 nm \times 1.1 nm. Those responsible for passively transporting particular molecules or ions usually have an obvious channel passing through them, within which there is a region in which the selection for those molecules is performed. For example, potassium channel KcsA (Figure 14-16) has a water-filled, cylindrically symmetric channel passing through it at one end of which is a constriction in which there is a symmetrically displayed set of acyl oxygens from the polypeptide backbone that select the potassium ions.^{343,344} In proteins that actively transport cations, such as Ca^{2+} -transporting ATPase (Figure 14-15),³⁵⁰ cytochrome-*c* oxidase,³³⁵ and cytochrome *o* ubiquinol oxidase,³⁴⁰ the passageway through which those cations pass is much narrower, less obvious, and convoluted so that the entrance into the center of the channel and the exit from the center of the channel by those ions can be controlled and coupled to conformational transitions in the protein. Those proteins responsible only for the passage of information such as mammalian rhodopsin³³¹ present no passageway for any metabolites, water, or cations by filling the membrane with solid protein; otherwise they would produce leaks.

Many integral membrane-bound proteins have large **globular domains** on one side of the membrane or the other. For example, proteins that act as receptors that sense the presence of molecules outside the cell, such as acetylcholine receptor,³⁴⁵ have globular domains on the extracytoplasmic surface of the membrane that are responsible for this function. Proteins that catalyze the active transport of cations, such as mammalian endoplasmic reticulum Ca^{2+} -transporting ATPase (Figure 14–15),^{350,351} have globular domains on the cytoplasmic surface of the membrane that convert the binding and hydrolysis of cytoplasmic MgATP into the movement of those cations against their gradients of concentration. Most of these globular domains resemble globular soluble proteins in the details of their structure, so it is only the structural details of the portions of these molecular models that are immersed within the bilayer of phospholipid and located in its immediate vicinity that are peculiar to these proteins.

The side chains of the amino acids forming the continuous surface of the protein in direct contact with the bilayer of phospholipid³⁷⁴ can be considered as a **sheath**

that encloses the protein and forms the interface between it and the membrane. The most dramatic illustration of one of these sheaths is the layer of side chains protruding from the continuous β barrel of 22 strands completely enclosing the interior of ferrichrome–iron receptor from *E. coli* (Figure 14–20). Within this particular sheath, there is a typical globular structure of β sheets and α helices,³⁵⁷ insulated from the hydrocarbon of the bilayer of the outer membrane by the sheath. The side chains of leucine (23), valine (14), tryptophan (13), phenylalanine (11), glycine (9), alanine (9), isoleucine (8), tyrosine (7), methionine (4), and proline (2) constitute 74% of this sheath. Polar side chains of glutamine (4), lysine (2), arginine (2), aspartate (2), glutamate (1), asparagine (1), serine (1), and histidine (1) that are located at the ends of the sheath in contact with the head groups of the phospholipid make up only 10%.

Although the sheath surrounding the protein is not

Figure 14–16: Skeletal drawing of the crystallographic molecular model of the membrane-spanning domain of potassium channel KcsA from *Streptomyces lividans*.³⁴⁴ Potassium channel KcsA is an α_4 homotetramer with cyclic symmetry of point group $4(C_4)$. Its four subunits are arrayed around a 4-fold rotational axis of symmetry normal to the plane of the membrane. Plasma membranes from *S. lividans* were dissolved in *n*-decyl β -D-maltoside, and potassium channel KcsA was purified from this solution.³⁴³ The carboxy-terminal 35 amino acids following Phenylalanine 125 were removed from each subunit of the purified tetramer by digesting the protein with chymotrypsin. Each of the amino-terminal domains of the subunits in the α_4 tetramer that resulted from the digestion was bound to the Fab fragment of a monoclonal immunoglobulin directed against this domain, and the complex between the Fab fragments and the tetramer of the four domains was purified and crystallized. Only the crystallographic molecular model of the membrane-spanning tetramer of the four truncated subunits is drawn. The side chains of all of the truncated subunits are drawn with thin line segments, but two different thicknesses of line segments were used to draw the polypeptide backbones of the subunits so that they could be distinguished. Only two of the subunits are numbered. There are two membrane-spanning α helices in each truncated subunit. In between these membrane-spanning α helices in each subunit is a loop of polypeptide that joins its three other quadrants in the center of the tetramer around the 4-fold rotational axis of symmetry to form a channel that selects only potassium ions for transport across the membrane. The gray circles represent three potassium ions that were found in this channel on their way across the protein in the map of electron density. The channel that selects the potassium ions is lined by the acyl oxygens of the four segments of polypeptide from the Threonines 75 to the Aspartates 80. The cations approach the channel by passing through a larger, water-filled vestibule connected to the cytoplasm of the cell and formed by the eight membrane-spanning α helices. This vestibule is in the center of the lower half of the model. The cytoplasmic end of the protein is at the bottom of the drawing. This drawing was produced with MolScript.⁷⁷⁸

so clearly visible in the regions of an integral membrane-bound protein that spans a membrane with a bundle of α helices, it can be delineated by scoring the exposure of the side chains in these α helices to the bilayer of phospholipid. For example, the sheath surrounding the membrane-spanning α helices in the photosynthetic reaction center (Figure 14-17) from *Rhodobacter sphaeroides* is formed from side chains that have greater than 20% of their respective surface areas exposed to the bilayer of phospholipid.³⁷⁴ Of those side chains that have greater than 50% of their respective surface areas exposed to the bilayer, 91% are leucines (15), isoleucines (12), phenylalanines (12), valines (7), alanines (6), glycines (5), tyrosines (5), tryptophans (4), and methionines (3); of those with 20–50% exposed, 71% are from this same set of side chains. In keeping with the α -helical secondary structure, only one proline, that at the end of one of the α helices, is exposed to the bilayer. The two glutamines and the one lysine that have more than 50% of their surface area exposed are at the edges of the membrane, as are the three glutamates and the single asparagine, glu-

Figure 14-17: Skeletal drawing of the polypeptide backbone of the crystallographic molecular model of photosynthetic reaction center from *Rhodospseudomonas viridis*.³²¹ A purified preparation of photosynthetic membranes was isolated from broken cells by differential centrifugation followed by isopycnic centrifugation (see Figure 14-1). The membranes were dissolved in *N*-dodecyl-*N*,*N*-dimethylamine *N*-oxide (14-14) and submitted to chromatography by molecular exclusion in a solution of the same detergent. Fractions containing reaction center were identified by its characteristic absorbance at 830 nm. These fractions were pooled, and crystals of reaction center were produced in concentrated solutions of ammonium sulfate. The protein is composed of four different subunits. The C subunit (drawn with thin gray line segments) is a cytochrome with four hemes that sits on the extracytoplasmic side (top) of the protein. The L subunit (thick black line segments) and the M subunits (thin black line segments) are homologous, share a common ancestor, have superposable structures, and each contains five membrane-spanning α helices arrayed about a 2-fold rotational axis of pseudosymmetry normal to the plane of the membrane. These membrane-spanning α helices form two cages that enclose the bacteriochlorophylls and bacteriopheophytins contained within the protein. The H subunit (thick gray line segments) is an anchored membrane-bound protein with a single membrane-spanning α helix. The globular domain of the H subunit grips the cytoplasmic surface (bottom) of the heterodimer of the L subunit and the M subunit. Only the hydrogen bonds in the membrane-spanning α helices are drawn. This drawing was produced with MolScript.⁷⁷⁸

tamine, and arginine that have 20–50% of their respective surface areas exposed. The side chains of these amino acids are in contact with the polar head groups of the phospholipids.

These observations illustrate the fact that the portion of each of the integral membrane-bound proteins that is immersed in the bilayer is surrounded by a sheath that is significantly enriched in hydrophobic amino acids. This sheath forms a **boundary between protein and lipid** that is compatible with the hydrocarbon in the middle of the membrane and the head groups at the two surfaces and dissolves the protein in the bilayer of phospholipid and cholesterol just as the polar surfaces of globular, water-soluble proteins dissolve them in water. The distribution of hydropathy over the surface of this sheath determines the **depth** at which the protein floats within the bilayer of phospholipid and its orientation relative to the plane of the membrane.³⁷⁴

In integral membrane-bound proteins that are situated in plasma membranes and intracellular membranes and that consequently span these membranes with a bundle of α helices, the few lysines, arginines, aspartates, asparagines, glutamates, glutamines, and tyrosines that they contain are usually located at the ends of these membrane-spanning α helices, and the **polar or charged nitrogens and oxygens** in their side chains reach out of the hydrocarbon of the bilayer of phospholipid into the polar interfaces on each side, as if their side chains were **snorkels**.³⁷⁵⁻³⁷⁷ Lysines, arginines, aspartates, and glutamines are located almost twice as often at the amino-terminal end as at the carboxy-terminal end of a

membrane-spanning α helix. An amino-terminal location assists in the emergence of their side chains from the hydrocarbon because the two rotamers ($\chi_1 = +66^\circ$ and $\chi_1 = -65^\circ$) at the β carbon that point their side chains in the amino-terminal direction are about twice as populated as the one ($\chi_1 = -177^\circ$) that points them towards the carboxy terminus.^{378–381} Lysines and arginines both in single, membrane-spanning α -helical anchors and membrane-spanning bundles of α helices in integral membrane-bound proteins³⁸² are about twice as likely to be located at the cytoplasmic ends of the α helices.³⁸³ This tendency is due in part to the negative surface charge on the cytoplasmic side of naturally occurring membranes.³⁸⁴

Within the sheath of hydrophobic side chains, the structure of an integral membrane-bound protein resembles the interior of a globular, water-soluble protein except for the fact that all membrane-spanning segments of integral membrane-bound proteins from plasma membranes and intracellular membranes, even

those well within the sheath, are α helices. Proteins that form channels for metabolites and inorganic ions often have significant aqueous pores passing most of the way through them (Figure 14–16), but proteins that do not have such pores still have locations occupied by molecules of water within the β barrel³⁵⁹ or within the bundle of α helices³²⁶ that spans the membrane. As in water-soluble proteins, these **locations occupied by molecules of water** can be clustered, or they can be entirely surrounded by donors and acceptors from the protein. There are also sites occupied by inorganic cations³³⁵ or anions³³⁰ in the membrane-spanning regions.

In those integral membrane-bound proteins that span the membrane with a bundle of α helices that contain no aqueous channels, the density with which their atoms are packed is about 5% greater than that of a water-soluble protein formed from a bundle of α helices,³⁸⁵ but the **packing of the α helices** is similar. Although the α helices of bacteriorhodopsin (Figure

Figure 14–18: Skeletal drawing of the polypeptide backbone of an individual protomer of the $(\alpha\beta\gamma\delta\epsilon\zeta\eta\theta\kappa)_2$ homodimer in the crystallographic molecular model of ubiquinol-cytochrome-*c* reductase from mitochondria of *Saccharomyces cerevisiae*.³⁷¹ Mitochondrial membranes from *S. cerevisiae* were dissolved in a solution of *n*-dodecyl β -D-maltoside, and ubiquinol-cytochrome-*c* reductase was purified chromatographically from this solution.³⁷² The protein was crystallized in a complex with a fragment of a monoclonal immunoglobulin containing only the V_H and V_L domains (Figure 11–1) in a solution of *n*-undecyl β -D-maltoside by use of poly(ethylene glycol) as a precipitant. The cytoplasmic, extramitochondrial surface of the protein is at the bottom of the drawing; the extracytoplasmic, intramitochondrial surface is at the top. The protein contains 10 subunits, only nine of which appeared in the map of electron density. The two intramitochondrial core proteins (431 and 352 aa; thin gray and thin black line segments, respectively) form a large, globular structure devoid of coenzymes and peripheral to the membrane (upper right corner of the drawing). Cytochrome *b* (385 aa; thick gray line segments) contains two hemes and is the major membrane-spanning subunit of the protein. It is almost entirely immersed in the bilayer. Cytochrome c_1 (248 aa; intermediate black line segments) contains one heme and is an anchored membrane-bound protein with one membrane-spanning segment (center of the drawing) and an extramitochondrial globular domain (bottom of the drawing). The Rieske iron-sulfur subunit (185 aa; thin black line segments) contains one iron-sulfur cluster and is another anchored membrane-bound protein, but, unlike cytochrome c_1 , its globular, extramitochondrial domain (lower right corner of the drawing) is unattached to the rest of the structure. Subunit VI (147 aa; thin black line segments) is a peripheral membrane-bound protein that is bound to the globular, extramitochondrial domain of cytochrome c_1 (lower left corner of the drawing) and that has no contact with the bilayer. Subunit VII (127 aa; thin black line segments) is another peripheral membrane-bound protein that is bound to the intramitochondrial surface of cytochrome *b* (upper left corner of the drawing). Subunits VIII and IX (94 and 65 aa, respectively; thick black line segments) each span the membrane with a single α helix (to the left and to the right in the drawing). Again, only the hydrogen bonds in the α helices that span the membrane are drawn. This drawing was produced with MolScript.⁷⁷⁸

Figure 14-19: Skeletal drawing of the polypeptide backbone of the crystallographic molecular model of porin Ompf from *E. coli*.³⁵⁵ A mixture of fragments of all of the membranes from a homogenate of *E. coli* were first extracted with 0.5% octyl poly(ethylene oxide), and the membranes that remained were then dissolved in 3.0% octyl poly(ethylene oxide). The porin Ompf was purified chromatographically from this latter solution and crystallized by use of poly(ethylene glycol) as a precipitant. The α_3 trimer of the porin is drawn. The subunit to the front is drawn with black line segments, and the hydrogen bonds within the membrane are included only in this subunit. The two symmetrically related subunits in the back are drawn with gray line segments. The 3-fold rotational axis of symmetry is vertical and normal to the plane of the membrane, which is horizontal. Notice that the β sheet of each subunit enclosed within the interfaces that form the trimer is not high enough to span the membrane as do the β sheets on the outside of the trimeric protein, so the protein makes sense only as a trimer. The extracellular surface of the protein is at the top of the drawing. Because the protein spans the outer membrane of the bacterium, the surface to the bottom of the drawing faces the periplasm, which is the space between the outer membrane and the plasma membrane of the bacterium. This drawing was produced with MolScript.⁷⁷⁸

14-14) are all almost parallel to each and normal to the plane of the membrane,³²⁵ in most of the proteins of this class, the α helices are tilted with respect to each other (Figures 14-15, 14-16, 14-17, and 14-18). For example, in the photosynthetic reaction center from

R. sphaeroides,³⁷⁴ the average angle of tilt is $+22^\circ$. About 50% of the angles Ω between two adjacent membrane-spanning α helices (Figure 6-23) in crystallographic molecular models of integral membrane-bound proteins have values between $+10^\circ$ and $+30^\circ$,^{386,387} but these angles can be either positive or negative, even within the same protein.^{331,337}

In a β barrel, the β strands are automatically held in rigid orientation by the regular array of interstrand hydrogen bonds, but when a bundle of α helices assembles in the membrane they are held together by an irregular array of adventitious interhelical hydrogen bonds. For example, in bacteriorhodopsin, which has a bundle of seven α helices spanning the membrane (Figure 14-14), there are 31 hydrogen bonds that interconnect 12 pairs of these α helices³²⁶ and that are in part responsible for their relative orientations and the tertiary structure they assume. Most of these **hydrogen bonds** are between donors and acceptors found at the ends of the α helices, locations in which polar and charged side chains are frequently found, but 10 of them are in the middle of the membrane within the regions of the hydrocarbon of the bilayer of phospholipid (Table 14-7). All of the ionizable side chains should be in the neutral form of their acid-base (Lysine 216 is the imine of a retinol) so that the carboxy groups of the aspartic and glutamic acids have both a donor and three acceptors. Many of these interhelical hydrogen bonds are from a donor or acceptor on the protein to a molecule of water and from there to a donor or acceptor on the protein. These bridging molecules of water are found at locations within the bilayer.

As has been noted previously, each of these hydrogen bonds has a significantly negative enthalpy of formation that is released during the assembly of these

^a α Helix A spans the membrane with amino acids 11 through 29; α helix B, 44 through 62; α helix C, 79 through 96; α helix D, 108 through 127; α helix E, 135 through 154; α helix F, 173 through 191; and α helix G, 204 through 223. ^bOnly hydrogen bonds within the hydrocarbon of the bilayer are tabulated. ^cHydrogen-bonded through a molecule of water. ^dLysine 216 is posttranslationally modified with a retinal.

α helices within the membrane to produce the tertiary structure of the protein. Once each membrane-spanning α helix has become inserted in the bilayer of phospholipid, however, the **hydrophobic effect** is no longer in operation. Consequently, the importance of hydrogen bonding and the importance of the hydrophobic effect in the formation of tertiary structure are reversed once that portion of the polypeptide is within the hydrocarbon of the bilayer of phospholipid. During the assembly of the α helices, hydrogen-bond donors and acceptors can be responsible for significant, favorable standard enthalpy of formation, yet no favorable change in standard free energy, other than that associated with the packing efficiency, occurs when two hydrophobic surfaces are juxtaposed. The situation, however, is similar to that observed in the folding of a water-soluble protein in that the hydrophobic effect in the one case immerses the α helix in the bilayer and in the other produces the initial hydrophobic collapse of the polypeptide. After these hydrophobically driven events, the establishment of the final tertiary structure relies not at all or much less, respectively, on the hydrophobic effect because it has already been expended.

Prolines are present in many of the α helices in membrane-spanning bundles.³⁸⁸ As it does in an α helix in a water-soluble protein, a proline always occupies a kink in a membrane-spanning α helix. There are also kinks in membrane-spanning α helices that do not incorporate a proline,³²⁶ but it has been noted that wherever there is such a kink in a membrane-spanning α helix there will be a high frequency of homologous proteins that have prolines at that position.³⁸⁸ In addition, it has been demonstrated that the introduction of a proline at an unkinked position in a membrane-spanning α helix usually produces a protein unable to assume its native structure,³⁸⁹ while changing a proline at a kink to an alanine has little effect on the protein.³⁸⁸ Evidently, a kink that has been established by evolution through natural selection in a membrane-spanning α helix prefers to have a proline at the position of the kink, but not exclusively, while established, unkinked segments of α helix are too rigidly held within the structure to tolerate the inevitable kink that results from inserting a proline.³⁸⁸ A proline just beyond one of the ends of a membrane-spanning α helix can promote the doubling back of the polypeptide to form the next membrane-spanning α helix.³⁹⁰

The question of whether or not there are **cystines** within the membrane-spanning segments of integral membrane-bound proteins is of chemical interest. First, the interior of a bilayer of phospholipid is devoid of glutathione or any other small mercaptan. Second, oxygen is more soluble in the hydrocarbon of a bilayer than it is in water. Third, the oxidation of two thiols to a disulfide performed by oxygen is a free radical reaction that should proceed normally within the hydrocarbon. Fourth, cystine is one of the most hydrophobic of the side

chains. In spite of these facts, there do not appear to be any cystines in the membrane-spanning segments of integral membrane-bound proteins. One of the first indications of this peculiar absence was the observation that acetylcholine receptor from *Torpedo californica*, although it has a total of 13 cysteines in its 20 membrane-spanning α helices, has no cystines in those membrane-spanning α helices.³⁹¹ Although there are a number of cystines in the extracytoplasmic portions of the crystallographic molecular models listed in Table

Figure 14-20: Skeletal drawing of the polypeptide backbone of the crystallographic molecular model of ferrichrome-iron receptor from *E. coli*.³⁵⁷ Membranes from a strain of *E. coli* that overexpresses ferrichrome-iron receptor were dissolved in 2% Triton X-100, and the ferrichrome-iron receptor was purified chromatographically from this solution. In the final chromatographic step, which was by molecular exclusion, the protein was transferred from 2% Triton X-100 to 1% *n*-octyl β -D-glucoside. It was crystallized from this solution by the use of poly(ethylene glycol) as a precipitant. The protein is a monomer, so the β sheet must be high enough to span the outer membrane all the way around. Only the hydrogen bonds in the portions of the β sheet that span the membrane are included. The extracellular surface of the protein is on the top; the surface facing the periplasm is on the bottom of the drawing. This drawing was produced with MolScript.^{77b}

14–6,^{331,333,335,337,351,391} there is none in any of the membrane-spanning portions of these proteins, with the exception of a cystine in the center of the large water-filled pore passing through maltoporin.³⁵³ This latter cystine, however, is not in contact with the hydrocarbon of the outer membrane.

The photosynthetic reaction center from *R. viridis* (Figure 14–17) has 11 **membrane-spanning α helices**. Each traverses the hydrocarbon of the bilayer of phospholipid in one unbroken α helix. The amino acid sequences of these 11 α helices³²² are –SLGVLSLFSGLMWFFTIGIWFYNA–, –LKEGGLWLIASFFMFVAVWSW WGRTYLRAQA–, –AWAFLSAIWLWMVLGFIRPILM–, –PFHGLSIAFLYGSALLFAMHGATILAV–, –MEGIHRWAIWM AVLVTLTGGIGILL–, –GFFGVATFFAALGIILAWSAVL–, –GGLWQIITICATGAFVSWALREVEICRKL–, –HIPFAFAIL AYLTLVLFPRPVM–, –PAHMIAISFFFTNALALALHGALVLS AA–, –GTLGIHRLGLLLSLAVFFSALCMII–, and –IAQLV WYAQWLVIWTVVLLYLRRDR–.^{392–394} In each of these amino acid sequences there is a region of at least 20 amino acids in length that contains no amino acids that are charged at neutral pH with the exception of the arginines at the carboxy-terminal ends of the third and the eighth α helices. The reason that these 11 α helices were able to be inserted into the bilayer of phospholipid is that they are composed of hydrophobic amino acids and the bilayer is an organic solvent into which the side chains of these amino acids have dissolved.

These 11 hydrophobic segments of amino acid sequence are similar to the five listed earlier for the single membrane-spanning α helices from anchored membrane-bound proteins but differ in flavor. The hydrogen-bond donors, tryptophan and tyrosine, are more uniformly distributed over the length of these segments; the neutral but hydrophilic hydrogen-bond donors and acceptors glutamine, asparagine, and histidine now occasionally appear; and the frequency with which glycine is encountered is greater. Each of these subtle changes indicates that these amino acid sequences are from a bundle of α helices gathered together as a protein rather than from individual α helices spanning the extremely hydrophobic environment of the membrane as isolated entities. Even in α helices completely buried in the center of one of these bundles, however, such as the three α helices –PRMNNMSFWLLPPSFLLLASSM–, –ASVDLTIFSLHLAGVSSILGAINFITTN–, and –LFVWSV MITAVLLLLSLPVLAAGITMLLTD– from bovine mitochondrial cytochrome-*c* oxidase,³³³ the preponderance of hydrophobic amino acids at the center of each persists.

Even though most integral membrane-bound proteins are dissolved in solutions of a nonionic detergent before they are crystallized (Table 14–6), they carry **molecules of phospholipid** from the original membranes along with them into the respective crystals, and if the maps of electron density are clear enough, these mole-

cules can be recognized and included in the crystallographic molecular model. For example, in a crystallographic molecular model of photosynthetic reaction center from *R. sphaeroides*, there is a molecule of diphosphatidylglycerol;³⁹⁵ in one for bovine mitochondrial cytochrome-*c* oxidase, there are five molecules of phosphatidylethanolamine and three molecules of phosphatidylglycerol;³³³ and in one for ubiquinol-cytochrome-*c* reductase from *S. cerevisiae*, there is a molecule of phosphatidylcholine, two of phosphatidylethanolamine, one of phosphatidylinositol, and one of diphosphatidylglycerol.³⁷¹ At least two diether lipids (see 14–8) are represented by their 1-(2,6,10,14-tetramethylhexadecan-16-yl)-2-(2,10,14-trimethylhexadecan-16-yl)glyceryl groups in the crystallographic molecular model of bacteriorhodopsin.³²⁶

The fatty acyl or isoprenyl chains of all of these molecules of phospholipid or diether lipid usually lie within the straight crevices running between the membrane-spanning α helices in an orientation roughly normal to the plane of the membrane, but in one case the fatty acyl groups penetrate sideways into spaces between the α helices,³⁷¹ and the head group of this particular phospholipid is 0.8 nm away from the plane in which head groups are normally located (Figure 14–2). The head groups of all of the other phospholipids in these crystallographic molecular models are in the expected positions, and they engage in many hydrogen bonds with side chains of the protein and molecules of water occupying fixed locations bridging those head groups and the protein.

It is possible that these rigidly fixed molecules of phospholipid are structurally essential just as many of the molecules of water in the interior of a molecule of protein are structurally essential. If so, these observations may explain why integral membrane-bound proteins often lose their biological activity and even their tertiary structure when the ratio of detergent to protein becomes too large. They may also be examples of molecules of phospholipid within the boundary layer that are most severely immobilized, just as fixed locations for molecules of water on the surface of a crystallographic molecular model are the most severely immobilized molecules of the waters of hydration.

The sheath of hydrophobic side chains surrounding an integral membrane-bound protein is immersed in the bilayer of phospholipid and surrounded by the hydrocarbon of the amphipathic and neutral lipids. The lipids in this boundary layer are those molecules of lipid the behavior of which is affected at a given instant by the presence of the protein. Molecules of **lipid in the boundary layer** can be formally distinguished from those molecules of lipid that behave as if they were in an unadulterated bilayer of the same amphipathic lipids.

This distinction resembles in its ambiguity the distinction between water of hydration associated with a protein (Table 6–4) and water in the bulk solution. In the case of water of hydration, there is a gradual diminution

of the influence of the protein the farther a particular molecule of water is from its surface, but a water molecule several shells from the protein may still be influenced by it because of the nets of hydrogen bonds that ensnare both water and protein. Likewise, a molecule of amphipathic lipid somewhat distant from the protein may be marginally influenced by it when one or two of its methylenes strike against the surface of the protein as the linear hydrocarbon writhes within the liquid paraffin, but molecules of amphipathic lipid embracing the protein should be more severely affected. Networks of hydrogen bonds among the hydrophilic head groups of the phospholipids and sphingomyelins (Figure 14-6) may also spread the influence of the protein beyond its immediate vicinity. In this context, lipid in the boundary layer³⁹⁶ surrounding the protein and under its influence has been defined operationally just as water of hydration has been defined operationally. Just as in the case of waters of hydration, a single numerical value for moles of lipid in the boundary layer (mole of protein)⁻¹ is measured.

When 1-palmitoyl-2-stearoylphosphatidylcholine, to which a dimethyl cyclic nitroxyl radical is attached at the 14th carbon of the stearyl group,

is incorporated into bilayers of phosphatidylcholine containing an integral membrane-bound protein such as Ca^{2+} -transporting ATPase, the electron spin resonance spectrum that is observed (Figure 14-21A)³⁹⁷ can be decomposed into two spectra (Figure 14-21B,C) of which it is the sum.^{396,398} One of the component spectra is the same as that of nitroxylphosphatidylcholine **14-16** in pure vesicles of liquid phosphatidylcholine (Figure 14-21F), and one is that of nitroxylphosphatidylcholine **14-16** when its motion is restricted (Figure 14-21E). It was concluded³⁹⁹ that there are two sets of nitroxylphosphatidylcholines **14-16** present in these bilayers, one set constituted by molecules of **restricted mobility** located in the boundary layer immediately adjacent to the protein and the other constituted by molecules of **unrestricted mobility** in the bulk bilayer of phospholipid. The rates at which lipids exchange at positions within the boundary layer⁴⁰⁰ are around 10^7 s^{-1} so no one molecule of phospholipid remains for a significant amount of time within it.

As the ratio between phosphatidylcholine from eggs of *G. gallus* and Ca^{2+} -transporting ATPase in these

Figure 14-21: Decomposition of the electron spin resonance spectrum of nitroxylphosphatidylcholine **14-16** in vesicles of phospholipid in which Ca^{2+} -transporting ATPase from *O. cuniculus* has been incorporated.³⁹⁷ Ca^{2+} -Transporting ATPase, from which all indigenous phospholipid had been removed, was incorporated into vesicles of phosphatidylcholine from eggs of *G. gallus* into which nitroxylphosphatidylcholine **14-16** was also incorporated. In the final suspension of vesicles containing the protein, the molar ratios of Ca^{2+} -transporting ATPase ($110,500 \text{ g mol}^{-1}$) to phosphatidylcholine to phosphatidylcholine nitroxyl radical were 1:55:0.4. The nitroxyl radical was acting as a probe present in dilute concentration within a solvent of phosphatidylcholine. The observed electron spin resonance spectrum (A) of this probe in this environment could be decomposed into two component spectra. One component (C), which accounted for 54% of the spins producing spectrum A, had the same spectrum as the probe dissolved in the same preparation of phosphatidylcholine in the absence of protein (F). The other component (B), which accounted for 46% of the spins producing spectrum A, was assumed to represent boundary lipid. It had the same spectrum as that of the probe dissolved in a viscous bilayer composed of dipalmitoylphosphatidylcholine and palmitoyloleoylphosphatidylcholine at a ratio of 4:1 (E). The effect of the immobilization of the probe by the viscous bilayer of phospholipid resembles the effect of the protein on the probe (compare spectra B and E). A summation of reference spectra E and F, at a molar ratio of 0.46 to 0.54, produced theoretical spectrum D, which reproduces the observed spectrum A. All spectra are the amplitude of the first derivative of the adsorption of the microwave energy as a function of the strength of the magnetic field (tesla). Reprinted with permission from ref 397. Copyright 1984 American Chemical Society.

membranes is increased, the fraction of restricted nitroxylphosphatidylcholine **14-16** decreases. This decrease results from a competition between unlabeled molecules of phosphatidylcholine and molecules of nitroxylphos-

phatidylcholine **14–16** for positions in the boundary layer adjacent to the protein and the increase in the concentration of the former. From the numerical values of the fraction of restricted nitroxylphosphatidylcholine **14–16** as a function of the molar ratio between phosphatidylcholine and protein, the ratio between the affinities of nitroxylphosphatidylcholine **14–16** and unmodified phosphatidylcholine for positions adjacent to protein can be estimated, and the number of molecules of phosphatidylcholine occupying positions adjacent to the protein can be calculated.⁴⁰¹

In the case of Ca^{2+} -transporting ATPase at 25 °C,^{397,398} phosphatidylcholine and nitroxylphosphatidylcholine **14–16** have equal affinity for positions around the protein and the number of positions is 22 mol (mol of protein)⁻¹. In other words, there are, on the average, 22 molecules of phospholipid in the boundary layer around a molecule of Ca^{2+} -transporting ATPase, each of which can exchange with no bias for a molecule of nitroxylphosphatidylcholine **14–16**, and these 22 molecules of natural, unlabeled phosphatidylcholine occupy locations at which a molecule of nitroxylphosphatidylcholine **14–16** would be restricted in its motion by the protein. Similar measurements with spin-labeled cholesterol demonstrated that cholesterol was able to occupy all of the positions around Ca^{2+} -transporting ATPase within the boundary layer but with an affinity about two-thirds that of natural phosphatidylcholine.³⁹⁷

The **number of lipids in the boundary layer** has been estimated to be 94 ± 10 for each homodimer of cytochrome-*c* oxidase,³⁹⁹ 40 ± 7 for each heteropentamer of acetylcholine receptor,⁴⁰² 21 ± 3 for each monomer of bovine rhodopsin,⁴⁰³ and 10 for each folded polypeptide of myelin proteolipid protein.⁴⁰⁴ The numbers of lipids in the boundary layer is roughly equal to the number of molecules of lipid needed to cover the surface of the sheath for that protein with one layer of linear alkane aligned normal to the plane of the membrane.⁴⁰⁵

It is not necessarily the case that when a position in the boundary layer is occupied by a natural phospholipid rather than nitroxylphosphatidylcholine **14–16**, the motion of that natural phospholipid is noticeably affected. The side chains of the amino acids presented by the sheath surrounding the membrane-spanning bundle of α helices to the linear hydrocarbon of the phospholipid are themselves branched hydrocarbons that are free to rotate fluidly, and the hydrocarbon of phosphatidylcholine may experience little change as it enters or leaves these positions. When Ca^{2+} -transporting ATPase was incorporated into vesicles of dioleoylphosphatidylcholine in which either the 2nd carbons or the 9th and 10th carbons on the two fatty acids were labeled with deuterium rather than a nitroxyl radical, the effect of the protein on the motion of these lipids could be followed by deuterium nuclear magnetic resonance spectroscopy.⁴⁰⁶ The protein was present at a ratio of about 1 mol (100 mol of phospholipid)⁻¹. Statistically signifi-

cant **increases in the anisotropy** at the 9th and 10th carbons were detected when the protein was added to the bilayer but not at the 2nd carbon. The increase in anisotropy observed, even with the assumption that only 20–30% of the lipid was in the boundary layer, was only about 10–20% for the lipids in these positions. This small increase indicates that the protein does not force the hydrocarbon in this region to assume conformations much more irregular than those it would normally assume. The deuterium spin-lattice relaxation times, which are measures of the fluidity of the hydrocarbon, were barely altered by the presence of the protein, and no evidence for two separate sets of phospholipids remaining distinct over time intervals greater than 5 ms was observed.

Just as with soluble proteins, many integral membrane-bound proteins (Table 14–6) are homooligomers (Figures 14–16 and 14–19) or heterooligomers (Figures 14–17 and 14–18). Now that synthetically pure detergents are available, it is possible to dissolve a membrane, and if an oligomeric protein of interest is stable enough, the dissolution can produce a monodisperse solution of that membrane-bound oligomer. Each complex between a micelle of the detergent and an oligomer of that protein in such a solution has the same shape, as judged by its frictional coefficient, and the same molar mass, as judged by sedimentation equilibrium.^{407,408} Furthermore, it seems to be the case that **the oligomer found in solution** upon dissolving the membrane is often, but not always,²²⁴ the same one originally present in the membrane.²²²

While **quantitative cross-linking** gives reliable determinations of the number of subunits in water-soluble oligomeric proteins and for integral membrane-bound proteins in solutions of detergent,^{224,347} it fails to do so for membrane-bound oligomers that are still within the membrane. The problem is that the membrane-bound proteins within a native membrane are always at too high a concentration, and it is technically difficult to dilute them sufficiently to prevent them from cross-linking intermolecularly. Even when the membranes contain only one protein, quantitative cross-linking usually produces covalent polymers so large that their complexes with dodecyl sulfate do not even enter an acrylamide gel upon electrophoresis.²²⁵ If particular care is taken to reconstitute a membrane-bound protein at high ratios of phospholipid to protein so that each reconstituted vesicle is large and each contains only a few molecules of the protein, intermolecular cross-linking can be suppressed sufficiently that intramolecular cross-linking can give an accurate assessment of the oligomeric state of the protein.⁴⁰⁹ The ideal preparation for assessment of the number of subunits in the oligomer of an integral membrane-bound protein by quantitative cross-linking would be a suspension of vesicles in which each vesicle contained only one copy or no copies of the oligomer.

Oligomeric proteins constructed from identical subunits always incorporate rotational axes of symmetry into their structures. In a bilayer of amphipathic lipids, all of the identical subunits of either an oligomeric, anchored membrane-bound protein or an oligomeric, integral membrane-bound protein are inserted so that they point in the same direction. Because the same hydrophobic segments of their common amino acid sequence span the bilayer, all folded polypeptides of the same sequence float at the same depth in the membrane and have the same orientation. These inescapable requirements placed upon the common structure of the subunits of oligomeric membrane-bound proteins force any rotational axis of symmetry relating the individual subunits in the protein to be normal to the plane of the bilayer. Therefore, a membrane-bound homooligomeric protein can have only one rotational axis of symmetry, and that axis will be normal to the plane of the membrane. Consequently, all **membrane-bound oligomeric proteins** must have **cyclic symmetry**, and dihedral symmetry⁴¹⁰ is prohibited. The same argument can be made for membrane-bound heterooligomers formed from homologous, superposable subunits. These heterooligomers will contain rotational axes of pseudosymmetry normal to the plane of the membrane.

Closed structures with rotational axes of symmetry are even more exclusive necessities for oligomeric membrane-bound proteins than they are for soluble proteins. A screw axis of symmetry is incompatible with the vectorial two-dimensional distribution of identical or homologous subunits enforced by the bilayer, and helical polymeric fibers are not available structures. The only interfaces that could propagate a linear polymer of indefinite length in a membrane would have to form from complementary faces arrayed at precisely 180° across from each other on each subunit, or the row of subunits produced by them would eventually come around upon itself to form an unbroken or a broken ring. During evolution by natural selection, therefore, every time two complementary faces appear at random on the surface of one monomer of a membrane-bound protein such that those two faces can produce a series of interfaces joining several of the subunits in an oligomer, either an incomplete ring or a complete ring of an integral number of subunits will always form. A complete ring, because no pair of complementary faces remains unassociated, is a more stable structure than an incomplete ring. If the angle between the two complementary faces on a single subunit is an integral quotient of 360°, where the integer is greater than or equal to 3, complete rings containing that number of subunits will form. Because only one rotational axis of symmetry normal to the bilayer is available, magic numbers such as four or six, applicable to soluble oligomeric proteins having sets of perpendicular rotational axes of symmetry, are irrelevant to membrane-bound oligomeric proteins. In addition, unlike a soluble protein such as hemoglobin, a membrane-bound pro-

tein cannot be tetrameric under one set of conditions and dimeric under another.^{410,411}

It is not surprising that the oligomeric membrane-bound proteins the structures of which have been directly observed are all assembled around **single rotational axes of symmetry normal to the plane of the bilayer**. In this case, the distinction between anchored and integral membrane-bound proteins is irrelevant because both are constrained by the same requirements. Thus both bacteriorhodopsin,⁴¹² an integral membrane-bound protein, and the hemagglutinin of influenza virus,²⁸⁷ an anchored membrane-bound protein, have three identical subunits arrayed around a 3-fold rotational axis of symmetry normal to the plane of the membrane. Photosynthetic reaction center, an integral membrane-bound protein containing two different polypeptides with homologous amino acid sequences,^{392,393} has those two folded polypeptides arrayed around a 2-fold rotational axis of pseudosymmetry normal to the plane of the membrane (Figure 14-17).⁴¹³ Exo- α -sialidase of influenza virus, an anchored membrane-bound protein, has four identical subunits arrayed around a 4-fold rotational axis of symmetry.⁴¹⁴

Acetylcholine receptors from *T. californica* and *T. marmorata* are integral membrane-bound proteins. Each is an $\alpha_2\beta\gamma\delta$ heteropentamer^{415,416} constructed from four unique polypeptides,^{417,418} designated α , β , γ , and δ on the basis of their electrophoretic mobilities. All four of these polypeptides are glycoproteins,^{391,419} and all four are homologous in sequence.⁴²⁰⁻⁴²³ All four can be readily aligned, and in the six pairwise comparisons the percent identity averages around 40%.⁴²² These four distinct subunits were derived from a common ancestor and all four of them assume the same unique superposable tertiary structure upon folding.³⁴⁶ The five subunits, $\alpha_2\beta\gamma\delta$, in the native structure of acetylcholine receptor are arrayed around a 5-fold **rotational axis of pseudosymmetry** normal to the plane of the membrane (Figure 14-22).^{424,425}

Gap junction connexon, an integral membrane-bound protein, has six identical subunits arrayed around a 6-fold rotational axis of symmetry.⁴²⁶ In each gap junction between two cells, each connexon, which is a ring of six subunits in the plasma membrane of one of the cells, is associated by a 2-fold rotational axis of symmetry with another gap junction connexon in the membrane of the other cell to produce a dodecamer that is a dimer of hexamers with dihedral symmetry of point group 622 (D_6) with one hexamer in each plasma membrane. Within the plasma membrane of a given cell, the connexons are in crystalline arrays of indefinite surface area.⁴²⁷ A different hexamer of identical subunits arrayed around a 6-fold rotational axis of symmetry normal to the plane of the bilayer⁴²⁸ is the major constituent of the luminal plasma membrane of urinary bladder, and this protein is also present in the cell in a crystalline array.⁴²⁹

There is a group of proteins the crystallographic

Figure 14-22: Map of electron scattering density of acetylcholine receptor embedded in a glass of amorphous ice.^{424,425} Membranes enriched in acetylcholine receptor were prepared from electric organs of *Torpedo marmorata* by differential centrifugation. The membranes were resuspended in 0.1 M tris(hydroxymethyl)aminomethane hydrochloride, pH 6.8, and allowed to stand at 10 °C for 1 month, at which time long (<1 μm) cylindrical tubes 70 nm in diameter had formed. These tubes were helical, crystalline arrays of molecules of acetylcholine receptor within tubular bilayers of the amphipathic lipid from the membranes. The asymmetric unit in the helical array was a dimer of identical acetylcholine receptors. The asymmetric units formed the rows of a 15-stranded left-handed helical array in one dimension and the rows of a 5-stranded right-handed helical array in the other dimension of the $(-15,5)$ surface lattice. These tubes were embedded in a thin layer of amorphous ice on a film of carbon on an electron microscopic grid. Digitized electron micrographs of these tubes were submitted to Fourier transformation. The layer lines of the resulting diffraction pattern were indexed, and variations in phase and amplitude along the layer lines were measured from these diffraction patterns. These functions were then submitted to Fourier-Bessel inversion to obtain a three-dimensional map of electron scattering density for the tube. (A) View perpendicular to the surface of the tube of this map of scattering density. The image was made by stacking about 20 successive sheets of clear plastic of the appropriate thickness, each with a cross section of the map traced upon it. The successive sections chosen were 0.5 nm apart. Reprinted with permission from *Nature*, ref 424. Copyright 1985 Macmillan Magazines Limited. (B) Cross section through the center of a molecule of acetylcholine receptor in a plane normal to the axis of the tube. The blocklike structure at the bottom of the image is thought to be a protein other than acetylcholine receptor. The bilayer of amphipathic lipid is to the right and left. There is a deep cylindrical depression on the upper, extracytoplasmic surface of the protein and a small shallow depression on the lower, cytoplasmic surface of the protein. The five subunits arrayed about a 5-fold rotational axis of pseudosymmetry produce a thick cylindrical pipe about 7 nm in diameter and 5 nm in height with a wall 2.5 nm thick extending out from the extracytoplasmic surface of the membrane. Reprinted with permission from ref 425. Copyright 1990 Rockefeller University Press.

molecular models of which at first glance seem to contradict the axiom that all rotational axes of symmetry in integral membrane-bound homooligomers must be normal to the plane of the membrane. Aquaporin serves as a paradigm for the proteins in this group. Aquaporin is an α_4 homotetramer, which as expected has cyclic symmetry of point group 4 (C_4). There is no doubt, however, that the subunit of the aquaporin tetramer (Figure 14-23)³⁴⁸ is the product of an internal duplication. This conclusion follows from the fact that the amino acid sequence from Valine 51 to Cysteine 88 in the first half of bovine aquaporin can be readily aligned (30% identity

with no gaps) with the amino acid sequence from Glycine 167 to Threonine 204 in the second half of the molecule. This alignment brings into register the amino acids forming the second and third membrane-incorporated α helices (Figure 14-23) from the first half of the folded polypeptide with those forming the membrane-incorporated sixth and seventh α helices, respectively, from the second half of the folded polypeptide. There are eight membrane-incorporated α helices in all, so these pairings are the ones expected from an internal duplication. Outside this central region of the protein, the two amino acid sequences cannot be aligned with statistical signifi-

cance, but when the crystallographic molecular model of the subunit is viewed from the proper angle (Figure 14–23), it can be seen that there is an obvious 2-fold rotational axis of pseudosymmetry that superposes the first half of the folded polypeptide onto the second half. This superposition is made all the more compelling by the fact that the peculiar structure of the third membrane-incorporated α helix, which passes only halfway across the membrane before the polypeptide doubles back, is exactly mimicked by that of the seventh membrane-incorporated α helix.

The puzzling aspect of this 2-fold rotational axis of pseudosymmetry within the subunit of aquaporin is that it is parallel to the plane of the membrane. Most soluble proteins or subunits of soluble proteins that are the products of duplications of the genes encoding their ancestors have 2-fold rotational axes of pseudosymmetry relating the duplicated halves (Figure 9–18). It has usually been assumed that these are the vestiges of 2-fold rotational axes of symmetry that related the two halves when they were identical subunits in a homodimer before the carboxy terminus of one subunit was joined to the amino terminus of the other subunit by the duplication of the ancestral gene. If this were the case in aquaporin, then 2-fold rotational axis of symmetry relating the two identical subunits of the homodimer that was the ancestral protein would have had to be parallel to the plane of the membrane.

Because this symmetry is not possible, it follows that there was no ancestral homodimer of aquaporin and that the gene that was duplicated was one encoding a monomeric integral membrane-bound protein. Because the amino terminus of that ancestral monomer was on the cytoplasmic side of the membrane and its carboxy terminus was on the extracytoplasmic side, once the fourth membrane-incorporated α helix of the new internally duplicated protein had been inserted into the membrane, the machinery responsible for inserting the ancestral monomer into the membrane came upon a segment of polypeptide that formed the first membrane-spanning α helix in the ancestral protein but was now on the wrong side of the membrane. It was simply incorporated in the opposite direction along with the other three α helices of the duplicated half. When the two halves of the internally duplicated protein cleaved to each other, as they were bound to do, the usual 2-fold rotational axis relating the two halves of a dimer was created. Because the two halves of the protein were inserted in the membrane in opposite directions, that 2-fold rotational axis of pseudosymmetry had to be parallel to the plane of the membrane.

There are a number of other integral membrane-bound proteins the subunits or monomers of which have 2-fold rotational axes of pseudosymmetry parallel to the plane of the membrane relating the two halves of what are assumed to be the products of internal duplications.^{430–434} Because the membrane-spanning portions of

these proteins are all bundles of membrane-spanning α helices, a situation that makes any superposition more likely, and because most of these proteins have evolved to the extent that obvious alignments of amino acid sequence can no longer be made, the conclusion that the two halves result from an internal duplication usually relies almost entirely on the order in which the superposed α helices occur in the sequence of the protein. The order in which the α helices paired by the superposition around the rotational axis of pseudosymmetry occur in the second half of the amino acid sequence is the same

Figure 14–23: Skeletal drawing of the polypeptide backbone of the crystallographic molecular model (Table 14–6) of one of the subunits of isoform 1 of aquaporin purified from bovine erythrocytes.³⁴⁸ The view is down the 2-fold rotational axis of pseudosymmetry relating the two halves of the internal duplication in this protein. This drawing was produced with MolScript.⁷⁷⁸

as the order in which they occur in the first half of the amino acid sequence.

In each of these other proteins, as is the case with aquaporin, the junction between the carboxy terminus of the first half of the protein and the amino terminus of the second half of the protein is located on the opposite side of the membrane from the amino terminus of the first half. In all of these other cases, this topography results from the fact that the two halves have an odd number of membrane-spanning α helices. Consequently, following the gene duplication, the first segment of polypeptide encoding a membrane-spanning α helix at the amino terminus of the second half of each of these proteins found itself on the wrong side of the membrane during the insertion of the complete protein into the membrane and was simply incorporated in the opposite direction from the direction in which its twin at the amino terminus of the first half of the protein had been incorporated. The existence of these proteins reiterates the fact that larger proteins are created by the fusions and duplications of genes encoding their smaller ancestors.

The interfaces within the membrane among the subunits of an oligomeric membrane-bound protein should be stabilized from dissociation by different non-covalent forces from those stabilizing interfaces within soluble proteins.⁴³⁵ Because the faces forming an **interface between subunits** become surrounded by hydrocarbon upon dissociation rather than by water, the hydrophobic effect should be irrelevant. On the other hand, hydrogen bonding, which provides little favorable free energy to the formation of an interface within a water-soluble protein, should exert its full effect on stabilizing the interface of an oligomeric membrane-bound protein within the bilayer because when an interface dissociates, the hydrogen-bond donors and acceptors within it lose their acceptors and donors, respectively. These considerations were validated in a study of the effect of site-directed mutation on the interface between two identical membrane-spanning α helices within the interface forming the α_2 dimer of glycophorin.^{435–437} When the threonine within the interface was mutated to an alanine, the increase in its dissociation constant was much greater than when that threonine was mutated to a serine. Changes in hydrophobicity produced by other mutations, however, did not correlate with the respective changes in dissociation constant, but changes in the detailed stereochemical fit of one face to the other did correlate with changes in dissociation constant. These results suggest that both hydrogen bonding and stereochemical fit, but not hydrophobicity, determine the strength of an interface within the hydrocarbon of a membrane.

For those integral membrane-bound proteins that have not yet been crystallized in three dimensions, molecular models of lower resolution are often obtained from **image reconstruction** of two-dimensional crystalline arrays of these proteins still within the membrane. The protein most suited for such an approach so far has

been bacteriorhodopsin from *H. salinarium* because it is already in a two-dimensional crystalline array within the plasma membrane of the bacterium.⁴³⁸ The space group of this two-dimensional array is *P3*, and the asymmetric units related by the 3-fold rotational axes of symmetry within the unit cell are individual subunits of bacteriorhodopsin (Figure 14–14). Although bacteriorhodopsin is one of the few membrane-bound proteins that is naturally crystalline, most integral membrane-bound proteins can be induced to crystallize in two dimensions.⁴³⁹ Such crystals are then embedded in a **glass of amorphous ice**⁴⁴⁰ and are examined in a **cryo-electron microscope**, an electron microscope in which the embedded specimen is maintained at a temperature of 4 K while images are prepared.⁴⁴¹

A **two-dimensional crystalline array** of an integral membrane-bound protein within a bilayer of lipids (Figure 14–24)⁴³⁹ is a three-dimensional distribution of electron scattering density, $\theta(x,y,z)$, that is periodic in the two dimensions of the plane of the membrane. The electrons that it scatters in an electron microscope will form an electron diffraction pattern (Figure 14–25).⁴⁴² This diffraction pattern does not arise from reflections generated by sets of parallel planes running through a three-dimensional lattice (Figure 4–8) but from reflections generated by sets of parallel lines running through the two-dimensional lattice (Figure 4–4) of the projection of the three-dimensional array on a plane normal to the beam of electrons. Each reflection has an amplitude, an index, and a phase, but as always, the phases cannot be measured directly.

The indexed set of amplitudes and phases of the electron diffraction pattern from such an array are the amplitudes and phases of the Fourier transform of the projection of the three-dimensional distribution of electron scattering density of the array upon the plane normal to the axis of the beam (Equation 9–5). Therefore, they are the amplitudes and phases of a central section through the three-dimensional Fourier transform of the three-dimensional distribution of electron scattering density (Equation 9–4).

An electron micrograph of a two-dimensional crystalline array of a membrane-bound protein (Figure 14–24) is a projection of the three-dimensional electron scattering density $\theta(x,y,z)$ of the array upon a plane normal to the axis of the beam of electrons (Equation 9–6). From the digitized distribution of contrast on the electron micrograph, the amplitudes and phases of the central section of the Fourier transform of the three-dimensional electron scattering density can be calculated by a computer (Equation 9–5). Because the array is of a two-dimensional crystal, the central section through its Fourier transform is a lattice of spots. Each spot in the transform calculated by the computer from the digitized micrograph corresponds to one of the reflections in the electron diffraction pattern (Figure 14–25) and has the same phase and the same relative amplitude as it does.

Figure 14-24: Electron micrograph of a two-dimensional crystalline array of bovine cytochrome-*c* oxidase.⁴³⁹ Mitochondria from bovine heart were sonicated, and the resulting fragments of membrane were separated by differential centrifugation. Fragments rich in cytochrome-*c* oxidase were extracted with Triton X-114 and then Triton X-100 to dissolve away other proteins. The purified particulate material was composed of fragments of membrane in which the only protein was cytochrome-*c* oxidase. These fragments of membrane were attached to carbon films and embedded in a glass of the negative stain uranyl acetate. Upon examination in the electron microscope, it was found that in many of the fragments the cytochrome-*c* oxidase had crystallized into two-dimensional arrays. The upper electron micrograph is of one of these arrays viewed normal to the electron beam. The lower electron micrograph is the same array tilted on a horizontal axis so that its plane was at an angle of 36° to the beam of electrons. Reprinted with permission from ref 439. Copyright 1977 Academic Press.

This permits the **phases** to be estimated from the micrograph and the **amplitudes** to be measured from the electron diffraction pattern.

The Fourier transform of the periodic three-dimensional distribution of electron density that is a three-dimensional crystal of a protein is a three-dimensional lattice of peaks in reciprocal space. Each peak has an amplitude and a phase. Each reflection in the diffraction of X-radiation from the crystal represents one of these peaks. The Fourier transform of the three-dimensional distribution of scattering density in a crystalline array of a membrane-bound protein, which is periodic in only two dimensions, is a lattice of parallel lines in reciprocal space. Each of these parallel **lattice lines** has an amplitude and a phase that vary periodically along its length. If the variations of the amplitudes and phases along each of these lattice lines could be measured, the three-dimensional distribution of electron scattering density in the unit cell of the crystalline array could be calculated by Fourier transformation of this set of functions.

Figure 14-25: Electron diffraction pattern produced by a two-dimensional crystalline array of bacteriorhodopsin from *H. salinarium*.⁴¹² Fragments of membrane containing crystalline arrays of bacteriorhodopsin were attached to a film of carbon and embedded in a glass of glucose. The specimen was centered in the beam of electrons of an electron microscope and a photographic plate was used to record the reflections of the diffraction pattern. The reflections emerge from the specimen at characteristic angles determined by the lattice, and they are recorded on a piece of film at a known distance from the specimen. The dark central peak is the majority of the electrons that passed through the specimen undeflected. The sharp dots of varying intensity are the reflections themselves. Reprinted with permission from ref 412. Copyright 1975 Academic Press.

If a crystalline array is **tilted** in the electron beam (Figure 14-24, lower panel), a projection along an axis tilted relative to the axis normal to the plane of the array is recorded on the micrograph, and the amplitudes and phases of the electron diffraction pattern, which are now the amplitudes and phases of the Fourier transform of this new projection, have changed. Each of the micrographs and electron diffraction patterns in a series in which the specimen is systematically tilted represents a different central section through the lattice of lines in the Fourier transform of the three-dimensional array of scattering density that is periodic in two dimensions.⁴⁴² If enough of these central sections are gathered, the amplitudes and phases of the Fourier transform within certain ranges along the lattice lines can be gathered (Figure 14-26).³²⁷ The amplitudes can be gathered from either electron diffraction patterns or Fourier transforms of the digitized contrast on electron micrographs, but the phases can be obtained only from Fourier transforms of the digitized distributions of contrast on the electron micrographs. In such reconstructions, the details of the scattering density fade away at the two ends of the molecule above and below the bilayer of phospholipid

Figure 14-26: Variation of intensity and phase along two of the lattice lines [(3,0) and (4,2)] in the Fourier transform of the three-dimensional distribution of electron scattering density within the two-dimensional crystal of bacteriorhodopsin from *H. salinarium*.³²⁷ The intensities are the intensities of the reflections on electron diffraction patterns of the array (Figure 14-25) tilted at various angles. The phases were determined from Fourier transforms of the distribution of contrast on electron micrographs of the specimens tilted at the same angles. The lattice lines that occur in the Fourier transform of the electron micrograph are the same as the lattice lines upon which the reflections of the electron diffraction lie because the electron diffraction pattern is the same Fourier transform of the same array. Each data point on each graph represents a measurement from a different electron diffraction pattern or a different electron micrograph, respectively, from a specimen at a different angle of tilt. As the angle of tilt is varied, different positions along the lattice lines are sampled. The phase (degrees) or intensity (in arbitrary units) is presented as a function of the distance along the lattice line (nanometer⁻¹). Reprinted with permission from *Nature*, ref 327. Copyright 1975 Macmillan Magazines Ltd.

because the specimen can be tilted only between -60° and $+60^\circ$, and the amplitudes and phases on the lattice lines arising from the unseen portions of the protein are outside the regions that can be sampled with these tilts.

When the amplitudes of the electron diffraction patterns of crystalline arrays of bacteriorhodopsin embedded in a glass of glucose and tilted at various angles were combined with the phases from the digitized distributions of contrast in electron micrographs taken at the same angles of tilt, a map of the three-dimensional electron scattering density within the asymmetric unit in the unit cell of the two-dimensional crystal of the protein could be calculated.^{327,328,443} At low resolution, when only reflections from lattice lines with Bragg spacing out to 0.7 nm were included in the calculation,³²⁷ seven **rods of scattering density** aligned roughly perpendicular to the plane of the array within the membrane were observed.^{327,328} The seven rods are the seven α helices that span the membrane in bacteriorhodopsin (Figure 14-14).

When reflections from lattice lines with Bragg spacing out to 0.35 nm were included in the calculation of the map of electron scattering density,³²⁸ the same seven rods of electron scattering density were observed, but the rods became more detailed at their ends so that some of the connections between the rods could be observed and, more importantly, protrusions of electron scattering density appeared along the rods. These protrusions represent the side chains of the amino acids in the sequence of the protein. From the few connections observed and the pattern of the largest protrusions along each rod (representing the aromatic amino acids), a molecular model of the polypeptide, built with the known amino acid sequence, could be unambiguously placed into the map of electron scattering density. The map of electron density could be further improved by eliminating the contribution of diffuse electron scattering to the amplitudes of the electron diffraction, and the crystallographic molecular model was submitted to

refinement against the observed amplitudes of the electron diffraction.⁴⁴³ The final, refined molecular model duplicated the X-ray crystallographic molecular model of the protein that was subsequently reported³²⁵ in the arrangement of the α helices and their relative positions and orientations but lacked many of the atomic details of the latter molecular model. In particular, the details of the structure outside the membrane were ill-defined in the molecular model from electron diffraction, because the range of tilt that could be performed did not permit reflections from these regions to be gathered to sufficiently small Bragg spacing.

It has also been possible to obtain a map of scattering density of acetylcholine receptor from *Torpedo marmorata* from electron scattering and image reconstruction (Figure 14-22). A map of scattering density calculated from data sets with small Bragg spacing has sufficient detail within the bilayer to observe the protrusions of the side chains from the four membrane-spanning α helices of each of its five homologous subunits. From the pattern of these protrusions and the necessary structural homology of the five subunits, it was possible to insert the amino acid sequences of the various membrane-spanning segments into the map of electron scattering density.³⁴⁵ The structure outside the membrane was again, ill-defined, but serendipitously, there already was a crystallographic molecular model of a water-soluble protein homologous to the globular extracytoplasmic portions of acetylcholine receptor. This crystallographic molecular model⁴⁴⁴ could be positioned in the map of scattering density for the portions of acetylcholine receptor on the extracytoplasmic surface of the bilayer of phospholipids, and the amino acid sequences of acetylcholine receptor could be substituted into the folded polypeptide that had been positioned. The molecular model that resulted could be submitted to refinement against the amplitudes of the electron diffraction to obtain a crystallographic molecular model of acetylcholine receptor both within the membrane and on its extracytoplasmic surface.³⁴⁶

Maps of electron-scattering density have been calculated from electron diffraction and Fourier transformation of digitized images of tilted specimens in cryo-electron microscopes for light-harvesting chlorophyll *a/b*-protein complex (Bragg spacing ≥ 0.34 nm),⁴⁴⁵ isoform 1 of human aquaporin (Bragg spacing ≥ 0.38 nm),^{446,447} sodium/proton antiporter NhaA (Bragg spacing ≥ 0.7 nm),⁴⁴⁸ gap-junction channel (Bragg spacing ≥ 0.75 nm),⁴⁴⁹ Na⁺/K⁺-exchanging ATPase (Bragg spacing ≥ 0.95 nm),⁴⁵⁰ and Ca²⁺-transporting ATPase (Bragg spacing ≥ 1.4 nm).⁴⁵¹ In the first two instances, the maps of electron scattering density were detailed enough to identify the membrane-spanning α helices and position them in their proper orientations and relative positions; but in the case of isoform 1 of aquaporin, an X-ray crystallographic molecular model (Bragg spacing ≥ 0.22 nm) was reported shortly afterward.³⁴⁸

Nuclear magnetic resonance has also been used to obtain structural information about either peptides forming single membrane-spanning α helices or small integral membrane-bound proteins with one or two membrane-spanning α helices. If the peptide or the small integral membrane-bound protein can be inserted into small, uniform micelles of detergent to form a monodisperse solution⁴³⁷ or if it can be monodispersely dissolved in a mixture of miscible organic solvents in water⁴⁵² in such a way that its normal structure is retained, the usual two- and three-dimensional nuclear magnetic resonance spectra can be gathered from these solutions, and the chemical shifts of the nuclei of ¹hydrogens, ¹³carbons, and ¹⁵nitrogens in the peptide or protein can be assigned, just as though it were a peptide or protein that normally dissolves unassisted in water. The nuclear Overhauser effects among the nuclei of the ¹hydrogens can then be used to define the structures of these peptides or proteins.

It is also possible to obtain two- and three-dimensional nuclear magnetic resonance spectra⁴⁵³⁻⁴⁵⁵ from peptides or small proteins that span a membrane in a single α helix when they are inserted into oriented multibilayers of phospholipid such as those described in Figure 14-4. The chemical shifts of the nuclei of ¹hydrogens and ¹⁵nitrogens can be assigned, and information about the tilt of the α helices in the bilayers of phospholipid can be obtained from the fluctuations of the coupling constants between nuclei of the respective α ¹hydrogens and adjacent amido ¹⁵nitrogens.⁴⁵⁶

Electron spin resonance from probes attached to membrane-bound proteins has been used to obtain information about membrane-spanning α helices in larger integral membrane-bound proteins formed from bundles of such α helices. All of the naturally occurring cysteines in an integral membrane-bound protein are mutated to other amino acids. A segment of the amino acid sequence that is thought to be a membrane-spanning α helix in the native structure of the resulting cysteineless protein is identified from its hydropathy. Each of the consecutive amino acids in that segment is mutated in turn to a cysteine to produce a set of single point mutants. Each mutant is covalently modified at the respective cysteine with (1-oxyl-2,2,5,5-tetramethylpyrroline-3-methyl)methanethiosulfonate (see 12-11). The frequency with which molecular oxygen is able to collide with the nitroxyl radical in each of the covalently labeled native proteins is then estimated from the effect that changes in the concentration of molecular oxygen in the sample have on the rates of relaxation of the respective unpaired electron. Molecular oxygen, because it is paramagnetic, catalyzes the **relaxation of the unpaired electron** when it encounters the nitroxyl radical.

When the consecutively modified positions in the amino acid sequence of the protein are in a membrane-spanning α helix on the outer surface of the native structure of the integral membrane-bound protein, the

accessibility of the respective nitroxyl radicals to oxygen varies periodically along that α helix as it directs them periodically into the hydrocarbon of the phospholipid in which the molecular oxygen is dissolved or into the center of the protein in which it is not (Figure 14-27A).^{457,458}

When the modified positions in the amino acid sequence of the modified protein are in a loop between two membrane-spanning α helices, the rates of relaxation of the respective unpaired electrons are accelerated by chelated paramagnetic ions such as chromium oxalate (Figure 14-27B)⁴⁵⁷ or nickel *N,N'*-dicarboxymethyl-1,2-diaminoethane dissolved in the aqueous phase to which the loop is exposed.⁴⁵⁹ The increase in relaxation by oxygen is less pronounced for nitroxyl radicals in these locations because oxygen is less soluble in water than in hydrocarbon.

A segment of amino acid sequence in the protein is identified as a membrane-spanning α helix in the native integral membrane-bound protein if the excited state of nitroxyl radicals attached to its amino acids is not relaxed by the chelated paramagnetic ions⁴⁵⁹ but does display a pattern of exposure to molecular oxygen that fluctuates with a period of 3.6 aa (Figure 14-27). In the case of bacteriorhodopsin from *H. salinarium*, the prediction that the polypeptide between Threonine 128 and Tyrosine

131 would be a loop between two α helices while the polypeptide between Serine 132 and Threonine 142 would be within an α helix spanning the membrane was validated when a crystallographic molecular model of the protein (Figure 14-14) became available.³²⁸ That the periodicity observed in the catalysis of the relaxation of the unpaired electron coincided with periodicity of the exposure of the respective side chain to the hydrocarbon of the bilayer of phospholipid was also validated by the model.

Similar **periodicities of exposure** of covalently attached nitroxyl radicals have been observed for sets of consecutive mutants to cysteine in segments of amino acid sequence from lactose permease of *E. coli*,⁴⁶⁰ diphtheria toxin from corynebacterium β ,⁴⁶¹ and citrate transport protein from *S. cerevisiae*.⁴⁶² It is assumed that these segments from these integral membrane-bound proteins are membrane-spanning α helices even though their crystallographic molecular models are not yet available.

Fluctuations, also with a period of 3.6 aa, in levels of expression in oocytes of *X. laevis* and apparent dissociation constant for acetylcholine upon consecutive mutation to tryptophan of amino acids in a segment of the amino acid sequence of acetylcholine receptor from *T. californica* were presented as evidence that this segment spanned the membrane as an α helix.⁴⁶³ Likewise,

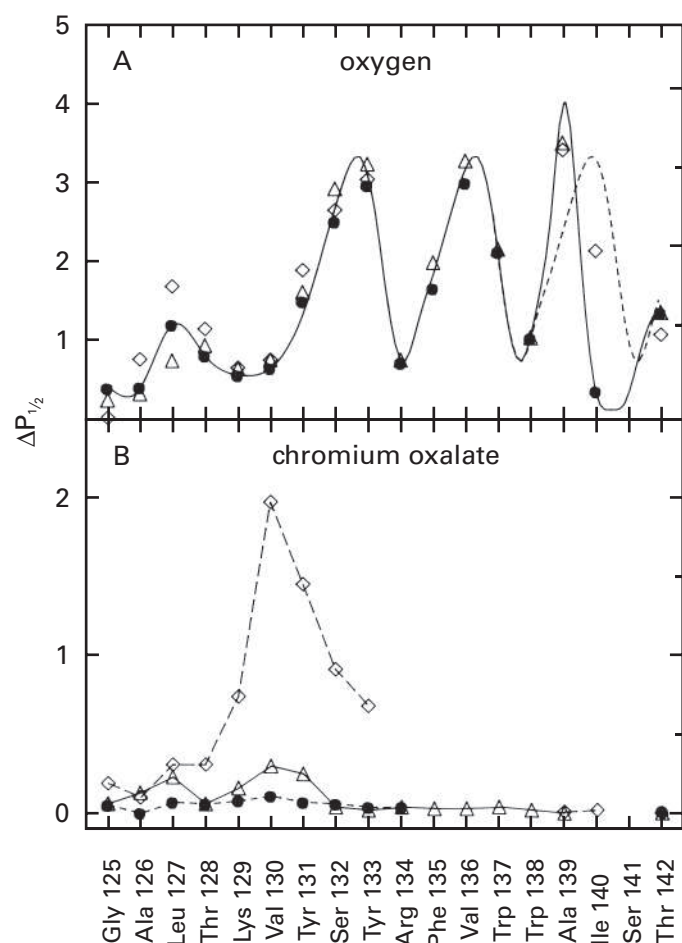

Figure 14-27: Periodic variation in exposure of side chains to the hydrocarbon of the bilayer of phospholipids along an α helix that spans the membrane in bacteriorhodopsin from *H. salinarium*.⁴⁵⁹ The gene for the protein was expressed in *E. coli*. All of the cysteines in the wild-type protein were replaced by site-directed mutation. A set of mutants of this cysteineless protein was then constructed and expressed. Each member of this set had one of the amino acids in the sequence from Glycine 125 to Threonine 142 replaced, respectively, by a cysteine, and the complete set contained each of the consecutive single point mutants. Each mutant protein was overexpressed in *E. coli*, and the product accumulated in the bacteria as a denatured precipitate. The respective polypeptides were purified⁴⁵⁸ and modified with (1-oxyl-2,2,5,5-tetramethylpyrrolidine-3-methyl)methanethiosulfonate at their single cysteines while in their unfolded states. The covalently modified, unfolded polypeptides were reconstituted to their native state by treatment with detergent, phospholipid, and retinal,⁴⁵⁸ and the refolded states of each protein were shown to be fully functional by kinetic and spectroscopic analysis, and by their ability to transport protons upon absorption of light. The spin-lattice relaxation time of the unpaired electron in each of the nitroxyl radicals was monitored indirectly by determining $P_{1/2}$, the continuous wave power at which the amplitude of the signal from the central absorption in the spectrum (Figure 12-35) was 50% of its absorption in the absence of saturation. The change in $P_{1/2}$ ($\Delta P_{1/2}$) for the respective nitroxyl radical at the noted position in the sequence in the presence, relative to the absence, of (A) molecular oxygen (O_2) and (B) chromium oxalate is presented. Measurements were made of native protein in the original reconstituted vesicles (●) or the vesicles dissolved in aqueous solutions 1% (Δ) or 10% (\diamond) in octyl glucoside. Compare the patterns of exposure to molecular oxygen (A) and chelated paramagnetic ion (B) to the crystallographic molecular model of the protein (Figure 14-14). Reprinted with permission from ref 457. Copyright 1990 American Association for the Advancement of Science.

consecutive site-directed mutation of a membrane-spanning α helix in lactose permease from *E. coli* has also suggested that the surface of the α helix facing the lipid is more tolerant to changes in the size of its side chains than the surface facing the interior of the protein, as long as the side chains remain hydrophobic.⁴⁶⁴ Consequently, when the frequency at which amino acids are substituted is examined as a function of their position in a set of aligned amino acid sequences of the same or a set of related integral membrane-bound proteins from different species of organisms, that frequency has also been observed to vary along segments that are membrane-spanning α helices with a period of about 3.6 aa,⁴⁶⁵ just as the exposure of a spin label to molecular oxygen varies (Figure 14–27). Those positions facing the interior of the protein are positions in which substitutions over time are less tolerated.

It is also possible to use **spin-labeled phospholipids** to determine whether or not a portion of membrane-bound protein is inserted into the bilayer of phospholipid and how deeply it sits within it. Phospholipids have been synthesized with a 3-oxa-1-oxyl-2,2,5,5-tetramethylpyrrolinyl group covalently attached to their head group and to carbon 5, 10, 12, and 14, respectively, of one of their fatty acyl chains (see 14–16). It has been well established that the fatty acyl groups bearing these nitroxyl radicals remain fully extended so each sits at a characteristic depth in the membrane, and the nitroxyl radical on the head group sits at the surface of the membrane. A 3-oxa-1-oxyl-2,2,5,5-tetramethylpyrrolinyl group will quench a nearby fluorescent chromophore attached to a protein. By comparing the degree of quenching of the fluorophore as a function of the mole fraction of the nitroxylphospholipid in the membrane for nitroxyl radicals covalently attached at different positions on the labeled phospholipid, the **depth at which the fluorophore sits in the bilayer** of phospholipid can be estimated.^{81,466} For example, it was estimated that a 3-(2',2'-dimethylnaphth-7'-yl)-3-oxopropyl group covalently attached as a fluorophore to the sulfur of a cysteine placed by site-directed mutation at position 81 in the amino acid sequence of cysteineless cholesterol oxidase from *Brevibacterium sterolicum* sits 0.8 ± 0.3 nm from the center of the bilayer when the native protein is inserted in the membrane.⁴⁶⁷

Although these spectroscopic methods have been applied to several integral membrane-bound proteins, the majority of the assignments of membrane-spanning α helices in proteins for which crystallographic molecular models are unavailable have been made from genetic and chemical observations.

The general problem of identifying within the amino acid sequence of an integral membrane-bound protein, for which a crystallographic molecular model is unavailable, those segments of greater than 20 aa in length that span the bilayer of phospholipid as α helices, rather than simply spanning the interior of the globular

protein on either side of the bilayer of phospholipid, is supposed to have both a computational solution and an experimental solution. The computational solution^{300,468–470} is based on one or the other of the scales of numerical values for the hydropathies of the amino acids. The values from one of these scales or differences between the values from two of the scales⁴⁷⁰ are averaged over the amino acid sequence of a given segment. If the mean numerical value of the average for the 21 aa in a given segment is greater than a certain magnitude, where hydrophobic amino acids have positive values and hydrophilic amino acids have negative values on the scale chosen, then there is a high probability that that segment spans the membrane as an α helix within the native structure of the folded polypeptide. For example, for the scale of Kyte and Doolittle, if the average numerical value of the hydropathy is greater than +1.6, the segment of 21 aa probably spans the membrane.^{300,470} In the case of the criterion of White and Wimley,⁴⁷⁰ it is the difference between the hydropathy displayed by an amino acid in a peptide during its partition into an isotropic organic phase (octanol) and the hydropathy displayed during partition onto the surface as opposed to the interior of a bilayer of phospholipid.

These **computational approaches to designating the membrane-spanning α helices** are based on the assumptions that the change in free energy for the insertion of an α helix into a 3.6 nm layer of hydrocarbon from an aqueous phase is directly related to the partition of model solutes for its amino acid side chains and peptide bonds between water and an isotropic phase of hydrocarbon,^{468,470} that scales of hydropathy regardless of their origin ultimately reflect the free energy of this partition; that the hydrocarbon of the bilayer of phospholipid is more nonpolar than the interior of any protein; and that a longer stretch of polypeptide, 24 amino acids, is required to span a bilayer than is required to span the interior of a molecule of protein.³⁰⁰

The 11 amino acid sequences known to span the membrane in photosynthetic reaction center from *R. viridis* (Figure 14–17) were designated as the only membrane-spanning α helices in its native structure by one of these computational algorithms^{392–394} before the crystallographic molecular model became available, and every hydrophobic segment of the amino acid sequence of this protein ultimately observed to span the membrane had been so designated. This result might be taken as an indication of the **reliability** of these predictions. In another instance, however, an entire set of assignments based on mean hydropathy seems to have failed. At least one of the computational algorithms designated five of the segments of the amino acid sequence of unspecific monooxygenase from mammalian liver as membrane-spanning α helices in addition to its amino-terminal anchor, which does span the membrane.⁴⁷¹ When, however, the amino-terminal anchor is removed from the protein and several other of its hydrophobic amino acids

are mutated to hydrophilic amino acids, the membrane-bound protein becomes a water-soluble protein that has been crystallized.^{294,472} From an examination of the resulting crystallographic molecular model, it is clear that, other than its amino-terminal anchor, mammalian unspecific monooxygenase contains no membrane-spanning α helices. In fact, the bacterial form of this monooxygenase^{294,473,474} is a normal, water-soluble protein the crystallographic molecular model of which is superposable on that of the mammalian protein.

In addition to such **overprediction**, these algorithms also miss some membrane-spanning α helices, particularly in large integral membrane-bound proteins in which several of the α helices that span the membrane pass entirely through the center of the protein without contacting the hydrocarbon of the bilayer of phospholipid. For example, of the 56 membrane-spanning α helices in the α_2 dimer of the crystallographic molecular model of bovine cytochrome-*c* oxidase (Table 14-6),³³³ 18 are not hydrophobic enough to have been designated as membrane-spanning, and 12 of those were passed over in an assignment of membrane-spanning α helices made before the crystallographic molecular model became available.³⁰⁰ Most of those that seem to be too hydrophilic pass through the center of the protein and have few or no contacts with the hydrocarbon of the bilayer of phospholipid.

Both the experience with unspecific monooxygenase, where hydrophobic segments that do not seem to span the bilayer of phospholipid were designated as hydrophobic enough to do so, and the experience with cytochrome-*c* oxidase, where hydrophobic segments that span the bilayer of phospholipid were not hydrophobic enough to be designated as doing so, suggest that there is no reliable method for making this designation by inspection alone. Some integral membrane-bound proteins may contain a set of membrane-spanning segments the hydrophobicities of which are so remarkable that they can be designated as traversing the bilayer of phospholipid without too much doubt. Other integral membrane-bound proteins, however, also contain another set of membrane-spanning segments that are hydrophobic but not so hydrophobic as to be distinguishable from those segments elsewhere within the amino sequence that merely span the globular portions of the protein on either side of the membrane. In many instances, it may be these less hydrophobic membrane-spanning segments, impossible to identify by inspection, that are most intimately involved with the function of the integral membrane-bound protein, particularly if it catalyzes the transport of a hydrophilic solute across the bilayer of phospholipid. This makes their identification even more desirable.

The success with which these various algorithms predict membrane-spanning sequences has been assessed by comparing their assignments to the actual membrane-spanning sequences in the available crystal-

lographic molecular models of integral membrane-bound proteins.⁴⁷⁵ The **accuracy** with which they predict these direct observations varies from 91% to 99%. The most widely used⁴⁷⁶⁻⁴⁸⁴ algorithm for predicting the membrane-spanning α helices of a membrane-bound protein of unknown structure, that of Kyte and Doolittle, has an accuracy of only 93% and overpredicts membrane-spanning α helices by 13%. This overprediction arises from the fact that many α helices that simply span a globular portion of the protein outside the membrane are hydrophobic enough to be mistakenly assigned as spanning the membrane. The most accurate algorithm for predicting membrane-spanning α helices (99%) and for avoiding overprediction (<1%) was that of Wimley and White.⁴⁸⁵

The success with which these algorithms can designate membrane-spanning α helices was assessed with a set of proteins already known to be anchored membrane-bound proteins or integral membrane-bound proteins. It is probably the case that the rate of success is much lower when one of them is asked to determine whether or not a protein is membrane-bound in the absence of any information other than its sequence, a purpose for which these algorithms are often used. This ambiguity arises because many proteins that are not bound to membranes have long sequences buried in their interior that are hydrophobic enough to appear to be membrane-spanning α helices. Such decisions about whether or not a protein is membrane-bound should be viewed with caution.

In spite of the success of the algorithm of Wimley and White, it is usually assumed that the segments identified computationally as membrane-spanning α helices should be considered only as candidates for spanning the membrane and that whether or not they do span the membrane should be validated experimentally.

The most direct experimental solution to the problem of identifying a membrane-spanning segment relies upon **covalent modification of the protein from within the liquid hydrocarbon** of the bilayer of phospholipid. Because only poorly nucleophilic amino acids are found within membrane-spanning segments, **nitrenes or carbenes** have been universally used as reagents for their selective modification. The precursor of a nitrene or carbene is incorporated into a hydrophobic molecule that partitions almost exclusively into the hydrocarbon of the bilayer of amphipathic lipids surrounding the membrane-spanning segments of the protein. The nitrene or carbene is generated from the precursor by photolysis, and it inserts into the membrane-spanning segments of the polypeptide, albeit in low yield. The intact polypeptides that are susceptible to the modification can be identified by electrophoresis in solutions of dodecyl sulfate,⁴⁸⁶⁻⁴⁸⁹ the regions of the polypeptides that have been modified can be identified by isolating and identifying peptides containing them,⁴⁹⁰⁻⁴⁹² and the particular amino acids modified can be identified by submitting the peptides to sequencing.⁴⁹³⁻⁴⁹⁶

The reagents that have been used are precursors of carbenes or nitrenes attached to two different types of **hydrophobic carriers**. 1-Tritiospiro[adamantane-4,3'-diazirine] (**14-17**),⁴⁸⁶ 5-[¹²⁵I]iodonaphthyl azide (**14-18**),⁴⁸⁸ 3-(trifluoromethyl)-3-(*m*-[¹²⁵I]iodophenyl)diazirine (**14-19**),⁴⁹⁷ and 1-azidopyrene (**14-20**)⁴⁹⁶ are examples of hydrophobic solutes that can diffuse freely through the liquid hydrocarbon of the bilayer of phospholipid:

Precursors of carbenes^{493,494,498,499} and nitrenes^{493,500} have also been incorporated covalently into phospholipids that can then be incorporated into the bilayers of phospholipids surrounding membrane-bound proteins. An example would be diazirinylphospholipid **14-21**:

In these derivatives of phospholipids, the precursor of the carbene or the nitrene can be incorporated into the fatty acyl chains, as in diazirinylphospholipid **14-21**, or it can be incorporated into the hydrophilic functional group esterified to the phosphate of the phospholipid.⁴⁹⁹ In the former case, amino acids within the hydrocarbon are the targets of the modification; and, in the latter case, amino acids at the two ends of the membrane-spanning segments.⁴⁹⁴

Originally it was thought that, by varying the position along the hydrocarbon of the fatty acid at which the carbene was located within a phospholipid, amino acids within the membrane-spanning segment located at dif-

ferent depths within the bilayer of phospholipid could be distinguished. Unfortunately, carbenes show a significant preference for insertion into nitrogen-hydrogen, oxygen-hydrogen, and sulfur-hydrogen bonds over carbon-hydrogen bonds, and this preference usually directs all of the carbenes in the liquid hydrocarbon, regardless of their mean depth in the bilayer of phospholipid, to the same one or two most susceptible amino acids in each membrane-spanning segment.^{493,494,496} Therefore, there is no obvious advantage to the derivatives of the phospholipids over the simpler hydrophobic precursors other than their elegance.

Often the incorporation observed with such hydrophobic reagents is consistent with the identification of membrane-spanning segments based on their mean hydropathy. Both glycophorin,⁴⁹⁴ which spans the membrane once, presumably with its only hydrophobic segment, and subunit IV of cytochrome-*c* oxidase,⁴⁹⁰ which also contains only one hydrophobic segment greater than 20 aa in length, which was later observed to span the membrane in the crystallographic molecular model,³³³ have been modified by either a carbene or a nitrene, respectively, incorporated into a phospholipid. The large majority of the incorporation on each case was located in a peptide 68 or 49 amino acids in length, respectively, that contained the hydrophobic segment of greater than 20 aa picked out by the computational algorithms. When (iodophenyl)diazirine (**14-19**) was used to modify bacteriorhodopsin, incorporation also was found to occur⁵⁰⁰ in a region of the amino acid sequence containing a segment that had been identified computationally as spanning the membrane and that was later shown to be in the center of a membrane-spanning α helix in the crystallographic molecular model.³²⁸

All five of the subunits of acetylcholine receptor (Figure 14-22) are homologous in amino acid sequence, and each contains four segments of amino acid sequence that were judged to be hydrophobic enough to span the membrane. Both 1-azidopyrene and 3-(trifluoromethyl)-3-(*m*-[¹²⁵I]iodophenyl)diazirine label all of the subunits in the native protein in its native membrane. A set of labeled peptides, identified by their sequences, has been isolated from digests of the labeled protein. Among the members of this set are contained the first, the third, and the fourth of the hydrophobic segments from one or the other of the subunits.⁴⁹⁶ In one of these peptides, two cysteines were identified as the sites of modification, further evidence for the electrophilicity of nitrenes and carbenes. In the molecular model derived from electron diffraction and image reconstruction,³⁴⁶ all 20 of the hydrophobic segments, four from each subunit of the protein, are membrane-spanning α helices.

When adamantyldiazirine (**14-17**) was used to modify canine Na⁺/K⁺-exchanging ATPase, however, and the long tryptic peptides of the intact polypeptide that were modified by the reagent were isolated and identified,^{491,501} it was found that substantial amounts of

adamantylidene had been incorporated into three tryptic peptides that did not contain hydrophobic segments designated computationally as membrane-spanning. These three peptides contained segments greater than 20 aa in length that were hydrophobic but not sufficiently hydrophobic to be picked out by their mean hydropathy. Their sequences are -VNFPVENL CFVGFISMIGPP-, -QIGMIQALGGFFTYFVILAE-, and -PTWWFCAFPYSLIFVYDEV-. The location of these three segments in the structure of Na⁺/K⁺-exchanging ATPase can be inferred from the location of the homologous sequences in the crystallographic molecular model of Ca²⁺-transporting ATPase from *O. cuniculus* (Figure 14–15).³⁵¹ The first is located in the globular cytoplasmic domain of the protein distant from the bilayer of phospholipid, but the latter two are in membrane-spanning α helices, in spite of their low mean hydropathy. Both of these membrane-spanning α helices are on the outside surface of the bundle of α helices within the bilayer of phospholipid (Figure 14–15). Three of the segments of the amino acid sequence of Na⁺/K⁺-exchanging ATPase designated as membrane-spanning by their high mean hydropathy were found within other tryptic peptides modified by adamantyldiazirine, and the homologues of these three segments do also span the membrane in the crystallographic molecular model of Ca²⁺-transporting ATPase.

The **topography** of a membrane-spanning protein is a complete designation of those segments of its polypeptide that span the membrane and of the sides of the membrane, cytoplasmic or extracytoplasmic, on which those segments of its polypeptide that are not within the hydrocarbon of the bilayer of phospholipid are located. The topography of a membrane-spanning protein can be defined by identifying in turn the location of one or more of the amino acids within each of the segments of its polypeptide outside the membrane. While assembling these individual topographic assignments, if one end of a segment of hydrophobic amino acids in the sequence of an integral membrane-bound protein can be shown to be located on its cytoplasmic surface and the other end on its extracytoplasmic surface, then it can be concluded that that segment spans the bilayer of phospholipid.

The identification of the side of a membrane, cytoplasmic or extracytoplasmic, upon which a particular amino acid or peptide from the polypeptide of an integral membrane-bound protein is located can be made with oriented, sealed structures and an impermeant reagent. The most reliable **oriented, sealed structures** are **intact cells**, such as erythrocytes,¹⁹¹ or intact organelles, such as undamaged mitochondria or lysosomes.⁵⁰² Erythrocytes are ideal for this purpose because sealed inside-out vesicles that present only the cytoplasmic surfaces of their membrane-bound proteins to the solution can be prepared from intact erythrocytes.¹¹⁹ Intact animal cells grown in tissue culture^{503,504} or spher-

oplasts of bacteria* have also been used in such experiments. **Mitochondria** as they are usually prepared contain both an outer membrane, which is the porous cellular membrane isolating these organelles from direct contact with the cytoplasm, and an inner membrane, which is the tight, impermeable boundary of the functional mitochondrion. The outer membrane can be removed⁵⁰⁵ to produce sealed, unwrapped mitochondria that present the cytoplasmic, extramitochondrial surfaces of their membrane-bound proteins to the external solution.⁵⁰⁶ Sealed, inside-out vesicles, which present the extracytoplasmic, intramitochondrial surfaces of their membrane-bound proteins to the solution, can be prepared from unwrapped mitochondria.⁵⁰⁷

Sealed vesicles often form spontaneously from fragments of the constituent membranes during homogenization of a tissue. As these structures are adventitious, they are not necessarily sealed to all hydrophilic solutes. For example, vesicles of plasma membrane can be isolated from the electric organ of *T. californica* that are sealed to large solutes such as proteins,⁵⁰⁸ but only a minority of them are sealed to small solutes such as the cations of alkali metals.⁵⁰⁹ Occasionally, however, a suspension of homogeneously and tightly sealed vesicles, in which all of the proteins are oriented as they were when the membrane containing them was in the cell, can be prepared from a homogenate.^{510,511}

It is also possible to use purified membrane-bound proteins reconstituted into sealed vesicles of phospholipid. It is usually the case that during a reconstitution the membrane-bound protein inserts at random in either of the two possible orientations, cytoplasmic surface directed outward or extracytoplasmic surface directed outward. If only one of these two surfaces is susceptible to endopeptidolytic digestion when the protein is in its native structure, as is often the case, digestion of the reconstituted vesicles will nick only those molecules of protein exposing that surface, and intact polypeptides, derived exclusively from molecules of protein inserted in the opposite orientation, can be purified by electrophoresis or molecular exclusion chromatography performed in solutions of dodecyl sulfate.^{512,513}

Many impermeant reagents have been used to modify integral membrane-bound proteins in such sealed, impermeable structures. Because a bilayer of phospholipid contains a continuous sheet of hydrocarbon 3.6 nm wide, charged solutes or solutes with large numbers of donors and acceptors for hydrogen bonds cannot pass through it. An **impermeant reagent for covalent modification** is such a hydrophilic solute that also contains an electrophilic functional group appro-

* A spheroplast is a bacterial cell that has been stripped of its outer membrane.

priate for the modification of proteins. Diazotized *p*-[³⁵S]sulfanilic acid (**14-22**),⁵¹⁴ *N*-formyl-[³⁵S]sulfinylmethionyl methylphosphate (**14-23**),⁵¹⁵ isethionyl [¹⁴C]acetimidate (**14-24**),⁵¹⁶ 2-S-[¹⁴C]thiuroniummethanesulfonate (**14-25**),⁵¹⁷

and pyridoxal phosphate⁵¹⁸ and sodium borohydride (Figure 10-3) are impermeant reagents that have been used to modify only the surface of a protein presented to the external solution in a suspension of sealed membranes.

For example, both intact bovine mitochondria and sealed inside-out vesicles of bovine mitochondria were separately modified with pyridoxal phosphate and sodium borohydride, and labeled ADP, ATP carrier, an integral membrane-bound protein, was purified from each sample. Thermolytic peptides containing the labeled lysines were isolated from the protein and identified by their amino-terminal sequences. It was found that Lysine 146 of the protein was modified by pyridoxal phosphate and sodium borohydride in the protein from the sealed inside-out vesicles, while Lysines 95, 198, 205, 259, and 267 were modified by pyridoxal phosphate and sodium borohydride in the protein from intact mitochondria.⁵¹⁹ Lysine 146 was assigned to the extracytoplasmic, intramitochondrial surface of the protein; and the other lysines, to its cytoplasmic, intramitochondrial surface.

The tryptic peptide HLLVMKGAPER, the amino acid sequence containing Lysine 501 from ovine Na⁺/K⁺-exchanging ATPase, could be isolated from digests of the intact protein by immunoadsorption with immunoglobulins G directed against its carboxy terminus. Lysine 501 would not incorporate pyridoxal phosphate when the protein was in sealed vesicles that presented only the extracytoplasmic surface of the protein to the solution but readily incorporated pyridoxal phosphate when the vesicles were opened by adding the surfactant saponin.⁵²⁰ Saponin, by combining with the cholesterol

in the bilayer of phospholipid, is able to form large (8.0 nm) holes in natural membranes⁵²¹ without significantly altering the membrane-bound proteins. The results of these experiments demonstrated that Lysine 501 is located on the cytoplasmic surface of Na⁺/K⁺-exchanging ATPase, a topographical assignment later verified crystallographically.³⁵¹

One of the drawbacks of labeling integral membrane-bound proteins with such impermeant electrophiles is that the shorter segments between two candidates for spanning the membrane often lack a suitable **nucleophilic side chain**. For example, in the MotA protein from *E. coli*, the short segment connecting the first and second candidates for spanning the membrane contains only a tyrosine, and the short segment connecting the third and the fourth contains only a glutamate, two nucleophiles that can be difficult to label. Consequently, **cysteines** were placed in turn within these segments at position 24, 190, and 196 in the amino acid sequence of the protein, respectively, in three separate **site-directed mutations** of the cysteineless version of the protein. The modification of each of these cysteines by the impermeant fluorescent reagent fluorescein 5-maleimide proceeded at similar rates whether the mutant protein was in intact spheroplasts of the bacteria or osmotically disrupted spheroplasts. Six other cysteines placed in the much larger segments connecting the second and the third candidate and following the fourth candidate for spanning the membrane reacted slowly with the fluorescein 5-maleimide in the intact spheroplasts and rapidly in the disrupted spheroplasts. These results demonstrated that positions 24, 190, and 196 are located in extracytoplasmic segments and the rest of the connecting segments are cytoplasmic, and that all four of the candidates for spanning the membrane do so.⁵²²

Similar experiments have been performed on segments of the amino acid sequence of several other integral membrane-bound proteins but in these instances in order to assess variations from position to position in accessibility to the aqueous phase rather than topography. Each amino acid in a particular segment was mutated in turn to a cysteine, and the susceptibility of that cysteine to modification by a polar electrophile was assayed.⁵²³⁻⁵²⁵ Variations in accessibility provided information about the structure of the polypeptide within that segment in the native state of the protein.

Enzymes can also be used as impermeant reagents. For example, the impermeant enzyme protein-glutamine γ -glutamyltransferase (Equation 13-45) has been used to catalyze the modification of exposed glutamines on the surfaces of membrane-bound proteins with fluorescent primary amines.⁵²⁶ The enzyme lactoperoxidase (Equation 10-33) has also been used as an impermeant reagent.⁵²⁷ Although this enzyme probably produces a small, diffusible, activated form of iodine, perhaps IOH, that species is so reactive that it never makes it across a bilayer of biological phospholipids.⁵²⁸

Endopeptidases or immunoglobulins G are also impermeant reagents. Each of the **endopeptidases** pronase,⁵²⁹ chymotrypsin,³²⁰ and papain⁵³⁰ is able to cleave native, human band 3 anion transport protein ($n_{aa} = 911$),⁵³¹ an integral membrane-spanning protein in human erythrocytes, within the short segment of the polypeptide, -QDHPLQKTYNYNVLMPKPWQGGLP-, between Glutamine 545 and Proline 568. Papain cleaves after Glutamine 550, and chymotrypsin cleaves after Tyrosine 553.⁵³¹ These cleavages occur quantitatively when any one of the endopeptidases is added to the extracytoplasmic solution in which intact erythrocytes are suspended. These results demonstrate that this short segment of amino acids is fully exposed on the extracytoplasmic surface of the intact protein. Two different **monoclonal immunoglobulins G** raised against purified native acetylcholine receptor from the electric organ of *T. californica* recognize as an antigen the synthetic peptide KAEEYILKKPRSELMFEEQ, which is an amino acid sequence from the interior of one of the five homologous polypeptides composing the protein. Presumably, the natural epitopes on the intact protein are composed of sequences from this region. It could be shown that these monoclonal immunoglobulins G were bound only at the cytoplasmic surfaces of membranes containing this protein.⁵³² From this result, it was concluded that this sequence in the native structure of acetylcholine receptor is exposed on the cytoplasmic surface of the protein, a topographical assignment later validated by the crystallographic molecular model derived from electron diffraction and image reconstruction.³⁴⁶

Because oligosaccharides are added to all glycoproteins in the extracytoplasmic lumina of the Golgi membranes, any asparagine, serine, or threonine in an integral membrane-bound protein that is glycosylated must be located on its extracytoplasmic surface. The asymmetry of the biosynthesis of these oligosaccharides can also be used to make topographical assignments for segments in the amino acid sequence of a protein that are not normally glycosylated. If a sequence encoding glycosylation, for example, -NST-,⁵³³ is introduced by site-directed mutation into a segment of amino acid sequence between two candidates for spanning the membrane found in an integral protein located in the plasma membrane, the **glycosylation** of the new asparagine in that sequence demonstrates that the segment is located on the extracytoplasmic surface of the protein.^{534,535} Unfortunately, the steric requirements for access of the asparagine during its glycosylation are fairly stringent,⁵³³ so no conclusion can be made from a negative result. In addition, this approach has been observed to give misleading assignments.^{536,537}

It is also possible to **insert by genetic manipulation entire enzymes** into a segment in the polypeptide of an integral membrane-bound protein located between two hydrophobic segments and use the activity of that enzyme to identify the location of the modified segment. For exam-

ple, alkaline phosphatase has been inserted consecutively into the hydrophilic segments between the 12 candidates for spanning the membrane in lactose permease from *E. coli*⁵³⁸ and the six candidates for spanning the membrane in MalG protein from *E. coli*,⁵³⁹ and the intact cells bearing each of these constructs were assayed for alkaline phosphatase activity with the impermeant reactant *p*-nitrophenyl phosphate. In both cases, alkaline phosphatase inserted into every other hydrophilic segment was located extracytoplasmically, results demonstrating that every candidate in each protein actually does span the membrane. Both β -lactamase^{540,541} and chloramphenicol *O*-acetyltransferase⁵⁴² have also been used in this way. The principal difficulty with these approaches is that the insertion of an entire molecule of protein into a short segment between two membrane-spanning segments could disrupt the normal topography of the protein. One way to minimize this problem is to insert the enzyme at random and select for modified proteins that retain their full biological activity in addition to having the extraneous enzymes inserted into the desired segments.⁵⁴³

Another drawback of all of the approaches for assessing topography that involve large numbers of site-directed mutations, such as the insertion of cysteines at consecutive positions in a cysteineless version of the protein or the fusion of an integral membrane-bound protein with another protein, is that there must be an **efficient expression system** for that integral membrane-bound protein. This requirement usually confines their use to bacteria because there are few convenient, efficient expression systems for most integral membrane-bound proteins from animals that produce high yields of the protein. For example, methods that rely on the production of fusion proteins have been applied almost exclusively to bacteria.

This lack of efficient expression systems is a common problem with evaluating the results of any site-directed mutation of membrane-bound proteins from animals. Occasionally one of these proteins can be expressed in a functional form in *E. coli*,⁵⁴⁴ but usually they must be expressed in cultured cell lines derived from animal tissue. Although the product of a site-directed mutation can often be detected immunochemically,⁵⁴⁵ its expression in animal cells usually precludes the production of sufficient quantities of a mutant for purification and direct study. Rather, the structural changes resulting from a mutation are inferred from changes in the function of the protein in intact cells^{546,547} or crude preparations of membranes from the cells. An extreme example is the expression in oocytes of *X. laevis* of ionic channels from nervous tissue or transport proteins for metabolites such as glucose, which can be detected only by the robust fluxes of the substrates that they produce across the membrane.^{523,548-550} It is also possible to detect expressed channels for water in these oocytes again because of the high water permeability they create.⁵⁵¹

The extensive **topographical experiments** that have been performed on human band 3 anion transport protein from erythrocytes serve as an example of the cumulative application of these strategies to one integral membrane-bound protein. Band 3 anion transport protein is an integral membrane-bound protein in the plasma membrane of the erythrocyte that is responsible for the transport of anions such as chloride, bicarbonate, or phosphate⁵⁵² across the membrane, and it is the integral membrane-bound protein present in the highest concentration in this plasma membrane. The human protein is composed of a single polypeptide 911 amino acids long that bears covalently attached carbohydrate⁵⁵² and spans the bilayer of phospholipid in its native structure.¹⁹¹ Human band 3 anion transport protein has a detachable domain on the cytoplasmic side of the bilayer of phospholipid that can be released by trypsin from fragments of membrane⁵⁵³ and that constitutes the first 360 amino acids from the amino terminus of the folded polypeptide.⁵³¹ After cleavage from the membrane, the detached domain is freely water-soluble.

The domain 550 amino acids long, left in the membrane after the amino-terminal domain has been detached by endopeptidolytic digestion and washed away, is still able to transport anions as rapidly as does the intact protein.⁵⁵⁴ Its amino acid sequence contains at least 10 individual hydrophobic segments, 20 aa or more in length, that are candidates for spanning the membrane (Figure 14-28).^{300,555} The formal amino terminus of this embedded domain in the human protein,⁵⁵⁶ Glycine 361, must be on the cytoplasmic surface of the protein because cleavage by trypsin at the α amide of Glycine 361 to release the detachable domain occurs at that surface.

Lysine 430 in human band 3 anion transport protein can be modified from the extracytoplasmic surface by formylation followed by reduction with sodium borohydride, which, under the appropriate conditions, is impermeant to intact erythrocytes,⁵³⁰ so the hydrophobic segment between Glutamine 404 and Glycine 428 (segment *a* in Figure 14-28) spans the membrane. Tyrosine 486 is modified extensively by lactoperoxidase and [¹²⁵I]I⁻ when the protein is in inside-out vesicles made from erythrocytes but only weakly when it is in intact cells, a result that places Tyrosine 486 on the cytoplasmic surface of the membrane. Consequently, the hydrophobic segment between Methionine 435 and Phenylalanine 478 (segment *b* in Figure 14-28) spans the membrane.⁵²⁸ In the region between Lysine 542 and Proline 568 (between segments *d* and *e* in Figure 14-28) there is a loop of polypeptide in the native structure of the protein that is susceptible to cleavage by pronase,⁵²⁹ chymotrypsin,³²⁰ pepsin A,⁵²⁷ and papain⁵³⁰ but only from the extracytoplasmic surface of the membrane. Consequently, the polypeptide spans the membrane once between Tyrosine 486 and Lysine 542. There are two hydrophobic segments greater than 20 aa in length in this region (segments *c* and *d* in Figure 14-28).

Tyrosine 596 is not iodinated by lactoperoxidase and [¹²⁵I]I⁻ when the lactoperoxidase is present only at the extracytoplasmic side of the membrane, and Asparagine 593 does not bear an *N*-linked oligosaccharide, even though it is in the proper sequence to be so modified. These negative results suggest that this part of the amino acid sequence is on the cytoplasmic surface of the membrane and that the hydrophobic segment between Asparagine 569 and Arginine 589 (segment *e* in Figure 14-28) spans the membrane.⁵²⁷

Tyrosine 628 is iodinated in the presence of extracytoplasmic lactoperoxidase and [¹²⁵I]I⁻,⁵²⁷ the peptide bond between Threonine 629 and Glutamine 630 is cleaved by extracytoplasmic papain⁵³⁰ in intact erythrocytes, and Asparagine 642 is glycosylated,⁵⁵⁷ so the hydrophobic segment between Lysine 600 and Aspartate 621 (segment *f* in Figure 14-28) spans the membrane. Pyridoxal phosphate and Na[³H]BH₄ can modify Lysine 691 when band 3 anion transport protein is in inside-out

Figure 14-28: Plot of the distribution of hydropathy over the amino acid sequence of murine band 3 anion carrier ($n_{aa} = 929$).⁵⁵⁵ Each amino acid in the sequence of amino acids is assigned its numerical value of hydropathy in the scale of Kyte and Doolittle.³⁰⁰ A moving average with a span of 11 positions is calculated from this sequence of numbers. The numerical value of mean hydropathy assigned to each position in the amino acid sequence is the average of the segment of the 11 positions of which it is the central number. Positive values indicate hydrophobic locations; negative values, hydrophilic locations. Ten long hydrophobic segments are found within the last 530 amino acids of the sequence (*a-j*). Segments *b*, *i*, and *j* are long enough (>40 amino acids) to contain two membrane-spanning α helices. The amino-terminal cytoplasmic domain in the murine protein is 19 amino acids longer than the one in the human protein, so each potential membrane-spanning segment is 19 amino acids farther along in the sequence of the murine protein. The human protein and the murine protein, however, can be aligned with 92% identity and a gap of only one amino acid over the last 530 amino acids. The hydrophilic segments in the amino acid sequence of the murine protein that have been assigned to the cytoplasmic (c) surface or extracytoplasmic (e) surface of the human protein by chemical experiments are designated. Adapted with permission from *Nature*, ref 555. Copyright 1985 Macmillan Magazines Ltd.

vesicles but not when it is in intact erythrocytes, so the hydrophobic segment between Proline 660 and Glutamate 681 (segment *g* in Figure 14–28) spans the membrane.⁵⁵⁸ Trypsin can cleave the polypeptide in the native protein at Lysine 743, but only from the cytoplasmic surface,^{536,559} so the hydrophobic segment between Lysine 698 and Proline 722 (segment *h* in Figure 14–28) does not span the membrane. Aspartate 821 is modified with 1-ethyl-3-[3-(trimethylammonio)propyl]carbodiimide and [³⁵S]sulfanilic acid (Figure 10–5) when the protein is in inside-out vesicles but not when it is in intact erythrocytes,⁵⁶⁰ so the long hydrophobic segment between Arginine 760 and Arginine 808 (segment *i* in Figure 14–28) spans the membrane either twice or not at all. The carboxy terminus of anion carrier when it is in inside-out vesicles but not when it is in right-side-out vesicles can bind an immunoglobulin raised against its amino acid sequence,⁵⁶¹ so the long hydrophobic segment between Lysine 829 and Arginine 870 (segment *j* in Figure 14–28) spans the membrane either twice or not at all.

One measure of the success of such topographical assignments is to compare the conclusions reached experimentally with crystallographic molecular models of the protein that become available at a later date. For example, the topographies of two of the subunits of bovine cytochrome-*c* oxidase were examined before its crystallographic molecular model (Table 14–6) became available. Chymotrypsin cleaves the polypeptide of subunit III in a region between Tryptophan 34 and Phenylalanine 37 as well as in a region between Tryptophan 99 and Tryptophan 116 when it has access only to the cytoplasmic, extramitochondrial surface of cytochrome-*c* oxidase in reconstituted vesicles.⁵⁶² Glutamate 90, within the hydrophobic segment between Arginine 79 and Histidine 103 in subunit III, is modified by dicyclohexylcarbodiimide,⁵⁶³ which is a hydrophobic carbodiimide, and this result placed this hydrophobic segment in the bilayer of phospholipid. The peptide bond of Lysine 7 of subunit IV was susceptible to cleavage when intact bovine cytochrome-*c* oxidase was digested with trypsin from its extracytoplasmic, intramitochondrial surface in inside-out vesicles of mitochondria⁵⁶⁴ and only when sealed vesicles, in which the protein is oriented with its cytoplasmic, extramitochondrial surface outward, were opened with nonionic detergent.⁵⁶² The polypeptide of subunit IV was also susceptible to digestion by pronase in intact, unwrapped mitochondria,⁵⁶⁵ which expose only the cytoplasmic, extramitochondrial surface of cytochrome-*c* oxidase. Both of these results taken together demonstrated that subunit IV does span the membrane in cytochrome-*c* oxidase, with its amino terminus on the extracytoplasmic side. All of these conclusions were validated by the crystallographic molecular model.

Each of the four homologous subunits of acetylcholine receptor from *T. californica* contains a cysteine

connecting the cysteines homologous to Cysteine 128 and Cysteine 142 in the α subunit.³⁹¹ In each subunit, a glycosylated asparagine precedes the respective cysteine homologous to Cysteine 142 in the α subunit.³⁹¹ Lysine 165 from the β subunit is accessible to modification by pyridoxal phosphate and Na[³H]BH₄ on the extracytoplasmic surface of sealed right-side-out vesicles derived from plasma membranes from the electric organ of *T. californica*.⁵⁶⁶ All of these facts placed the hydrophilic portions containing the first 210 aa in each of the four subunits on the extracytoplasmic side of the membrane. It has already been noted that an immunoglobulin recognizing the sequence from Lysine 360 to Glutamine 378 in the γ subunit is recognized by an immunoglobulin at the cytoplasmic surface of the protein. Lysine 380 from the α subunit is accessible to modification by pyridoxal phosphate and Na[³H]BH₄ only when sealed right-side-out vesicles derived from plasma membranes of electric organ from *T. californica* are opened with saponin, but Lysine 486 from the γ subunit is accessible on the extracytoplasmic surface of the same vesicles.⁵¹¹ These results placed the former lysine on the cytoplasmic side and the latter on the extracytoplasmic side of the membrane. All of these results have been validated by the crystallographic molecular model of this protein derived from electron diffraction and image reconstruction.³⁴⁵

There are seven integral membrane-bound proteins that catalyze the active transport of inorganic cations across cellular membranes at the expense of the hydrolysis of MgATP. These are Na⁺/K⁺-exchanging ATPase (Na⁺/K⁺-ATPase) from animal plasma membranes, Ca²⁺-transporting ATPase (ER Ca²⁺-ATPase) from animal endoplasmic reticulum, calmodulin-regulated Ca²⁺-transporting ATPase from animal plasma membranes, H⁺/K⁺-exchanging ATPase from the luminal plasma membranes of gastric mucosa, K⁺-transporting ATPase from bacterial plasma membranes, H⁺-exchanging ATPase from fungal plasma membranes, and H⁺-exchanging ATPase from plant plasma membranes. Each of these seven proteins has a long polypeptide, designated the α polypeptide, which when in its native state is responsible for the catalysis of the respective active transport. All of the seven α polypeptides are homologous in sequence,^{567–571} and therefore each folds to create an α subunit that is superposable upon the native structure of all of the others.

Tryptic cleavages of the α subunit of canine Na⁺/K⁺-ATPase in the native membrane that occur at Arginine 262 and Lysine 30 can take place only when trypsin has access to the cytoplasmic surface of the protein.⁵⁷² Trypsin is able to cleave ER Ca²⁺-ATPase of *O. cuniculus* from the cytoplasmic surface of intact endoplasmic reticulum,⁵⁷³ at Arginine 198.⁵⁷⁴ Aspartate 369 is located in the active site of ovine Na⁺/K⁺-ATPase⁵⁷⁵ on its cytoplasmic surface. Lysine 766, Lysine 943, and Lysine 1012 in the α subunit of ovine Na⁺/K⁺-ATPase can be modified with pyridoxal phosphate and Na[³H]BH₄ when they are in sealed right-

side-out vesicles of plasma membrane only if those vesicles are opened with saponin,⁵⁷⁶⁻⁵⁷⁸ results that placed these amino acids on the cytoplasmic surface of the membrane. When Cu^{2+} is added to sealed right-side-out vesicles of plasma membrane, it catalyzes the oxidative cleavage of the α subunit of porcine Na^+/K^+ -ATPase in the presence of ascorbate and H_2O_2 within the segment between Tyrosine 895 and Lysine 905 and within the segment between Proline 965 and Threonine 979,⁵⁷⁹ results that placed these amino acids on the extracytoplasmic surface of the membrane. Immunoglobulins directed against the amino terminus and immunoglobulins directed against the carboxy terminus of H^+ -exporting ATPase from *Neurospora crassa* were bound only to the cytoplasmic surface of plasma membranes, and the amino terminus and carboxy terminus of the same protein were removed by trypsin only when it had access to the cytoplasmic surface of plasma membranes.⁵⁸⁰ The domain on human calmodulin-regulated Ca^{2+} -transporting ATPase to which calmodulin binds from the cytoplasmic surface of the membrane⁵⁸¹ is located on the carboxy terminus of the protein. All of these topographical observations have been validated by the crystallographic molecular model of ER Ca^{2+} -ATPase.³⁵¹

Once the membrane-spanning α helices in an integral membrane-bound protein have been identified, it is possible to determine how they are arranged within the membrane. For example, pairs of cysteines can be inserted systematically by site-directed mutation, one into each of two membrane-spanning segments in a cysteineless version of an integral membrane-bound protein, and those cysteines, if they are adjacent to each other in the native structure of the protein, can be cross-linked with a hydrophobic cross-linking reagent or turned into a cystine by oxidation. Any such **covalent cross-link between two membrane-spanning α helices** places them adjacent to each other in the bundle of α helices within the bilayer of phospholipid.⁵⁸²⁻⁵⁸⁵ Advantage can also be taken of the favorable free energy of formation of a hydrogen bond within the membrane. The replacement of a neutral amino acid within the membrane with a polar hydrogen-bond donor or acceptor will usually disrupt the structure of the protein, causing it to lose its function, but if a polar hydrogen-bond acceptor or donor, respectively, is then placed in an adjacent membrane-spanning α helix near enough to the polar donor or acceptor to form a hydrogen bond, the structure of the protein, and hence its function, can be rescued.⁵⁸⁶ The return of function demonstrates that the two α helices are adjacent to each other. Unfortunately, because of the need for an efficient system for expression and the need to score large numbers of mutants, these approaches have so far been confined to the analysis of integral membrane-bound proteins from bacteria.

As can be done with any other set of proteins, the amino acid sequences of integral membrane-bound proteins can be aligned, and statistically significant relation-

ships can be used to identify isoforms of the same protein in the same genome⁵⁸⁷⁻⁵⁹² or related proteins from different species of organisms. Often, similarities in the patterns of distribution of the hydrophobic segments that are candidates for spanning the membrane strengthen the conclusion that all of the aligned proteins share a common ancestor.⁵⁹³ One difficulty that arises in such **alignments of amino acid sequences**, however, is that, because the choice made by natural selection of the side chains to span the membrane is heavily biased in favor of the small set of the most hydrophobic, the amino acid sequences of unrelated membrane-spanning segments often seem to be more closely related to each other than unrelated amino acid sequences in general do.⁵⁹⁴ Nevertheless, in alignments of the amino acid sequences of integral membrane-bound proteins that are distantly related, the percentage of identity is about the same within membrane-spanning sequences as it is in sequences outside of the membrane.⁵⁹⁵

Almost all integral membrane-bound proteins remain in the membrane for their entire lives, but there are a set of proteins that begin their lives as water-soluble proteins, and if they are called upon, end their lives as integral membrane-bound proteins. The function of most of these proteins is to punch a hole in a membrane, either to short-circuit the normal gradients of metabolites and ions between the cytoplasm and the environment and thereby kill the cell or to permit another protein with which they are associated to thread its way through the hole and enter the foreign cell, usually as an act of subterfuge.

An example of a **protein that punches a hole in a membrane** is α -hemolysin from *S. aureus* (Table 14-6). The protein begins its life as a water-soluble monomer of 293 aa. To insert into the membrane of the cell it is to kill, each monomer puts forth a hairpin of β structure about 30 aa in length, and seven of these hairpins⁵⁹⁶ assemble side by side to form a cylindrical β barrel that after insertion spans the membrane of the doomed cell and forms the hole³⁶¹ through which the ions and metabolites pour. The large portion of each monomer on the exterior of the membrane associates with its six neighbors to form a thick torus of cyclic symmetry of point group 7 (C_7) on the outside of the cell that resembles the extracellular portion of acetylcholine receptor (Figure 14-22).

Colicin E1, which is secreted by *E. coli*, binds to proteins on the extracytoplasmic surface of cells other than *E. coli* that are to be killed. The portion of the protein responsible for forming the hole is a bundle of 10 α helices in the water-soluble form of the protein.⁵⁹⁷ Two of these α helices are completely buried in the center of the bundle. They are 16 and 17 amino acids in length and are composed entirely of hydrophobic amino acids. In addition, the amino acid sequences flanking these helices are also composed only of hydrophobic amino acids. When this portion of the protein has adsorbed to the surface of the bilayer of phospholipid of the mem-

brane of the cell that is to be killed, the hairpin of the central two hydrophobic α helices inserts into the hydrocarbon⁵⁹⁸ and associates with identical hairpins of α helices inserted into the membrane by other molecules of colicin E1 to form the mortal hole.

Cholera toxin from *V. cholerae*,⁵⁹⁹ heat-labile enterotoxin from *E. coli*,⁶⁰⁰ and verotoxin-1 from *E. coli*^{601,602} are homologous heterooligomers that create a **pore through the membrane through which a polypeptide is threaded**. Each contain a substructure that is a pentamer of identical subunits with cyclic symmetry of point group 5 (C_5). These pentameric rings are responsible for forming a pore through the membrane of the cell that is the target of the toxin. Another, unrelated subunit of the complex that forms the actual toxin is then threaded through the pore to intoxicate the cell. In the center of each of these pentameric rings is a symmetric ring of five identical α helices, one from each subunit; the five α helices are parallel to each other and to the 5-fold rotational axis of symmetry that superposes them. The length of these α helices varies from 11 to 20 aa, depending on the protein, but each is amphipathic.^{599,603} The ring of five subunits recognizes the oligosaccharide on a particular glycolipid in the membrane of the cell that it will eventually intoxicate and binds directly to the sugars.^{602,604} The pentamer then adsorbs to the surface of the bilayer of phospholipid⁶⁰⁵ and, presumably, the ring of α helices inserts into the membrane and the other subunit is threaded through the hydrophilic pore at its center. In the crystallographic molecular model of the intact, water-soluble complex of the components of the toxin, the carboxy terminus of this other subunit is already threaded into the pore, ready to enter the cell.⁶⁰⁰

In diphtheria toxin, another toxin that threads one of its domains into a cell through a pore formed by another of its domains, the domain that inserts a portion of its structure into the membrane to form the pore⁶⁰⁶ has a structure reminiscent of the pore-forming domain in colicin E1. It is a bundle of nine α helices, and the central core of this bundle is two α helices that are unusually hydrophobic,⁶⁰⁷ which are thought to form the pore itself.

Lipoproteins are complexes between specific proteins and heterogeneous mixtures of phospholipid, cholesterol, **triacylglycerol**, and **fatty acyl esters of cholesterol** that store the lipids they contain in repositories such as yolk or that transport the lipids they contain through extracellular fluids such as the serum of blood. The lipoprotein in the yolk of eggs is a complex between the protein vitellogenin and the lipids. The lipoproteins in serum are chylomicrons, very low density lipoprotein, low density lipoprotein, and high density lipoprotein.

In the mature lipoprotein in yolk, each molecule of the complex contains the posttranslationally modified version of one molecule of **vitellogenin**. In the yolks of

eggs from *G. gallus*, the vitellogenin (1897 aa) is posttranslationally cleaved into four fragments: lipovitellin I (1124 aa), phosvitin (252 aa), lipovitellin II (235 aa), and yolk glycoprotein 42 (284 aa).^{608,609} Each of these fragments has its own name because they were identified before intact vitellogenin was identified when they seemed to be separate proteins. The most peculiar and independent of these fragments is phosvitin, which contains 123 serines (50% of its amino acids), of which about 25 are phosphorylated. It is the vitellogenin lipoprotein in the yolks of eggs from *G. gallus* that is the source of the natural phosphatidylcholine that is purified from them.

The crystallographic molecular model of the mature lipoprotein formed between the lipid and these fragments of vitellogenin from *Ichthyomyzon unicuspis* contains a large globular cavity about 2.5 nm in diameter in which the lipid is located.⁶¹⁰ This **ball of lipid** is surrounded by three **slabs of β sheet** of 15, 9, and 6 strands in width, respectively, and one α helix.^{611,612} There are significant openings in this central cavity to the surrounding aqueous solution. The cavity contains about 30–35 molecules of lipid, about 20–25 of which are phospholipid, so the surfaces of the ball of lipid exposed to the solution are presumably paved by the head groups of these molecules of phospholipid, as are the surfaces of a bilayer of phospholipid. In the maps of electron density, several complete molecules of phospholipid could be observed as well as many fragments of linear alkane tucked into crevices formed by the pleats of the β sheets,⁶¹³ just as the linear alkane or the phospholipids in the crystallographic molecular models of integral membrane-bound proteins are tucked into crevices between the α helices. These complete molecules of phospholipid and fragments of linear alkane are not distributed as they would be in a spherical micelle, so the lipid must be irregularly packed into the cavity. The remaining approximately 10 molecules of lipid other than the phospholipid are triacylglycerols, cholesterol, and fatty acyl esters of cholesterol. None of the steroid has yet appeared in the maps of electron density and may be disordered within the interior of the ball of lipid.

The two major classes of lipoproteins in mammalian serum are low density lipoprotein (LDL) and high density lipoprotein (HDL). **Very low density lipoprotein** is a precursor from which lipid is stripped to produce low density lipoprotein. **Chylomicrons** seem to be hybrids of low and high density lipoprotein containing large amounts (84% by weight) of triacylglycerol.

Molecules of **low density lipoprotein** are spheres of lipid and protein that are remarkably uniform in size; their diameters are about 22 nm.⁶¹⁴ Unlike a molecule of the vitellogenin lipoprotein in yolk, which is a large protein in which a smaller ball of lipid is confined, low density lipoprotein is a large **sphere of lipid** (80% by weight) controlled by a much smaller amount of protein (20% by

weight). The sphere of lipid is composed on the average of about 2000 fatty acyl esters of cholesterol, 200 molecules of triacylglycerol, 1000 molecules of phospholipid, and 1000 molecules of cholesterol. The molar ratio of unesterified cholesterol to phospholipid is similar to that in the bilayer of a biological membrane. There is enough phospholipid and cholesterol to cover 70% of the sphere with a monolayer of the same dimensions as the monolayer of a biological membrane.⁶¹⁴ The remainder of the surface is covered by the protein.

Each molecule of low density lipoprotein contains one molecule of **apolipoprotein B100**.⁶¹⁵ Human apolipoprotein B100 is 4536 aa long. In addition to providing the remainder of the surface of a low density lipoprotein, apolipoprotein B100 sets the size of the sphere. That it does so was demonstrated by producing in cells in culture, by limited treatment with puromycin, a set of 13 different variants of low density lipoprotein, each formed from a fragment of apolipoprotein B100 of a different length from 1100 to 3600 aa. The lengths of the equators of these spherical variants of low density lipoprotein were directly proportional to the length of the fragment of apolipoprotein B100 they contained.⁶¹⁴ It was concluded that apolipoprotein B100 is a **belt around the waist** of a native low density lipoprotein; the length of the belt determines the size of the waist of the sphere of lipid.⁶¹⁵ Within the core of a molecule of low density lipoprotein, the lipid constituted by the fatty acyl ester of cholesterol and triacylglycerol may not be an isotropic fluid. Lamellar structures have been observed in this region in image reconstructions of molecules of low density lipoprotein embedded in amorphous ice.⁶¹⁶ These lamellae may or may not be present at physiological temperatures.

High density lipoprotein has similar molar ratios of fatty acyl esters of cholesterol, triacylglycerol, cholesterol, and phospholipid to those of low density lipoprotein and is also about 20% protein. Unlike the vitellogenin lipoprotein in yolk and low density lipoprotein, however, high density lipoproteins, even within the same individual, are a mixture of molecules of different size ranging in diameter from 4 to 10 nm. This is probably due to the fact that there are three different apolipoproteins, A1, A4, and A5, that are incorporated into the various high density lipoproteins. Each of these proteins is formed from **internal multiples** of a repeating segment 22 aa long. Each of these segments from any one of the three proteins can be aligned with any segment from any one of the three proteins with an average of 22% identity and no gaps. Human apolipoprotein A1 has 9 of these repeats; human apolipoprotein A4 has 13; and human apolipoprotein A5 has 13. A version of apolipoprotein A1 missing the first 43 aa of the 243 aa protein was expressed in *E. coli* and crystallized. The crystallographic molecular model of this variant of apolipoprotein A1 is a large ring formed from a consecutive series of α -helical segments, most of

which are 22 aa long.⁶¹⁷ The native molecules of high density lipoprotein may be enclosed by such rings of α -helical segments. The circular dichroic spectra of high density lipoprotein do suggest that the protein they contain is mostly α -helical.⁶¹⁸ Probes of lipid structure suggest that the phospholipid and cholesterol of high density lipoprotein are in a monolayer,⁶¹⁹ but the smallest high density lipoproteins are only about as wide as two molecules of phospholipid in a tail to tail orientation. This fact makes it hard to imagine how the lipid could be organized.

Problem 14-2: Membranes containing only cytochrome-c oxidase can be isolated from mitochondria. By successive extractions with acetone, it is possible to deplete these membranes of their phospholipids and obtain preparations with different ratios of protein to phospholipid. The protein in these preparations retains its native conformation at all times. The following spin label was incorporated into the membranes containing different amounts of phospholipid:

2-ethyl-2-(14-carboxytetradecyl)-
4,4-dimethyloxazolidene *N*-oxyl radical

The ratio of protein to spin label was held constant. The ESR spectrum of each preparation was taken with the following result:

Electron spin resonance spectra of the spin label in buffered aqueous dispersions of membrane-bound cytochrome-*c* oxidase with various lipid contents. Ratio of spin label to protein remained constant. The lipid to protein ratio expressed as milligrams of lipid (milligram of protein)⁻¹ is indicated at the far left. Left, spectra normalized to the center-line height; right, the same spectra normalized to give equivalent values after two integrations. Therefore, the right column represents constant concentration of spin label. Reprinted with permission from ref 396. Copyright 1973 National Academy of Sciences.

The left-hand column gives an idea of spectral shape; the right-hand column, amplitude of the signal. The top spectrum is that of an immobilized probe; the bottom spectrum, of a mobile one. Explain these observations.

Problem 14-3: Label each of the following reagents as a hydrophobic reagent for modifying membrane-spanning segments of a protein or as an impermeant reagent. Indicate the reactive position in each reagent with an arrow, and circle the portion of the molecule that renders it hydrophobic or impermeant, respectively.

Problem 14-4: For what purpose were the following reagents synthesized and used to study membrane-bound proteins?

Phenyl [³⁵S]isothiocyanate modified the lysine in the segment -PNTALLSLVLMAGTFFFAMMLRKF- in an intact, native membrane-bound protein. Where is this lysine probably located relative to the bilayer of phospholipid?

Problem 14-5:

- The density of protein is 1.35 g cm⁻³. If one polypeptide of anion carrier were coiled so as to form a hard sphere, what would be its diameter? Compare this diameter to the width of a bilayer of phospholipid.
- N*-Formyl-[³⁵S]sulfinylmethionyl methylphosphate (**14-23**) reacts indiscriminately with lysines on the surfaces of protein molecules exposed to the solution in preparations of sealed membranes to form a derivative of the ε amino group that is radioactive. This reagent cannot pass through a membrane because of its polar character. Write the mechanism of this modification of lysine.

Intact erythrocytes were mixed with this reagent, and the reaction was allowed to proceed for 10 min. The cells were then washed three times with buffer. Band 3 anion transport protein was purified from these cells and was found to be radioactive. The polypeptide from this radioactive protein was cleaved with the endopeptidase thermolysin, and the digest was spread on a two-dimensional chromatogram. The chromatogram was placed over a sheet of photographic film and set aside for several days. The film was developed and radioactive peptides were located visually. The following is a diagrammatic representation of the spots observed on this film.

(C) Why was thermolysin used rather than trypsin?

This experiment was repeated with erythrocytes that had been broken open instead of intact erythrocytes. A representation of the spots observed on this film is shown in the following diagram.

You should convince yourself that each spot on the peptide maps corresponds to a unique lysine on a surface of the anion carrier. You should also understand that each erythrocyte contains 3×10^5 copies of band 3 anion transport protein in its membrane.

- (D) What two fundamental chemical properties of integral membrane-bound proteins are demonstrated by this experiment? How?
- (E) How does the surface area of the anion carrier exposed to the exterior of the cell compare to the surface area exposed to the cytoplasm?

Problem 14-6: Rhodopsin is a protein that is firmly embedded in the membranes of a vertebrate rod. If the sacs of membrane known as disks are purified from these rods, the only protein they contain in significant quantity is rhodopsin, an integral membrane-bound protein. Purified disks were dissolved in a solution of nonionic detergent and mixed with excess phospholipid in the same detergent. When the detergent was slowly removed, small unilamellar vesicles, 40–70 nm in diameter, form spontaneously. The rhodopsin molecules ended up embedded in the membranes of the vesicle. Spectral measurements demonstrated that the tertiary structure of the rhodopsin in the vesicles is the same as it was in the disk.

- (A) Papain, an endopeptidase, cleaves native rhodopsin at only one position in its entire sequence to yield two fragments from the original molecule of protein. In disk membranes, papain cleaves every rhodopsin molecule. In the reconstituted vesicles, it can cleave only 65% of the rhodopsin molecules. Draw a diagram of a reconstituted vesicle with bilayers of phospholipid and rhodopsin molecules and explain why 35% of the rhodopsin is resistant to cleavage.
- (B) Reconstituted vesicles were labeled with [125 I]iodide ion and lactoperoxidase, an enzyme that cannot pass through a bilayer of phospholipid. Those rhodopsin molecules that cannot be cleaved by papain are nevertheless labeled by lactoperoxidase. What does this experiment demonstrate about the rhodopsin molecule? How?

The Fluid Mosaic¹¹⁷

Every membrane in a living cell, regardless of its total surface area and shape, is an individual, intact, **isolated solution**. In each case, the solvent is a fluid bilayer of phospholipids and other amphipathic lipids of the appropriate surface area and shape, and the solutes are anchored membrane-bound proteins and integral membrane-bound proteins. The bilayer is a film of liquid paraffin and fused rings of hydrocarbon 3.6 nm in width sandwiched between thin hydrophilic lamellae 0.5–0.7 nm wide. The bilayer of phospholipid is isotropic in the two dimensions of the surface defined by its width. Because every membrane in a cell is a closed sac, this surface is finite, continuous, and unbounded. Each protein floats upon the sheet of the bilayer at an unvarying draught; its membrane-spanning α helices cannot move up or down in the bilayer owing to the hydrophobic effect. These proteins, however, unless pinned to structures outside the membrane, are free to diffuse in the two unbounded dimensions of the bilayer.

That the **solvent** from which biological membranes are composed is a **bilayer of amphipathic lipids** has

been demonstrated in many ways. The **diffraction of X-radiation** by biological membranes is mainly from the bilayer they contain. A myelinated nerve is a bundle of parallel axons each coated with a tubular spiral of myelin, which is the plasma membrane of a Schwann cell wrapped around and around the axon. Therefore, the plasma membranes of all the Schwann cells are cylindrically oriented. A myelinated nerve diffracts X-radiation. From the diffraction pattern, a radial distribution of electron density normal to the axis of an axon can be computed,⁶²⁰ and it is indistinguishable from that of multibilayers formed from an equimolar mixture of phosphatidylcholine and cholesterol (Figure 14-4D). Vesicles of biological membranes such as plasma membrane from erythrocytes, plasma membrane from the bacterium *M. laidlawii*, or endoplasmic reticulum from skeletal muscle diffract X-radiation in a circular pattern that can be thought of as the diffraction pattern of oriented bilayers of phospholipid (Figure 14-4A,C) spun around its center so that its equatorial and meridional reflections form circles. These circular diffraction patterns from biological membranes have the same periodicity as the diffraction patterns from vesicles containing only the lipids from the respective membranes,⁶²¹ and the amplitudes and periodicities of these diffraction patterns can be explained if they are assumed to arise from shells with distributions of electron density identical to those of bilayers of cholesterol and phosphatidylcholine (Figure 14-4C).⁶⁶

When **spin-labeled probes** are incorporated into biological membranes, they behave almost as if they were incorporated into bilayers of pure phospholipid. In oriented biological membranes such as flattened endoplasmic reticulum,⁶²² nerves,⁶²³ or oriented erythrocytes,⁶²³ fatty acids containing dimethyl nitroxyl radical **14-10** at various locations along the hydrocarbon incorporate with their long axes perpendicular to the surface of the membrane as they do in bilayers of phospholipid, and they display anisotropic motion resembling that displayed in oriented bilayers of pure amphipathic lipids. When 2,2,6,6-tetramethylpiperidine *N*-oxide

14-26

is incorporated into vesicles of endoplasmic reticulum from skeletal muscle, its spectrum is the same as its spectrum in vesicles of pure amphipathic lipid, and the absolute amplitude of its absorbance can be used to show that at least 85% of the amphipathic lipid in the endoplasmic reticulum is present as an unperturbed bilayer of phospholipid.⁶²⁴

Various microorganisms, such as fatty acid aux-

otrophs of *E. coli*, can be forced to incorporate high percentages of specific fatty acids into their plasma membranes. In preparations of these native membranes with a more homogeneous lipid composition, **phase transitions** between solid bilayers of phospholipid, with their hydrocarbons packed in hexagonal array, and liquid bilayers of phospholipid, with their hydrocarbons in the disordered fluid state, can be detected by X-ray diffraction.⁶²⁵ The phase transitions observed with such biological membranes are very similar to those observed when pure bilayers of the lipids extracted from these membranes undergo the same solid to liquid transformation.

These transitions can also be monitored by fluorescent probes. Fluorescent molecules such as *N*-phenyl-1-naphthylamine⁶²⁶ are hydrophobic enough to partition preferentially into the hydrocarbon of the bilayer of phospholipid and register the transition between solid and liquid by changes in the intensity of their emission of fluorescence. In vesicles of the amphipathic lipids purified from bacteria of *E. coli* the membranes of which were enriched in various fatty acids, in the intact native membranes purified from these cells, and in the whole cells themselves, the fluorescent probes detected the same phase transitions.⁶²⁷ Quantitative analysis of these results showed that at least 80% of the amphipathic lipid in the native membranes was in the form of a bilayer indistinguishable in its phase transitions from a bilayer of the purified lipids.⁶²⁶

It has already been noted that in a biological membrane each membrane-bound protein has its particular vectorial orientation. This orientation is maintained through the lifetime of a molecule of that protein by its inability to rotate even once 180° around any axis parallel to the surface of the membrane. For this to occur, the hydrophilic surfaces of the protein on the two sides of the membrane would have to pass through the 3.6 nm of hydrocarbon within the bilayer of phospholipid. This would require that the hydrogen bonds ensnaring these surfaces in the lattices of the liquid water (Figure 6-38) would all have to break simultaneously to permit the protein to capsiz. Apparently, this cannot be accomplished.

It is also the case that the phospholipids in a cellular membrane are asymmetrically distributed.⁶²⁸ These **asymmetric distributions of the phospholipids** have been demonstrated by submitting sealed, oriented biological membranes to digestion with phospholipases under nonlytic conditions^{629,630} or to modification with impermeant reagents,^{628,631} by extracting phospholipids from only one monolayer of a membrane with proteins that bind them preferentially,⁶³⁰ and by exchanging the phospholipids accessible on the outer monolayer of sealed membranes with radioactive phospholipids in other vesicles⁶³² in a reaction catalyzed by phospholipid transfer proteins.⁶³³ A phospholipid transfer protein carries a specific phospholipid tightly bound to itself,⁶³⁴ which it is able to exchange for another phospholipid of the same type at the external monolayer of a sealed

membrane. Spontaneous exchange of phospholipid between the outer monolayer of a membrane and vesicles of phospholipid in the absence of phospholipid transfer protein is also rapid enough to monitor asymmetry when the phospholipid exchanging is the dimyristoyl version.⁶³⁵ It is also possible to incorporate phospholipids labeled with 7-nitro-2,1,3-benzoxadiazol-4-yl groups on their fatty acyl substituents, allow the cells to equilibrate these labeled phospholipids across their plasma membranes, and then reduce the nitro groups to amino groups only on the outer monolayer of the resulting plasma membranes with impermeant dithionite.^{636,637} The reduction quenches the fluorescence only of those labeled phospholipids in the outer monolayer, and the resulting decrease in the fluorescence of the 7-nitro-2,1,3-benzoxadiazol-4-yl groups quantifies the asymmetry.

By one or the other of these procedures, the distributions of the various types of phospholipid across the bilayers of various biological membranes have been determined. In each case, the total moles of phospholipid in one monolayer always equals, within experimental error, the total moles in the other monolayer of the membrane, but the distribution of each type between the two monolayers is biased (Table 14-8). **Phosphatidylethanolamine and phosphatidylserine** are concentrated in the **cytoplasmic monolayers** of plasma membranes. Sphingomyelin is enriched in the extracytoplasmic monolayer of plasma membranes. Phosphatidylcholine, in animals, or phosphatidylglycerol, in bacteria, seems simply to make up the differences between the two monolayers.*

It is unclear whether or not cholesterol is asymmetrically distributed across biological membranes. Two independent measurements of cholesterol distribution in human erythrocytes found an equal ratio⁶⁴¹ or a ratio of about 2-fold in favor of the extracytoplasmic monolayer.⁶⁴² The membrane of influenza virus, derived directly from the plasma membrane of its host, has cholesterol evenly distributed between its two monolayers.⁹² Cholesterol, an aliphatic alcohol, should be able to pass readily through the bilayer.

The asymmetries in the distribution of the phospholipids are maintained by the enzyme **phospholipid-translocating ATPase**.^{643,644} This enzyme catalyzes the transport of phosphatidylethanolamine and phosphatidylserine from the extracytoplasmic monolayer of a membrane to the cytoplasmic monolayer^{645,646} and couples the transport to the hydrolysis of ATP.⁶⁴⁷ It is a

member of the same family of cation-transporting ATPases as Ca^{2+} -transporting ATPase (Figure 14-15).⁶⁴⁸ The active transport of the amino phospholipids to the cytoplasmic monolayer catalyzed by the enzyme drives phosphatidylcholine and sphingomyelin to the outer monolayer passively.^{643,645}

In sonicated vesicles of purified phospholipids, the rate at which a phospholipid, labeled in its head group with a tetramethyl cyclic nitroxyl radical, can pass from the external monolayer to the internal monolayer is slow. The time required for the distribution to come halfway to equilibrium at 30 °C was measured to be 6 h, but there was evidence that oxidation of the phospholipids was adventitiously accelerating the rate.⁶⁴⁹ When an exchange protein specific for phosphatidylcholine was used to exchange the phosphatidylcholine in small unilamellar vesicles of pure phosphatidylcholine, a very slowly exchanging component ($t_{1/2} \geq 10$ days at 37 °C) was observed that accounted for about 40% of the total phosphatidylcholine. This slow component was assigned to phosphatidylcholine on the inner monolayer that had to transfer to the outer monolayer before it could exchange.⁶³² In large unilamellar vesicles, however, the rate at which phosphatidylcholine can transfer between monolayers is more rapid.⁶³⁵ Equilibration occurs in less than 3 h at 37 °C in large unilamellar vesicles of pure dimyristoylphosphatidylcholine.

In biological membranes the **transfer of phospholipids between the two monolayers** of the bilayer seems to occur at about the same rate as that in large unilamellar vesicles of pure phospholipids or somewhat faster. [³²P]Phosphatidylcholine was observed to transfer from the extracytoplasmic monolayer to the cytoplasmic monolayer in an erythrocyte with a half-time for equilibration of 1–2 h at 37 °C.⁶³⁸ The same phospholipid labeled in its hydrophilic functional group with the same tetramethyl cyclic nitroxyl radical that equilibrated slowly in small vesicles of pure phospholipid could equilibrate in vesicles of membrane from the electric organ of *Electrophorus electricus* with a half-time of less than 10 min at 15 °C.⁶⁵⁰ In *Bacillus megaterium*, newly synthesized phosphatidylethanolamine in the cytoplasmic monolayer reaches equilibrium between the two monolayers within 30 min at 24 °C.⁶⁵¹ It is these passive equilibrations that must be constantly compensated for by the active transport of the aminophospholipids into the cytoplasmic monolayer of the plasma membrane catalyzed by phospholipid-translocating ATPase.

There is another enzyme, phospholipid scramblase,^{652,653} that catalyzes the passive transport of phospholipids between the two monolayers of a plasma membrane. The activity of this enzyme is controlled by levels of Ca^{2+} , so that the rapid equilibration of the phospholipids in the two monolayers catalyzed by this enzyme occurs only in particular circumstances.⁶³⁶ This control avoids the futile waste of MgATP that would occur if the enzyme were active continuously.

* There is an interesting inversion in the case of the membranes of unwrapped mitochondria in which phosphatidylethanolamine is concentrated in the extracytoplasmic, intramitochondrial monolayer and phosphatidylcholine is concentrated in the cytoplasmic, extramitochondrial monolayer, perhaps as a vestige of the ancestry of the mitochondrion, which is thought to have arisen from a prokaryotic symbiote.

Table 14–8: Asymmetric Distribution of Phospholipid and Sphingomyelin between the Two Sides of a Biological Membrane

	phospholipid ^a (% of total)													
	extracytoplasmic monolayer							cytoplasmic monolayer						
	PC ^b	PE	PS	SM	PG	DPG	PI	PC	PE	PS	SM	PG	DPG	PI
plasma membranes														
human erythrocyte ^{629,630}	20	5	<1	20			0.4	10	25	10	5			1.6
erythrocyte of <i>R. norvegicus</i> ⁶³⁸	30	5	1 ^c	10				15	20	15 ^c	<1			
human erythrocyte ⁶³¹	ND ^d	5	<1	ND				ND	25	15	ND			
<i>Bacillus megaterium</i> ⁶³¹		25			25 ^e				50			<5 ^e		
disks from rod outer segment ⁶³⁹	ND	10	5	ND				ND	30	5	ND			
unwrapped bovine mitochondria ⁶⁴⁰	10	20				15		30	10				5	

^aNumbers are mole percentages in each monolayer based on the total amount of phospholipid in the membrane. ^bPC, phosphatidylcholine; PE, phosphatidylethanolamine; SM, sphingomyelin; PG, phosphatidylglycerol; DPG, diphosphatidylglycerol; PI, phosphatidylinositol. ^cPhosphatidylserine plus phosphatidylinositol. ^dND, not determined. ^eBy difference.

As is the case with mixtures of pure phospholipid and cholesterol, the lipids in the bilayers of biological membranes can separate laterally into distinct phases. In particular, a separate phase that is enriched in cholesterol and sphingomyelin exists in plasma membranes of animal cells. This phase separates as patches of less fluid lipid that are surrounded by the rest of the lipid, which is more fluid. These patches are **rafts**.⁶⁵⁴ Rafts have a higher frequency of saturated fatty acyl groups on their lipids, a property characteristic of sphingomyelin that may explain its preferential inclusion. It is the higher concentration of **saturated fatty acyl groups** that causes the bilayer of a raft to be less fluid. Separated phases that resemble the rafts in natural membranes can be produced experimentally by adding cholesterol and phospholipids or sphingomyelins containing only saturated fatty acyl groups to multibilayers^{655,656} or monolayers⁶⁵⁷ composed of purified phospholipids with the normal composition of unsaturated fatty acids.

Rafts can be purified from the remainder of a biological membrane because they are much less soluble in the detergent Triton X-100 (14-12).⁶⁵⁸ When membranes from animal cells are dissolved with Triton X-100 at 4 °C, the rafts can be isolated as large aggregates. Rafts isolated in this way are enriched in lipid and depleted in protein relative to the rest of the membrane in which they are found.⁶⁵⁴ In addition to the **cholesterol and sphingomyelin**, rafts contain a high concentration of **glycosphingolipids**⁶⁵⁸ such as glucosylceramide, galactosylceramide, lactosylceramide, and globoside (Table 14-1). **Glycosylphosphatidylinositol-anchored proteins**,⁶⁵⁸⁻⁶⁶⁰ triply palmitoylated caveolin,⁶⁶¹ and doubly palmitoylated protein-tyrosine kinases⁶⁶² have been found to be preferentially associated with rafts. These proteins, like the glycolipids, insert only their fatty acyl groups into the membrane so their protein sits upon the raft. As a result, the raft itself is mostly assembled from lipid. The sizes of the rafts can be ascertained by measuring the sizes of the patches of these proteins sitting on them. These patches are about 300–500 nm in diameter.^{663,664}

Although rotational diffusion of a molecule of an integral membrane-bound protein about any axis parallel to the surface of the membrane does not occur and rotational diffusion of a molecule of phospholipid about any axis parallel to the surface of the membrane is slow, integral membrane-bound proteins, anchored membrane-bound proteins, and phospholipids all display one degree of rapid rotational diffusion about axes normal to the surface of the membrane and two degrees of translational diffusion along axes parallel to the surface of the membrane. These diffusional degrees of freedom are prescribed by the fact that a bilayer of amphipathic lipids is a two-dimensional solvent, and solutes dissolved in this solvent find themselves in a **two-dimensional solution**.

The translational diffusion of proteins over the two

dimensions of a plasma membrane was strikingly demonstrated by an experiment involving the **fusion of two cells**.⁶⁶⁵ Immunoglobulins G specific for antigens on the surface of murine (c11D) and human (VA-2) cells, respectively, were produced. These immunoglobulins were covalently modified with different fluorescent reagents, one that fluoresced green and one that fluoresced orange, respectively. The addition of the former immunoglobulins to mouse cells turned proteins in their plasma membranes green, and the addition of the latter immunoglobulins to human cells turned proteins in their plasma membranes orange. When a mouse cell was fused with a human cell, the hybrid was initially stained green at one side and orange at the other, but the two sets of antigenic proteins then diffused over the plasma membrane of the hybrid until, within 40 min, they were each uniformly distributed. This intermixing resulted from two-dimensional translational diffusion.

In a three-dimensional, isotropic solvent, such as an aqueous solution, the observed translational diffusion coefficient, D_T , is the proportionality constant (Equation 1-63) between the net flux, J , of a certain solute across a unit area, in a plane normal to its direction of net flux, and the gradient of its concentration, c , along the direction of net flux, x :

$$J = -D_T \left(\frac{\partial c}{\partial x} \right)_t \quad (14-2)$$

The units on J are moles centimeter⁻² second⁻¹, and on the gradient of concentration c they are (moles centimeter⁻³) centimeter⁻¹. Therefore, the units of D_T are centimeters² second⁻¹. The mean square displacement, $\overline{d^2}$, that the molecules of the solute will experience over a given time interval, t , is related to the diffusion coefficient by the equation

$$\overline{d^2} = 4 D_T t \quad (14-3)$$

In a three-dimensional solution, molecules of the solute will also experience rotational motion as well as translational motion, and the observed rotational diffusion coefficient, D_R , for this rotational motion can be defined, in analogy with Equation 14-3, as

$$D_R = \frac{\overline{\theta^2}}{2t} \quad (14-4)$$

where $\overline{\theta^2}$ is the mean square angular displacement experienced in time t . If θ is expressed in radians, the units on D_R are radians second⁻¹.

The theoretical relationship that is used to calculate a frictional coefficient for translational motion in three dimensions, f_{T3} , from the observed translational diffusion coefficient is

$$f_{T3} = \frac{k_B T}{D_T} \quad (14-5)$$

where k_B is Boltzmann's constant and T is the temperature. An analogous theoretical relationship that is used to calculate a frictional coefficient for rotational motion in three dimensions, f_{R3} , from the observed rotational diffusion coefficient can be written

$$f_{R3} = \frac{k_B T}{D_R} \quad (14-6)$$

If the molecules of the solute were hard spheres of radius r in a solvent of viscosity η (Equation 1-66), then

$$f_{T3} = 6\pi\eta r \quad (14-7)$$

and

$$f_{R3} = 8\pi\eta r^3 \quad (14-8)$$

Equations 14-7 and 14-8 are theoretical equations relating the frictional coefficient to the dimensions of the sphere.

Diffusion of a solute in a two-dimensional solvent, isotropic in those two dimensions, can be treated in parallel. The solvent is two-dimensional because the solute is confined to rotate only about an axis normal to the plane defined by the two dimensions and to translate in only the two dimensions. The observed **one-dimensional rotational diffusion coefficient** D_{R1} is defined by Equation 14-4 where the angular displacement is only around the axis normal to the plane. The observed **two-dimensional translational diffusion coefficient**, D_{T2} , is the proportionality constant (Equation 14-2) between the net flux of a substance across a unit width on a line normal to its direction of net flux, in moles centimeter⁻¹ second⁻¹, and the gradient of its concentration along the direction of net flux, in (moles centimeter⁻²) centimeter⁻¹. The units of D_{T2} are also centimeter² second⁻¹. The mean square displacement of one molecule is still governed by Equation 14-3. This relationship has been verified experimentally by following the lateral movements as a function of time of single, fluorescently labeled molecules of phospholipid in a bilayer of dioleoyl phosphatidylcholine.⁶⁶⁶ The frictional coefficient for one-dimensional rotational diffusion, f_{R1} , can be calculated from the observed rotational diffusion coefficient by a theoretical equation analogous to Equation 14-6, and the frictional coefficient for translation in a two-dimensional solvent, f_{T2} , can be calculated from the observed translational diffusion coefficient by a theoretical equation analogous to Equation 14-5, with the substitution of f_{R1} and f_{T2} for f_{R3} and f_{T3} , respectively.

When diffusion of a solute such as an integral membrane-bound protein in a two-dimensional solvent such as a bilayer of phospholipids is evaluated, it is usually assumed that the molecule can be treated as an equivalent right circular cylinder of radius r . The theoretical equations relating the **frictional coefficient** for its rotational diffusion, f_{R1} , to the dimensions of a right cylinder of any radius r in a two-dimensional solvent of width h about an axis normal to the surface of the solvent have an exact solution, which is

$$f_{R1} = 4\pi\eta_H r^2 h \quad (14-9)$$

For right cylinders of radius r that are the size of integral membrane-bound proteins (Figures 14-14 to 14-18) undergoing two-dimensional translational diffusion in a sheet of liquid paraffin with a width, h , of about 3-4 nm and a viscosity, η_H , significantly greater than that of the water that sandwiches the liquid paraffin on both sides with a viscosity, η_W , of 0.9 mPa s, at 298 K

$$f_{T2} \cong 4\pi\eta_H h \left(\ln \frac{\eta_H h}{\eta_W r} - \gamma_E \right)^{-1} \quad (14-10)$$

where γ_E is Euler's constant (0.5772).⁶⁶⁷ This theoretical relationship relating the frictional coefficient, f_{T2} , for its translational diffusion to the dimensions of a right cylinder is not exact because the equations for slow viscous flow used to derive Equation 14-7 in three dimensions have no exact solution in two dimensions.

Unlike Equations 14-7 and 14-8, Equations 14-10 and 14-9 cannot be used quantitatively to determine the equivalent of a Stokes' radius a (Equation 1-67) or the shape of a molecule of protein (Figure 12-1) or lipid in a bilayer of phospholipid. It is not possible to determine independently the value of η_H experienced by the diffusing solute because a bilayer of natural amphipathic lipids is not an isotropic sheet of liquid hydrocarbon (Figure 14-2). It is also not known what value should be used for h , the width of the bilayer. These equations, however, can be used qualitatively to show that the diffusion coefficients measured are in reasonable agreement with the sizes of the diffusing solutes, the width of a bilayer, and the expected viscosity of the liquid hydrocarbon.

The rotational diffusion constant for a naturally fluorescent molecule of protein such as bacteriorhodopsin or rhodopsin with their tightly bound retinals or a molecule of protein modified with a fixed fluorescent reagent is measured by monitoring the **decay in the anisotropy** of the fluorescence⁶⁶⁸ or phosphorescence⁶⁶⁹ of the chromophore following excitation with a flash of polarized light. The rotational diffusion coefficient of bacteriorhodopsin in bilayers of dimyristoylphosphatidylcholine is affected little by the concentration of the protein in the bilayer, and at 30 °C it is equal to $7 \times 10^4 \text{ s}^{-1}$. The

rotational diffusion coefficient of rhodopsin in densely packed disks of photoreceptors is $5 \times 10^4 \text{ s}^{-1}$ at 20°C .¹⁹² If the radius of an imaginary cylindrical bacteriorhodopsin, r , is taken as 2.0 nm and the width of the bilayer, h , as 4.5 nm, then the viscosity of the bilayer, η_{H} , sensed by the rotating protein (Equation 14–9), is 400 mPa s.

Large multilamellar vesicles of dimyristoylphosphatidylcholine, 25–50 μm across, can be prepared so that they contain various concentrations of bacteriorhodopsin.⁶⁷⁰ Because bacteriorhodopsin is fluorescent, the distribution of the protein over the membranes of a vesicle can be monitored in a microscope by the distribution of fluorescence. When a circular area 5 μm in diameter in the middle of a vesicle is submitted to intense irradiation by a laser, the retinal within the circle is photolytically bleached. After bleaching, the molecules of bacteriorhodopsin in the circular area are no longer fluorescent, but those surrounding the circle still are. As translational diffusion takes place, the circle slowly fills with fluorescent molecules entering from the perimeter, and the bleached circle gradually disappears. From such **recovery of fluorescence following photobleaching**,^{671,672} the translational diffusion coefficient D_{T_2} of the unbleached bacteriorhodopsin moving into the circle can be calculated.

Measurements were made of the two-dimensional translational diffusion coefficient for bacteriorhodopsin at several different temperatures and concentrations of the protein in the bilayers.⁶⁷⁰ The values varied between 0.1×10^{-8} and $4 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$. As the mole fraction of bacteriorhodopsin in the bilayer was decreased from 1 mol (30 mol of phospholipid)⁻¹ to 1 mol (210 mol of phospholipid)⁻¹, the translational diffusion coefficient increased from 0.1×10^{-8} to $1.6 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 25°C . Because the diffusion coefficient was still increasing significantly at the lowest concentration at which measurements could be made, the translational diffusion coefficient at zero density, $D_{\text{T}_2}^0$, could not be determined accurately by extrapolation.

At the lowest concentrations of protein examined at 30°C , the translational diffusion coefficient of bacteriorhodopsin, $3.4 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$, is that of a cylinder of protein with a radius r equal to 2.0 nm, in a bilayer of phospholipid with a width, h , of 4.5 nm, the **viscosity** of whose hydrocarbon, η_{H} , is 110 mPa s. The broadest dimension of the bundle of α helices in a single molecule of bacteriorhodopsin is about 4 nm (Figure 14–14), the width of a bilayer of natural phospholipid and cholesterol, including the hydrophilic functional groups, is 4–5 nm (Figure 14–4D), the viscosity of motor oil at 30°C is between 100 and 200 mPa s, and the viscosity of vegetable oil at 30°C is about 50 mPa s. Because realistic numerical values for these three parameters can be used to calculate, by Equations 14–9 and 14–10, a diffusion coefficient equal to the one that is measured, it appears that bacteriorhodopsin, at least when it is in bilayers of dimyristoylphosphatidylcholine, is diffusing freely and

predictably within the two-dimensional solvent formed by those bilayers. Its diffusion is a random walk driven by thermal energy through an isotropic, viscous medium just as is the diffusion of a soluble protein through an isotropic aqueous solution.

Translational diffusion coefficients have been measured for other integral membrane-bound proteins. Bacteriorhodopsin and rhodopsin are already fluorescent, but a purified membrane-bound protein can be covalently modified with a fluorescent electrophilic reagent and then incorporated into bilayers of phospholipid, and its two-dimensional translational diffusion coefficients can be measured⁶⁷³ by monitoring recovery of fluorescence following photobleaching. For anion carrier at a surface concentration of 1 mol (200 mol of phospholipid)⁻¹, the translational diffusion coefficient is $1.6 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 30°C .⁶⁷⁴ The translational diffusion coefficients of bovine rhodopsin, Ca^{2+} -transporting ATPase from endoplasmic reticulum of skeletal muscle, and acetylcholine receptor have all been determined by fluorescence photobleaching recovery at several temperatures in reconstituted membranes at high dilution [< 1 mol of protein (3000 mol of phospholipid)⁻¹].⁶⁷³ The values for the translational diffusion coefficients at 25°C are between 1.4×10^{-8} and $2 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ for all three proteins, and they are indistinguishable within the ranges of their standard deviations. From Equation 14–10, the viscosity calculated for the bilayer from these latter measurements is between 100 and 200 mPa s.

At high dilution at 25°C , the translational diffusion coefficients of all integral membrane-bound proteins are between 1×10^{-8} and $2 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$. This means that after 1 s the average value of the square of the distance that a protein will be situated from the position it occupied initially will be $10 \mu\text{m}^2$. In a densely packed plasma membrane, however, the translational diffusion coefficients are significantly less. For example, for rhodopsin at 20°C , densely packed in the disks in photoreceptors, the translational diffusion coefficient⁶⁷⁵ is $0.3 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$. A value of $0.02 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 37°C has been determined for randomly labeled proteins in the plasma membranes of L-6 cells.⁶⁷⁶ In the latter situation, the **mean square displacement** for one of these proteins after 1 s will be only $0.1 \mu\text{m}^2$. The diameter of a normal eukaryotic cell is about $20 \mu\text{m}$. Therefore, it should take about 100 min for a protein with this low value for its translational diffusion coefficient to spread over the plasma membrane of a cell of this size if the protein were added at only one point on its surface.

It is the **dense packing of the proteins** in a normal biological membrane that causes the diffusion coefficients of most proteins to be much less than they are when they are moving unhindered over a bilayer of phospholipids. The value of $0.02 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 37°C measured for the diffusion coefficient of proteins in a plasma membrane is in the same range as diffusion coef-

ficients of $0.06 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 25 °C for ubiquinol-cytochrome-*c* reductase in mitochondrial membranes⁶⁷⁷ and $0.006 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ for phycobilisomes in membranes of thylakoids.⁶⁷⁸ When the concentration of protein in the mitochondrial membranes was decreased systematically by incorporating endogenous phospholipid, the diffusion coefficient of ubiquinol-cytochrome-*c* reductase increased monotonically. Upon a 7-fold dilution, its diffusion coefficient had increased almost 20-fold.⁶⁷⁷

The translational diffusion coefficients of integral membrane-bound proteins vary dramatically with concentration but insignificantly with variations in the apparent radius, *r*, of the equivalent cylinder because of the logarithmic dependence of the frictional coefficient on this latter parameter (Equation 14–10). These are two additional reasons why translational diffusion coefficients cannot be used to provide any insight into the shapes of these proteins in the bilayer of phospholipid.

The **phospholipids** in a membrane also display translational diffusion. This can be followed by using phospholipids, such as phosphatidylethanolamine, that have been modified by fluorescent reagents, in the case of phosphatidylethanolamine at its primary amine. The **translational diffusion coefficients** for such a fluorescent lipid in bilayers of various phospholipids are between 4×10^{-8} and $9 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 25 °C.^{673,679,680} These values compare favorably with those calculated from spin-exchange among molecules of a nitroxylphosphatidylcholine in vesicles of various natural phospholipids, which are about $10 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 45 °C.⁶⁸¹ In bilayers of dimyristoylphosphatidylcholine and cholesterol at various ratios, the diffusion coefficients for a fluorescent phospholipid are between 1×10^{-8} and $3 \times 10^{-8} \text{ cm}^2 \text{ s}^{-1}$ at 25 °C.¹⁰³ The translational diffusion coefficients for lipids are not much greater than those for proteins.

Even though the diffusion coefficients for phospholipids are not much larger than those for proteins, Equation 14–10 does not describe their behavior. It fails to do so because a phospholipid does not span the membrane completely so the viscosity of the fluids at its two ends are dramatically different⁶⁸² and because, unlike a membrane-spanning protein, its cross-sectional area is the same as those of the phospholipids forming the bilayer.^{103,679,683}

Associated with the bilayer of a biological membrane is a microviscosity. The **microviscosity** is the viscosity experienced by a small hydrophobic solute dissolved in the liquid hydrocarbon while it is rotating isotropically. Because it is measured by following rotation, the microviscosity is the viscosity of the solvent in the immediate vicinity of the small solute. This microviscosity is generally estimated from the polarization retained in the fluorescence of a hydrophobic, fluorescent solute such as 2-methylanthracene⁶⁸⁴ after its excitation with a flash of polarized light. A hydrophobic

solute is used so that most of the molecules of that solute in the sample have been incorporated into the hydrocarbon of the bilayer of phospholipid. The more rapidly the solute is reorienting within the bilayer of phospholipid during the lifetime of the excited state, the greater will be the loss of its polarization. This loss of polarization can be calibrated by the behavior of the fluorescent solute in hydrocarbon solvents of known macroscopic viscosity.⁶⁸⁴

In bilayers made in the laboratory from purified natural phospholipid, microviscosities between 100 and 200 mPa s have been observed at 25 °C.^{685,686} The microviscosity determined in vesicles formed from only the lipids in a biological membrane is almost the same as that determined for the complete biological membranes from which the lipids were extracted,⁶⁸⁶ and addition of an integral membrane-bound protein to vesicles of pure phospholipid affects the microviscosity only slightly.⁶⁸⁷ These results suggest that the regions within the bilayer of phospholipid occupied by the fluorescent solutes used to monitor this property are mainly the **bulk lipid** between the molecules of protein. Because it is the rotational diffusion of the probe that senses the microviscosity rather than its translational diffusion, the presence of protein, which provides obstacles mainly to translation, has only a small effect. Nevertheless, the microviscosities determined are in the same range as the viscosities that seem to be controlling the translational and rotational diffusion of molecules of protein when they are dissolved at low concentrations in bilayers of phospholipids. The composition of the fatty acyl groups in the phospholipids forming biological membranes (Table 14–3) has been adjusted through evolution by natural selection to compensate for the different mean body temperatures of cold-blooded animals so that a similar microviscosity is maintained regardless of the mean temperature of the environment.⁶⁸⁸

The addition of **cholesterol** increases the observed microviscosity of bilayers of phospholipid by a factor of 5–10,⁶⁸⁵ an effect that seems to be considerably larger than that of cholesterol on the translational diffusion coefficient of phospholipids.¹⁰³ The addition of cholesterol to bilayers of phospholipid, however, increases the rotational diffusion coefficients of 1,6-diphenyl-1,3,5-hexatriene dissolved in them only by factors of 2.⁹⁶ These results suggest that the viscosity of the bilayer becomes more anisotropic upon addition of cholesterol.

Epidermal growth factor receptor is an integral membrane-bound protein that depends on its ability to diffuse translationally over a bilayer of phospholipid to accomplish its function. Epidermal growth factor is a polypeptide hormone that stimulates the growth of cells from a variety of tissues. Epidermal growth factor receptor is the protein in the plasma membrane of a cell to which epidermal growth factor binds to exert its effect on the cell. Human epidermal growth factor is a small (53 aa) soluble protein; human epidermal growth factor

receptor is a large (1186 aa) monomeric glycoprotein that spans the membrane.¹⁸² Epidermal growth factor receptor is a member of a group of structurally and functionally related receptors for growth factors on the cell surface characterized by an intrinsic activity for protein tyrosine kinase.¹⁸¹ The initial response in the cascade leading to the mitosis caused by the binding of epidermal growth factor to epidermal growth factor receptor is the activation of this protein-tyrosine kinase.

The amino acid sequence of human epidermal growth factor receptor¹⁸² can be divided into **two domains** of about equal size that are located on opposite sides of the plasma membrane. The extracytoplasmic domain of the protein (620 aa) contains the binding site for epidermal growth factor.¹⁸⁴ The cytoplasmic domain of the protein (540 aa) contains the active site for protein-tyrosine kinase.¹⁸³ Both of these domains have been produced independently, in their entirety, and they are well-behaved soluble proteins with the respective functions.^{183,184} Both have been crystallized, and crystallographic molecular models are available for each of them.⁶⁸⁹⁻⁶⁹¹ In the intact native protein the short segment between these two domains is composed of 23 hydrophobic amino acids, 15 of which are leucine, isoleucine, valine, methionine, or phenylalanine. There is no doubt that this segment spans the membrane, presumably in one α helix, connecting by this tether the extracytoplasmic domain and the cytoplasmic domain in the complete native protein. It has been shown that mutations, insertions, or deletions in this membrane-spanning segment have little effect on activation of the protein-tyrosine kinase,^{692,693} hence, its role in the activation of the protein-tyrosine kinase activity must not involve any severe structural requirements, short of spanning the bilayer of phospholipid and conjoining the two domains.

There have been a number of reports implicating the **dimerization** of epidermal growth factor receptor in the activation of its protein-tyrosine kinase. Moderate yields of covalent chemical cross-linking between monomers are observed but only after epidermal growth factor has been bound,^{694,695} bivalent immunoglobulins against epidermal growth factor receptor, but not Fab fragments from these immunoglobulins, can activate its tyrosine kinase in the absence of epidermal growth factor,⁶⁹⁶⁻⁶⁹⁸ and mutant forms of epidermal growth factor receptor can suppress the activation of wild-type epidermal growth factor receptor.

It has been possible to follow the dimerization of monomeric epidermal growth factor receptor as a function of time by quantitative cross-linking,⁶⁹⁹ just as the tetramerization of phosphoglycerate mutase was followed by quantitative cross-linking (Figure 13-17). After epidermal growth factor was added to epidermal growth factor receptor dissolved in a solution of the detergent Triton X-100 (14-12), the initially monomeric protein dimerized in a reaction that could be shown to be **kinet-**

ically second-order in the concentration of protein. When the activation of protein-tyrosine kinase activity was followed in the same preparations, it was found that it was also a process second-order in the concentration of epidermal growth factor receptor and that the second-order rate constants for dimerization and the activation of protein-tyrosine kinase were identical. It follows that the rate-limiting step in the activation of the enzyme is dimerization of the protein. In the plasma membrane, this dimerization must result from collisions between monomers of epidermal growth factor receptor as they diffuse in two dimensions across the surface of the bilayer of phospholipid.

Because the protein spans the membrane in a single α helix, it seems unlikely that the order to dimerize is transmitted through this α helix across membrane, and consequently it should be the case that the binding of epidermal growth factor to the extracytoplasmic domain causes the extracytoplasmic domain to dimerize. In fact, the crystallographic molecular models of the extracytoplasmic domain of human epidermal growth factor receptor are symmetrical dimers of the complex between the protein and either epidermal growth factor⁶⁹⁰ or a related hormone.⁶⁸⁹ Even though the cytoplasmic domains of two intact molecules of epidermal growth factor receptor sterically inhibit the **dimerization of the extracytoplasmic domains**,⁵⁴⁵ during dimerization of the intact protein, dimerization of the cytoplasmic domains through an interface between them is also required for activation of the protein-tyrosine kinase. This conclusion follows from the facts that bivalent immunoglobulins G directed against the carboxy terminus of the protein activate its protein-tyrosine kinase to a level comparable to the activation by epidermal growth factor⁶⁹⁸ and that when epidermal growth factor is removed from the binding sites on dimerized protein, the intact protein dissociates into monomers greater than 40-fold more slowly than does a deletion mutant lacking the complete cytoplasmic domain.⁵⁴⁵

Therefore, dimerization of the extracytoplasmic domains produced by the binding of epidermal growth factor drags together the cytoplasmic domains, which are tethered through the membrane-spanning segment. The resulting juxtaposition of the cytoplasmic domains, which initially involves a steric problem because they are not positioned properly, nevertheless promotes, in turn, their dimerization through an interface that forms between them after they become properly aligned. The **dimerization of the cytoplasmic domains** leads to the activation of the protein-tyrosine kinase. In the crystallographic molecular model of the cytoplasmic domain, the asymmetric unit is a monomer, but because the space group of the crystal is *I*23, two monomers are related by an exact 2-fold rotational axis of symmetry, and the interface between them may be the same as the one in the dimeric cytoplasmic domains in the activated native protein.⁶⁹¹

Both observations of the kinetics of activation of epidermal growth factor receptor⁷⁰⁰ and of the binding of epidermal growth factor⁷⁰¹ and the crystallographic molecular models of the liganded, dimeric extracytoplasmic domains of epidermal growth factor receptor^{689,690} and the related fibroblast growth factor receptor⁷⁰² demonstrate that each monomer of the receptor binds a molecule of the respective hormone. The resulting dimer is rotationally symmetric, each subunit carrying its own molecule of hormone. In fact, the two symmetrically arrayed molecules of hormone are on completely opposite sides of the dimers in the crystallographic molecular models. **Growth hormone receptor**, however, which is unrelated to epidermal growth factor receptor but which also dimerizes upon binding of its hormone, forms a different kind of complex in which one molecule of hormone is bound by two molecules of the receptor.^{703,704} It is the formation of this **asymmetric complex** that dimerizes growth factor receptor and leads to its activation.⁷⁰⁵ One peculiarity of this process of activation, which is a consequence of both the fact that one molecule of hormone gathers together two molecules of receptor and the fact that molecules of receptor are not dimers before the hormone is added, is that high concentrations of growth hormone inhibit both the dimerization⁷⁰³ and the activation of growth hormone receptor.⁷⁰⁵ These facts require that monomers of growth hormone receptor be diffusing independently of each other through the plasma membrane before they are dimerized by binding to the two opposite sides of growth hormone.

There is another set of membrane-bound proteins that also relies on translational diffusion over the surface of the plasma membrane to fulfill its biological function. This is the **adenylate cyclase system**. The role of this set of proteins is also to respond to the presence of an agonist in the medium surrounding the cell. Binding of the agonist to the extracytoplasmic surface of a particular protein in the plasma membrane either activates or inhibits adenylate cyclase, which is the enzymatic activity of an active site at the cytoplasmic surface of a different protein in the same plasma membrane. This active site is responsible for the reaction

If the agonist increases the rate of production of cyclic AMP catalyzed by this enzyme, it is stimulatory; if it decreases the production, it is inhibitory.

The agonist initiates the process by binding to one of a set of receptors, each of which is a membrane-bound protein. A typical example of one of these receptors is **β -adrenergic receptor**. This protein has the site to which a **β -adrenergic agonist** such as epinephrine or norepinephrine binds as the first step in the stimulation of adenylate cyclase. β -Adrenergic receptor has been purified to homogeneity from microsomes of plasma membrane from hamster lung that have been dissolved in the

nonionic detergent digitonin.⁷⁰⁶ The ability of the receptor to bind agonist was used as an assay, and the purification involved affinity adsorption to a solid phase to which a β -adrenergic antagonist had been attached (Table 1-3). The purified receptor is a membrane-spanning glycoprotein. The polypeptide composing the protein from the hamster is 418 aa in length and contains seven hydrophobic segments, each greater than 20 aa in length, that are candidates to be α helices spanning the membrane.^{707,708}

β -Adrenergic receptor is a member of a **large family** of integral membrane-bound proteins responsible for responding to signals such as hormones, odorants, neurotransmitters, and light. In the human genome there are at least 950 genes encoding members of this family.⁷⁰⁹ Rhodopsin (Table 14-6) belongs to this family, and bacteriorhodopsin (Figure 14-14) is a homologous bacterial protein. Beginning 6 aa before its first membrane-spanning α helix and finishing 16 aa beyond the last, the amino acid sequence of human rhodopsin can be aligned with high statistical significance with that of human β 1-adrenergic receptor (21% identity; 2.6 gap percentage), so the structure of β 1-adrenergic receptor must be superposable upon that of rhodopsin⁷¹⁰ and hence upon that of bacteriorhodopsin (Figure 14-14). In particular, the seven hydrophobic segments in β 1-adrenergic receptor must be α helices that span the membrane. The segment (59 aa) of amino acid sequence on the extracytoplasmic side of the membrane amino-terminal to the first membrane-spanning α helix and the two segments (80 and 97 aa) on the cytoplasmic side of the membrane between the fifth and the sixth membrane-spanning α helices and carboxy-terminal to the seventh, respectively, are much longer in human β -adrenergic receptor than they are in bacteriorhodopsin and constitute extracytoplasmic and cytoplasmic domains involved in the binding of the hormone and the transmission of the information.

The **adenylate cyclase** itself is a much larger protein. The isoform of the human enzyme that responds to binding of an agonist to a β -adrenergic receptor is 1353 aa in length. As with all of the isoforms of the enzyme, the amino acid sequence of the adenylate cyclase contains 12 hydrophobic segments thought to span the plasma membrane as α helices. The pattern in which these α helices occur as well as alignments of segments of amino acid sequence suggest that the protein is a product of an internal duplication.⁷¹¹ In particular, two segments of amino acid sequence that contain no membrane-spanning α helices, each about 220 aa long, occur respectively in the middle of the protein, which is the carboxy terminus of the first half of the polypeptide, and at the carboxy terminus of the complete protein, which is the carboxy terminus of the second half of the polypeptide. The sequences of these two segments can be aligned,⁷¹¹ and their crystallographic molecular models are superposable.⁷¹² Each is preceded by six hydrophobic segments in close succession. Together, the two homol-

ogous segments that have no membrane-spanning α helices form a large cytoplasmic domain that is responsible for the catalysis of adenylate cyclase (Equation 14–11)⁷¹³ and for which crystallographic molecular models are available.^{711,712} In the various crystallographic molecular models, the two homologous cytoplasmic domains have superposable structures and are related to each other by a 2-fold rotational axis of pseudosymmetry.

The final component in the overall adenylate cyclase system is a guanosine nucleotide-binding protein or **G-protein**. There are several types of G-proteins present in the same membrane, one type mediating the stimulation of adenylate cyclase, another type mediating its inhibition, and other types with other roles in other systems.

The stimulation or inhibition of adenylate cyclase by an agonist requires the constant presence of **GTP** under physiological conditions⁷¹⁴ owing to the requirement that the stimulatory G-protein have GTP bound to it before the active site on adenylate cyclase can be stimulated to produce cyclic AMP. The stimulatory G-protein involved in this process binds GTP tightly⁷¹⁵ and under the appropriate circumstances catalyzes a slow hydrolysis of the GTP to GDP and inorganic phosphate.⁷¹⁶ Both of these properties are reminiscent of the binding and hydrolysis of GTP performed by tubulin. The rate of hydrolysis of GTP at the active site of a stimulatory G-protein is enhanced by the binding of agonist to β -adrenergic receptor,^{717,718} and this is expressed as a guanosine triphosphatase that is activated by the agonist.

Just as the slow hydrolysis of GTP in a microtubule is a timing device to give the growing end enough time to find its goal before it is eliminated for its failure to do so, the **slow hydrolysis of GTP** bound to the stimulatory G-protein is a timing device to terminate the activity of adenylate cyclase when the agonist is no longer present at the extracytoplasmic surface of the cell.^{716,719} When an agonist is abruptly removed from the binding site on β -adrenergic receptor by adding an antagonist to the solution in which the membranes are suspended, the adenylate cyclase activity decays slowly.⁷²⁰ The rate at which the adenylate cyclase activity decays is equal to the rate at which GTP is hydrolyzed within the active site of the G-protein that is coupled to β -adrenergic receptor and adenylate cyclase.⁷¹⁹ If this hydrolysis of GTP is blocked by cholera toxin, a specific inhibitor of this process, the adenylate cyclase no longer decays with time. The decrease in the rate of the GTPase activity as a function of the concentration of cholera toxin parallels the decrease in the fraction of the adenylate cyclase that is turned off.⁷¹⁶ The hydrolysis of the guanine nucleotide can also be prevented by the use of a chemical analogue of GTP such as guanosine 5'-O-(3-thiotriphosphate) that cannot be hydrolyzed by the G-protein. One of these analogues, as does cholera toxin, produces

adenylate cyclase activity that does not turn off when agonist is driven from the receptor.⁷¹⁶

After the GTP is hydrolyzed, GDP remains tightly bound to the G-protein, preventing the binding of GTP if the β -adrenergic receptor is unoccupied. The binding of agonist to the receptor, however, accelerates the dissociation of this bound GDP.⁷²¹

Therefore, the overall sequence of steps is the following. Guanosine triphosphate binds to the stimulatory G-protein activated by the binding of agonist to β -adrenergic receptor, and this complex between GTP and G-protein stimulates the production of cyclic AMP at the active site on adenylate cyclase as long as the GTP remains unhydrolyzed. Following hydrolysis, the tightly bound GDP prevents the G-protein from activating adenylate cyclase. When that GDP is released in a dissociation stimulated by β -adrenergic receptor to which agonist is bound, the empty site can again bind GTP.

Purified G-proteins are each constructed from **three different subunits**, α , β , and γ . The α polypeptides from all of the various G-proteins are highly homologous in sequence (averaging about 60% identity in pairwise comparisons),⁷²² but they differ significantly in length ($n_{aa} = 310\text{--}400$)⁷²² because of three regions in which long insertions can occur. The α polypeptide of the human stimulatory G-protein that is involved in the β -adrenergic system is 394 aa long;⁷²³ the β polypeptide, 340 aa; and the γ polypeptide, 70 aa. There is a crystallographic molecular model of an intact $\alpha\beta\gamma$ heterotrimeric G-protein.⁷²⁴ The α subunit has the tertiary structure of the proteins in an even larger family that bind guanosine nucleotides and control various cellular functions.⁷²⁵ The β subunit is a β propeller of seven blades (Figure 6–13).

The G-proteins involved in coupling receptors such as β -adrenergic receptor to their ultimate biological response are bound to membranes because they are **posttranslationally modified with lipid**.⁷²⁶ The α subunits are palmitoylated at a cysteine near their amino terminus (Cysteine 3 in the G-protein responsible for coupling β -adrenergic receptor to adenylate cyclase), and some are also myristoylated at their amino terminal. The γ subunits are S-geranylgeranylated (Figure 3–16) at a cysteine four amino acids from their carboxy termini. None of the subunits, however, has a membrane-spanning segment.⁷²⁴

Molecules of adenylate cyclase and molecules of β -adrenergic receptor diffuse about independently over the bilayer of phospholipids forming a membrane.⁷²⁷ There is no evidence that they associate with each other to form a specific complex. When increasing fractions of the β -adrenergic receptors in a membrane are destroyed by covalent modification, the final activities of adenylate cyclase achieved following addition of an agonist remain the same (Figure 14–29A).⁷²⁸ This observation is inconsistent with a strong, specific association between β -adrenergic receptors and adenylate cyclase because a permanently inactivated β -adrenergic receptor does not

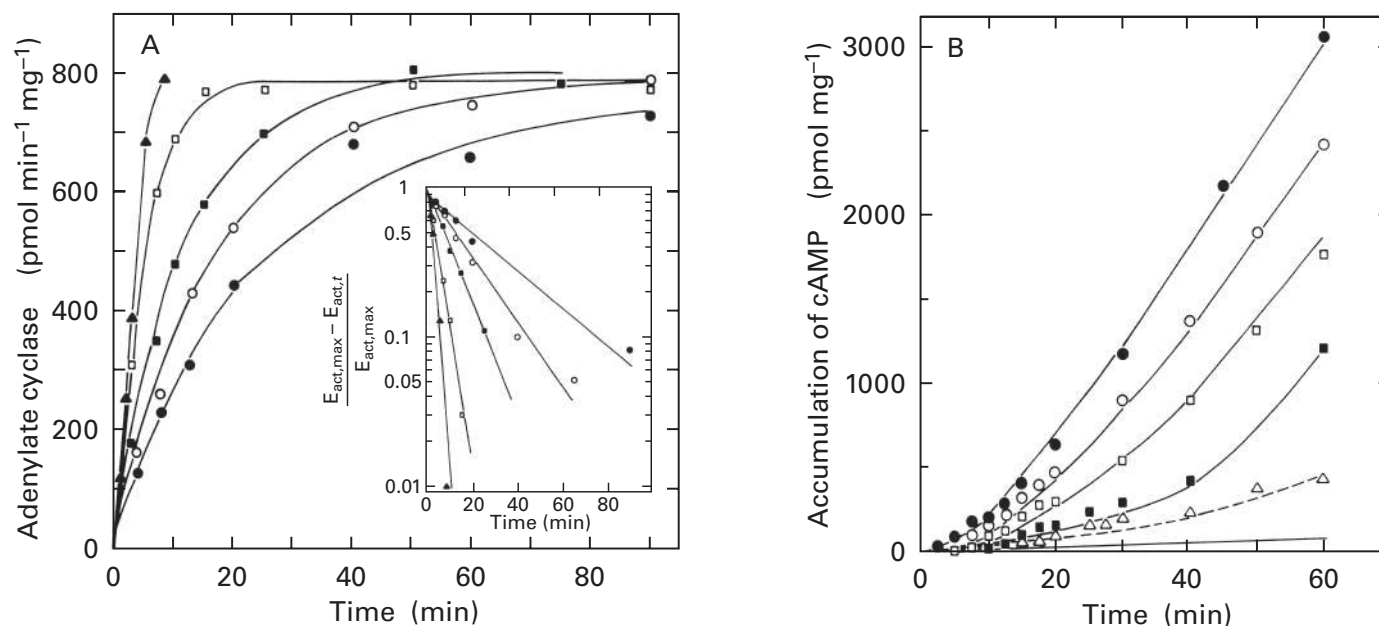

Figure 14-29: Rate of activation of adenylate cyclase as a function of the concentration of functional, occupied β -adrenergic receptor.⁷²⁸ (A) Samples of plasma membranes from erythrocytes of *Meleagris gallopavo* were exposed to various concentrations (\blacktriangle , none; \square , 17 μ M; \blacksquare , 43 μ M; \circ , 100 μ M; and \bullet , 230 μ M) of *N*-[2-hydroxy-3-(1-naphthoxy)propyl]-*N'*-(bromoacetyl)ethylenediamine, a specific, covalent, irreversible inhibitor of β -adrenergic receptor, to destroy the functional ability of various fractions of the receptor. Equivalent amounts of each sample (1.4 mg mL⁻¹) were mixed at 25 °C with saturating concentrations of the agonist epinephrine and guanosine β,γ -imidotriphosphate, an analogue of GTP that cannot be hydrolyzed by G-proteins. At various times, samples were removed, and the specific activity (picomoles of cyclic-3',5'-AMP minute⁻¹ milligram⁻¹) of adenylate cyclase was determined. As time progressed, the specific activity of the enzyme in the membranes increased monotonically until a maximum activity, $E_{act,max}$, was reached. The specific activity of adenylate cyclase is plotted as a function of time (minutes). Inset: Data in panel A are replotted on a semilogarithmic field to show that the approach to maximum activity is a first-order process. The amount of the competent adenylate cyclase that has not yet been activated at a given time t , $E_{inact,t}$, is equal to the amount of enzymatic activity at full activation, $E_{act,max}$, minus the adenylate cyclase activity observed at time t , $E_{act,t}$. The amount of adenylate cyclase activity that has not yet been activated is normalized by dividing by $E_{act,max}$. This normalized value is plotted as a function of time (minutes). (B) Equivalent samples of plasma membranes from erythrocytes of *M. gallopavo* (1.4 mg mL⁻¹) were mixed in several tubes with MgATP at 25 °C, and agonist-activated adenylate cyclase was initiated by adding guanosine β,γ -imidotriphosphate and various concentrations of the agonist epinephrine (\triangle , 0.5 μ M; \blacksquare , 1.0 μ M; \square , 3.0 μ M; \circ , 6 μ M; and \bullet , 15 μ M). At the indicated times, samples were removed from each tube and the total accumulations of cyclic-3',5'-AMP were assessed. The total accumulation of cyclic-3',5'-AMP [picomoles of cyclic-3',5'-AMP (milligram of protein)⁻¹] is plotted as a function of time (minutes). Panel B represents the integrated accumulation of cyclic-3',5'-AMP, and panel A shows the rate at which it is accumulating at any time. Reprinted with permission from ref 728. Copyright 1978 American Chemical Society.

produce a permanently unresponsive adenylate cyclase. Rather, it is the stimulatory G-protein that couples the binding of agonist on the β -adrenergic receptor to the activation of adenylate cyclase.

When the complete system for adenylate cyclase is depleted of G-protein by affinity adsorption, no **coupling between binding of an agonist and adenylate cyclase activity** can occur until it is added back.⁷²⁹ The membranes of Cyc-549 lymphoma cells contain both a β -adrenergic receptor and adenylate cyclase but lack a stimulatory G-protein and cannot display agonist-activated adenylate cyclase activity. When homogeneous stimulatory G-protein is added to these membranes, agonist-activated adenylate cyclase activity appears.⁷³⁰ Therefore, the G-protein must perform the coupling.

The complex between the β subunit and the γ subunit of the stimulatory G-protein binds tightly and

specifically to β -adrenergic receptor whether or not an agonist is bound.⁷³¹ The α subunit of the stimulatory G-protein also binds specifically and just as tightly to the β -adrenergic receptor whether or not it has guanosine 5'-O-(3-thiotriphosphate) bound to it. It forms an even tighter complex, however, with the β subunit and γ subunit of the stimulatory G-protein when it is unliganded with GTP or an analogue of GTP than when it is.⁷³¹ A complex between one β -adrenergic receptor and one G-protein has been identified in solutions derived from plasma membranes dissolved in nonionic detergent, but only when they are pretreated with β -adrenergic agonists.⁷³² In addition, the incorporation of purified homogeneous G-protein and purified homogeneous β -adrenergic receptor together into phospholipid vesicles causes the receptor to have a higher affinity for agonist, by a factor of more than 100, than it does in the absence of G-protein.⁷³³ This effect must result from the

formation of a **complex between β -adrenergic receptor and the respective G-protein** in these membranes, but it is eliminated by the addition of GTP, which binds to the G-protein.

The α subunit dissociates completely from the β subunit and γ subunit of stimulatory G-protein when GTP or a GTP analogue that cannot be hydrolyzed is bound to it.^{731,734,735} Consequently, the affinity of the α subunit of the stimulatory G-protein for the complex between β -adrenergic receptor and the β subunit and γ subunit of the stimulatory G-protein probably decreases after the β -adrenergic receptor has bound agonist and promoted the binding of GTP to the α subunit of the stimulatory G-protein.

From all of these observations, the **sequence of events at the β -adrenergic receptor** is thought to be the following.⁷³⁶ Before agonist binds there is a specific complex among β -adrenergic receptor, the β subunit and γ subunit of stimulatory G-protein,^{737,738} and the α subunit of stimulatory G-protein to which GDP is bound. Upon the binding of an agonist to β -adrenergic receptor, the dissociation of the GDP is stimulated as well as the association of GTP with the resulting empty α subunit of the stimulatory G-protein.^{739,740} The binding of GTP weakens the affinity of the α subunit of stimulatory G-protein for the remainder of this complex. This weakening increases the rate at which the α subunit exchanges between the complex and the bilayer of phospholipids in which it is in free solution. When it is dissociated from the complex in free solution within the bilayer of phospholipids, the complex between GTP and the α subunit is able to collide with a molecule of adenylate cyclase.

The α subunit of the stimulatory G-protein when it has guanosine 5'-O-(3-thiotriphosphate) bound to it forms a strong complex with the cytoplasmic domain of adenylate cyclase,⁷⁴¹ for which a crystallographic molecular model is available.⁷¹² The formation of this **complex between α subunit of the stimulatory G-protein and adenylate cyclase** stimulates the enzymatic activity of the cytoplasmic domain of adenylate cyclase by a factor of greater than 1000.⁷⁴¹ A tight complex between one intact molecule of adenylate cyclase and one molecule of G-protein has also been identified in solutions derived from plasma membranes dissolved with nonionic detergents.⁷⁴²

The system for adenylate cyclase in erythrocytes from *M. gallopavo* that is stimulated by β -adrenergic agonists takes several minutes to reach full enzymatic activity after a β -adrenergic agonist is added to a suspension of plasma membranes (Figure 14-29B).⁷²⁸ As the fraction of the β -adrenergic receptors occupied by agonist is increased, the duration of the lag preceding the expression of full enzymatic activity decreases (Figure 14-29B). The relationship between the rate at which full enzymatic activity is established, the final level of activity of the enzyme, and the fraction of the β -adrenergic

receptors occupied by agonist, which was determined by a direct measurement of bound agonist in separate experiments, is consistent⁷²⁸ with the **kinetic mechanism**

where $K_{d,A}$ is the dissociation constant for agonist, R is β -adrenergic receptor, A is agonist, E_{inact} is inactive adenylate cyclase, and E_{act} is active adenylate cyclase.

The meaning of the second step in the mechanism is that the rate at which adenylate cyclase is activated is directly proportional to the concentration of liganded β -adrenergic receptor, $A \cdot R$, and the concentration of inactive competent adenylate cyclase, E_{inact} , and consequently is first-order in each of these concentrations. When β -adrenergic receptor is saturated with agonist, all of the receptor is in the liganded form $A \cdot R$, and the reaction is governed solely by this second step (Equation 14-13). When the concentration of the complex between agonist and receptor at saturation $[A \cdot R]_{\text{sat}}$ is decreased systematically by decreasing the concentration of the competent β -adrenergic receptor by a specific covalent modification, the rate of production of active adenylate cyclase, E_{act} , containing the activated active site, decreases in direct proportion to the decrease in the concentration of occupied receptors at saturation (Figure 14-29A).⁷²⁸ Consequently, the rate of the reaction defined by the second step in the mechanism is **first-order in the concentration of occupied β -adrenergic receptor**. When β -adrenergic receptor is saturated with agonist, the rate of formation of active adenylate cyclase, E_{act} , is **first-order in the concentration of the unactivated adenylate cyclase**, E_{inact} (inset to Figure 14-29A).

The reaction governed by k_D (Equation 14-13) results from the **collision of two proteins** while they diffuse through the bilayer of phospholipids. When the microviscosity of the membrane, as judged by the residual polarization of a hydrophobic fluorescent molecule, is decreased by adding *cis*-vaccenic acid, the rate of production of active adenylate cyclase at saturating concentrations of agonist increases monotonically.⁷²⁸ When the viscosity of the plasma membrane is increased by removing some of its bulk phospholipid, the ability of the binding of agonist to β -adrenergic receptor to activate adenylate cyclase is significantly inhibited.⁷⁴³ It has also been observed that when the macroscopic viscosity of the membranes in the disks of retinal rods is decreased by halving the concentration of rhodopsin in them, the rate of phototransduction is accelerated 1.7-fold.⁷⁴⁴

Phototransduction results from the coupling of rhodopsin to cyclic GMP phosphodiesterase in a manner homologous to the coupling of β -adrenergic receptor to adenylate cyclase.

If, as is generally assumed, the two proteins that are colliding within the membrane to activate the enzymatic activity are adenylate cyclase and the complex between GTP and the α subunit of the stimulatory G-protein, it necessarily follows that the concentration of the complex between GTP and the α subunit of stimulatory G-protein in the bilayer of phospholipids must at all times be directly proportional to the concentration of liganded β -adrenergic receptor. To be so, the complex between GTP and the α subunit of stimulatory G-protein must be in constant communication with β -adrenergic receptor. Consequently, the α subunit and the complex between β -adrenergic receptor and the β subunit and γ subunit of stimulatory G-protein must be rapidly associating with and dissociating from each other in an equilibrium that maintains the required proportionality.^{728,745} The fact that one complex between agonist and β -adrenergic receptor is able to catalyze the exchange of GDP for GTP on more than 10 α subunits of stimulatory G-protein in the space of a few seconds^{736,737,746} suggests that the equilibration between these two proteins is much more rapid than the activation of adenylate cyclase (Figure 14-29). The fact that the α subunit of stimulatory G-protein is attached to the membrane only through its posttranslational lipid allows it to diffuse across the membrane more rapidly than if it were an integral membrane-bound protein, and this property increases the rate of its equilibration with β -adrenergic receptor.

A **membrane within a living cell** often differs in shape and extension from the same membrane purified from a homogenate of that cell. Small organelles such as mitochondria, chloroplasts, and lysosomes remain intact and are not visibly or functionally altered during gentle disruption of the cell and purification by centrifugation. The endoplasmic reticulum is constantly changing in its shape and contiguity even within the living cytoplasm, a property reflected in the fact that, upon homogenization, it readily disintegrates into small microsomes. The plasma membrane, however, in its natural state in an intact cell, is required to remain at all times a continuous enclosure surrounding the cytoplasm even while it must maintain a total surface area much greater than the membranes of any of the stable organelles it contains. When the cell is homogenized, the plasma membrane, as does the endoplasmic reticulum, also disintegrates into small microsomes, but much more reluctantly.

This reluctance seems to result from the fact that plasma membranes are skins stretched and pinned upon a frame. In bacteria and fungi, the frames are the outer membranes and cell walls on the extracytoplasmic surface, for when these integuments are digested away, a fragile, naked spheroplast remains that is easily disintegrated. In animal cells, however, there is often a frame on

the cytoplasmic side of the plasma membrane upon which the membrane is stretched and to which it is pinned. A limited number of molecules of integral membrane-bound proteins and lipids function as the pins. These pins connect the continuous bilayer of the plasma membrane to the frame at random points scattered over its surface but do not noticeably affect the physical properties of the bilayer of phospholipid. The stability provided by any one of these supports allows a plasma membrane to remain unbroken over its entire surface area even though it is a thin, fragile fluid film that disintegrates when it is removed from the frame.

The **cytoskeleton** is the frame upon which the plasma membrane of an animal cell is stretched and pinned. Although most of the proteins are free to diffuse, the proteins pinning the plasma membrane to the cytoskeleton do not. In the short run, the membrane is fixed at these points of attachment but fluid everywhere else. When the cytoskeleton collapses and, as a result, the pins cluster rather than remaining spread out, the unsupported plasma membrane in the abandoned regions slowly fragments into microsomes.⁷⁴⁷

The cytoskeleton of an **erythrocyte** is the best characterized. The proteins constituting the cytoskeleton of an erythrocyte are, however, found in most of the cells from other tissues and are thought to perform the same role in these other types of cells. When erythrocytes are added to a solution of nonionic detergent, the plasma membrane dissolves and leaves behind its cytoskeleton that has the shape of an erythrocyte but is a basket rather than a bag.⁷⁴⁸ The cytoskeleton exposed by this treatment contains mainly spectrin, actin,⁷⁴⁹ and protein 4.1.

Spectrin⁷⁵⁰ was originally identified by Rosenthal, Kregenow, and Moses⁷⁵¹ as a protein composing a fuzzy network on the cytoplasmic side of the plasma membrane of an erythrocyte. It was isolated by extraction of plasma membranes from erythrocytes at low ionic strength in the presence of a chelating agent for multivalent cations.⁷⁵¹ The protein from human erythrocytes is composed of an α polypeptide (2418 aa) and a β polypeptide (2136 aa)⁷⁵² and is an $\alpha\beta$ heterodimer or $(\alpha\beta)_2$ heterotetramer depending upon the conditions.⁷⁵³ The purified heterodimer has a high intrinsic viscosity ($[\eta] = 140 \text{ cm}^3 \text{ g}^{-1}$),⁷⁵⁴ indicating that it is elongated. The two polypeptides of the $\alpha\beta$ heterodimer are homologous in sequence, and each contains internally repeating domains (Figure 7-16).⁷⁵⁵ In electron micrographs, the $\alpha\beta$ heterodimer appears as a flexible two-stranded segment of rope about 100 nm long (Figure 14-30B).⁷⁵⁶ The two strands are not held together along their entire length and tend to splay. An $(\alpha\beta)_2$ heterotetramer is formed from two dimers associating end to end (Figure 14-30A).

The **actin** in the cytoskeleton is in the form of short thin filaments (Figure 9-1B) with a uniform length of 12-14 monomers.⁷⁵⁷⁻⁷⁵⁹ The protein dematin⁷⁶⁰ is associated with these actin filaments and controls the associations between them.⁷⁶¹

Figure 14-30: Electron micrographs of individual molecules of human spectrin as the $(\alpha\beta)_2$ heterotetramer (A) or $\alpha\beta$ heterodimer (B).⁷⁵⁶ Human erythrocytes were washed and lysed, and the resulting plasma membranes were washed to remove the hemoglobin. The purified plasma membranes were extracted with 0.1 mM EDTA, pH 8, at 0 °C for 40 h, and the membranes were then removed by centrifugation. The released spectrin was purified from the extract by molecular exclusion chromatography. Solutions containing the spectrin were brought to 70% glycerol and sprayed onto freshly cleaved mica. The surface of the mica was then sprayed at an angle of 9° to the surface with a mixture of platinum and carbon vaporized by electric discharge. The spray was applied while the sample was rapidly rotating about an axis normal to the surface. This causes the molecules to be surrounded by drifts of platinum, which is electron-dense. These drifts produce an outline of the molecules of protein. The film of platinum and carbon was then transferred from the mica to a grid for electron microscopy. The molecules are represented by the tortuous, elongated outlines. Magnification 170000×. Reprinted with permission from ref 756. Copyright 1979 Academic Press.

Human **protein 4.1** is a monomer with a polypeptide 864 aa in length. It is a globular protein that can bind to an $\alpha\beta$ heterodimer of spectrin near the other end of the rope from that which combines with another $\alpha\beta$ heterodimer to form the $(\alpha\beta)_2$ heterotetramer.^{762,763} When purified actin, protein 4.1, and spectrin are mixed together with ATP, they spontaneously form a macroscopic gel made up of heterotetramers of spectrin cross-linked by the short filaments of actin.⁷⁶⁴ This gel presumably is analogous to the meshwork seen in the cytoskeleton. Protein 4.1 promotes this association of spectrin and actin⁷⁶⁴⁻⁷⁶⁶ by binding simultaneously to a molecule of spectrin and a short filament of actin and linking them together.⁷⁶⁷

One set of the pins attaching the plasma membrane of an erythrocyte to the cytoskeleton is formed from two proteins, ankyrin and band 3 anion transport protein. Human erythrocytic ankyrin is a monomer constructed from one single polypeptide about 1880 aa in length.^{762,768} **Ankyrin** has a fairly high frictional ratio ($f/f_0 = 1.46$),⁷⁶⁸ and in electron micrographs it appears as a cluster of three to five globular domains.⁷⁶² In keeping with this structure, it has a detachable domain ($n_{aa} = 650$) that contains the binding site specific for spectrin.⁷⁶⁹ Ankyrin binds tightly to spectrin near the end of the rope that associates to form the $(\alpha\beta)_2$ heterotetramer, the opposite end from that to which protein 4.1 binds.⁷⁶² Intact ankyrin can also bind to the amino-terminal, detachable domain of band 3 anion transport protein in a simple bimolecular reaction ($K_d = 10^{-8}$ M) as well as to intact band 3 anion transport protein in solutions of nonionic detergents.⁷⁷⁰ A freely soluble heterodimer containing one polypeptide of ankyrin and one polypeptide from band 3 anion transport protein can be purified in solutions of nonionic detergent.⁷⁷¹

Because intact ankyrin binds tightly to both **band 3**

anion transport protein, which is an integral membrane-bound protein, and spectrin, which is incorporated into the cytoskeleton, it can link the cytoskeleton to the plasma membrane. As there are fewer molecules of ankyrin in an erythrocyte than molecules of band 3 anion transport protein, only a minority of the molecules of band 3 anion transport protein, presumably chosen at random, are linked to the cytoskeleton. Unlike the unattached molecules of band 3 anion transport protein, those that are attached to ankyrin and pin the cytoskeleton to the membrane are unable to diffuse translationally⁷⁷² or rotationally⁷⁶⁷ because they are attached rigidly to the cytoskeleton. Membrane protein band 4.2 stabilizes this interaction between ankyrin and band 3 anion transport protein.⁷⁷³

At the other end of an $\alpha\beta$ heterodimer of spectrin, the protein 4.1 that is creating the interaction of spectrin and actin is also linking the cytoskeleton to the membrane. Protein 4.1 binds strongly to phosphatidylserine on the inner surface of the bilayer of phospholipids⁷⁷⁴ and also to the cytoplasmic portion of glycophorin C⁷⁷⁵ and glycophorin A.⁷⁷⁶

In the short run, the molecules of band 3 anion transport protein, phosphatidylserine, glycophorin A, and glycophorin C are the stationary points around which flow the traffic of the proteins and lipids of the plasma membrane. In the long run, as the cell changes shape and size, these points of attachment also rearrange fluidly to accommodate the changes.

The pinning of the plasma membrane onto the cytoskeleton and the sculpting of the various membranes into the cellular organelles, like the assembly of microtubules, filaments of actin, and thick filaments or the mixing of a vast array of soluble proteins at high concentration to produce cytoplasm, seamlessly transforms protein chemistry into cell biology.

When endoplasmic reticulum is treated with trypsin or pancreatic triacylglycerol lipase contaminated with trypsin, only the peptide bond following Lysine 90 is cleaved, and a protein containing the first 90 amino acids of cytochrome b_5 falls off the membrane. This soluble protein can be purified and crystallized, and its structure has been determined by X-ray crystallography. This protein will be referred to as cytochrome b_5 (trypsin) or cytochrome b_5 (lipase), respectively.

- Explain these observations in terms of the distribution of specific amino acids in the sequence of the protein.
- Draw a representation of the complete cytochrome b_5 molecule attached to the membrane.

It is possible to release, by the use of a detergent, intact cytochrome b_5 from microsomes of endoplasmic reticulum and to purify this protein. This protein will be referred to as cytochrome b_5 (detergent).

- When various amounts of cytochrome b_5 (detergent) or cytochrome b_5 (lipase) are mixed with endoplasmic reticulum membranes and incubated for 18 h at 2 °C, and the membranes are then washed extensively, the detergent form attaches to the membranes while the lipase form does not (see the following figure). Explain this observation.

Binding of cytochrome b_5 (detergent) (●) or cytochrome b_5 (lipase) (○) to microsomes of endoplasmic reticulum from liver of *O. cuniculus*. The results are expressed as the moles of exogenous cytochrome b_5 bound to the microsomes for every mole of endogenous cytochrome b_5 in the microsomes as a function of the moles of exogenous cytochrome b_5 added for every mole of endogenous cytochrome b_5 present. The points marked with × were samples that were washed further in 0.5 M NaCl, pH 8.0, to remove any loosely bound cytochrome b_5 . Reprinted with permission from ref 275. Copyright 1972 *Journal of Biological Chemistry*.

Cytochrome- b_5 reductase is also attached to the endoplasmic reticulum. It catalyzes the following reaction:

The native endoplasmic reticulum membrane contains one molecule of cytochrome- b_5 reductase and 10 molecules of cytochrome b_5 for every $2.5 \times 10^3 \text{ nm}^2$ (see the following figure).

Schematic representation of the spatial relationships between phospholipid, cytochrome b_5 , and cytochrome- b_5 reductase on the surface of a microsomal vesicle. The surface areas used for these components were phospholipid, 0.63 nm^2 ; cytochrome b_5 , 4 nm^2 ; and cytochrome- b_5 reductase, 10 nm^2 . The entire area (diameter = 56 nm) would include 4000 molecules of phospholipid. The endogenous concentrations of the two proteins would place approximately 10 molecules of cytochrome b_5 (●) and approximately 1 molecule of reductase (●) in this area, assuming a random distribution on the outer surface of the membrane. The left sector indicates the molecular density with only endogenous cytochrome b_5 , and the right sector, the density with a 10-fold molar excess of cytochrome b_5 (detergent) (○). Reprinted with permission from ref 275. Copyright 1972 *Journal of Biological Chemistry*.

When all of these cytochrome b_5 molecules are in the oxidized form and the reaction is initiated by addition of reducing equivalents, the time required for the reduction of half of all the cytochrome b_5 molecules in the two types of membranes by the reductase is 0.47 s for the unenriched membranes and 0.13 s for the enriched membranes.

- (D) What ability must cytochrome b_5 possess in order to participate as a reactant in this reaction?
- (E) Why is the $t_{1/2}$ shorter in the case of the enriched membranes?
- (F) The concentration of cytochrome b_5 in the solution during the reduction experiments with the enriched membranes just described was about $2 \times 10^{-6} \text{ M}$, and the rate of the reaction catalyzed by the reductase was independent of the concentration of membranes suspended in the solution. In order to observe the same turnover rate, however, when cytochrome b_5 (trypsin) was the substrate, its concentration had to be $5 \times 10^{-5} \text{ M}$ and the rate

of the reaction catalyzed by the enzyme depended on the concentration of cytochrome b_5 (trypsin) in the solution. Explain these observations.

Problem 14-8: Calculate the translational diffusion coefficients at 20°C for integral membrane-bound proteins the apparent radii, α , of whose bundles of α helices are 1.0 , 2.0 , 4.0 , and 5.0 nm . Assume that the viscosity of the bilayer of phospholipid is 100 mPa s and the width of the bilayer of phospholipid is 5 nm .

Problem 14-9: The vertebrate rod is a cell in the retina responsible for registering light rays in the visual process. The end of the cell that performs this task is called the outer segment. It is a cylinder filled with disks, which are flattened circular, closed sacs pinched off from the plasma membrane.

Diagram showing frog rod outer segment. The lamellar membranous structure of the rod outer segments consists of a stack of sacs, except near the base, where it consists of infoldings of the cell plasma membrane that are being pinched off. Reprinted with permission from ref 777. Copyright 1970 Scientific American Inc.

The disks are stacked in the rod as poker chips are stacked in a rack. In this way, greater than 90% of the membrane from which the disk is made lies normal to the cylindrical axis of the rod outer segment.

Rhodopsin (Table 14-6) is the only protein dissolved in the disk membrane.

- (A) In an outline of the cross section of a disk draw a schematic diagram of the molecular structure of the disk membrane. Include rhodopsin molecules, labeled with an arrow indicating direction of insertion, and phospholipids.

Rhodopsin is a protein to which is attached, by an imine linkage, one molecule of 11-*cis*-retinal. When 11-*cis*-retinal is exposed to intense light it isomerizes to all-*trans*-retinal. This process is known as bleaching and results in a color change from orange to clear.

- (B) What does the following experiment demonstrate about the properties of a protein such as rhodopsin in a biological membrane? Reprinted with permission from *Nature*, ref 675. Copyright 1974 Macmillan Magazines Limited.

Rod outer segments were obtained by gently shaking retinas dissected under dim red light from the eyes of frog (*Rana catesbeiana*) and mudpuppy (*Necturus maculosus*) which had been dark-adapted for more than 10 h. The rods were shaken into a microchamber containing a standard Ringer solution and examined in a Shimadzu 50L microspectrophotometer (MSP) fitted with a high quantum efficiency photomultiplier (Hamamatsu type R375). Single rods which appeared intact and which lay flat on the bottom of the chamber were selected for observation, and all observations were completed within 30 min after the rods were isolated. The rhodopsin in isolated rods, once bleached, does not regenerate, hence dim red light was used for selection, focusing, and alignment.

The measuring beam of the MSP was limited by an aperture and a condensing lens to form a rectangle about $2 \times 20 \mu\text{m}$ in cross section. The long axis of the rectangle was aligned with the long axis of the rod and a simple motor-driven "alternator" optically shifted the rectangular measuring beam back and forth between the two sides of the rod. Thus the absorbance of the rhodopsin on each side of the rod could be compared directly. The wavelength of the measuring beam was set at the absorption peak of the visual pigment: 500 nm for frog, 530 nm for mudpuppy.

With suitable alignment and focusing the absorbance was essentially equal on both sides of the unbleached rods, as shown by the first pair of measurements on an unbleached rod at the beginning of each of the two recordings in the figure below. The alternator was then stopped momentarily and the intensity of the measuring beam was increased about 1000-fold to bleach some pigment on one side of the rod.

The exponential decrease in absorbance during the bleach was recorded, and then the intensity was dropped to the original level and the alternator turned on again. The figure below shows that immediately after the bleach the absorbance on the unbleached side was little changed, but there was a marked drop in absorbance on the bleached side. Within the next few seconds, however, the absorbance of the unbleached side decreased while that on the bleached side increased, and within less than 1 min the absorbance of the two sides became equal, reaching a final level midway between that of each side immediately after the bleach.

The diagrams of a rod depict the pigment distribution corresponding in time with the absorbance measurements shown below. The arrows indicate the location on the rod at which each absorbance measurement was made. Recordings made from two different rods are shown to give an indication of the repeatability of the measurements. In each experiment the chart recorder was run continuously, as shown by the time base. The alternator also ran continuously except during the bleach. The records thus consist of a repeated pattern in which absorbance measurements were made first on the left side, then the right side of the rod. Between each pair of measurements baseline measurements were also made to ensure that no drifts occurred (for clarity, these were omitted from the figure). The spikes on the traces were caused by switching transients in the alternator. The diameter of a disk is essentially equal to the width of the rod, and the width is measured in the MSP after completing each experiment.

 3-[(3-cholamidopropyl)dimethyl-
 lammonio]-1-propane-
 sulfonate, 770
 decyl β - β -glucoside, 770
 decyl β - β -maltoside, 770
 N,N-dimethyldecylamine *N*-oxide,
 770
 N,N-dimethyldodecylamine
 N-oxide, 769–70
 N,N-dimethyloctylamine *N*-oxide,
 770
 dodecyl β - β -glucoside, 770
 dodecyl β - β -maltoside, 770
 octyl β - β -glucoside, 770
 saponins, 769
- Tritons, 769
 Triton X-100, 770
- dethiobiotin synthase
 electrospray mass spectrometry, 417
- deuterium nuclear magnetic
 resonance spectroscopy
 bilayer of phospholipid, 757
 boundary layer of phospholipid,
 786
 4,6-di(bromomethyl)-3,7-dimethyl-
 1,5-diazabicyclo[3.3.0]octadiene-
 2,7-dione
 reagent for cross-linking, 549
- diacylglycerol kinase
 integral membrane-bound protein,
 766
- 2,2-dialkylglycine decarboxylase
 (pyruvate)
 point group, 470–71
- diameter of the particles
 chromatography, 6
- diaminopimelate epimerase
 domains, 383
- diazonium salts
 reagents for covalent modification,
 538
- 5-diazonium-1-hydrotetrazole
 reagent for covalent modification,
 538
- diazotized *p*-[³⁵S]sulfanilic acid
 impermeant reagent for covalent
 modification, 799
- dicarboxylate transporter
 immunostaining, 566
- dicarboxylic acids
 intramolecular hydrogen bonds,
 227
- dicyclohexyl carbodiimide
 reagent for covalent modification,
 539
- 2',3'-dideoxynucleotide
 sequencing of DNA, 104
- dielectric relaxation
 hydration of a protein, 297
 hydrophobic effect, 233
 water, 195
- diethyl pyrocarbonate, 550
 reagent for covalent modification,
 536
- difference in pK_a
 hydrogen bond, 210
- difference maps of electron density
 crystallography, 173
- difference maps of scattering density
 image reconstruction, 502

 dihydrolipoyllysine-residue (2-methylpropanoyl)transferase
 quaternary structure, 490
 dihydrolipoyllysine-residue succinyltransferase
 aligning amino acid sequence, 360
 mismatched symmetry, 511
 quaternary structure, 490
 space groups, 463
 dihydroneopterin aldolase
 interfaces, 480
 dihydroorotase
 domains, 379
 dilauroyl-*N,N*-dimethylphosphatidylethanolamine
 crystallographic molecular model, 753
 dilauroylphosphatidic acid
 crystallographic molecular model, 753
 dilauroylphosphatidylethanolamine
 crystallographic molecular model, 753
 dimer
 fundamental unit of quaternary structure, 474
 dimer of dimers
 point group 222, 471
 dimers of water
 water, 190
 dimethyl suberimidate
 cross-linking, 440
 6,7-dimethyl-8-ribityllumazine synthase
 icosahedral symmetry, 488
 interfaces, 488
 5-(dimethylamino)naphthalene-1-sulfonyl fluoride
 fluorescent reagent for covalent modification, 536
N,N-dimethyldecylamine *N*-oxide
 detergent, 770
N,N-dimethyldodecylamine *N*-oxide
 detergent, 769–770
N,N-dimethyloctylamine *N*-oxide
 detergent, 770
 dimyristoylphosphatidylcholine
 crystallographic molecular model, 753
 dimyristoylphosphatidylglycerol
 crystallographic molecular model, 753
 dipeptidyl-peptidase IV
 purification, 773
 diphenylethanedione
 reagent for covalent modification, 539
 diphosphatidylglycerol
 asymmetry of, 810
 phospholipid, 749
 diphtheria toxin
 punching a hole in a membrane, 804
 diphtheria toxin repressor
 dipolar interactions
 electron paramagnetic resonance, 649
 metalloproteins, 332–33
 disc electrophoresis, 42–44
 disordered water
 water in crystallographic molecular models, 290
 distance between dipoles
 fluorescence resonance energy transfer, 605
 distance distribution function
 X-ray scattering, 581
 distance measurements
 fluorescence resonance energy transfer, 607–9
 distribution coefficient
 molecular exclusion, 12
 distribution of electron density
 crystallography, 156
 distribution of scattering density
 image reconstruction, 501
 β -dystroglycan
 heterologous associations, 513
 disulfide
 cysteine, 81–82
 disulfide interchange, 124
 5,5'-dithiobis(2-nitrobenzoate)
 reagent for covalent modification, 537
 dithiothreitol
 use, 124
 divalent metal ions
 ion pairs, 203
 DNA-(apurinic or apyrimidinic site) lyase
 metalloproteins, 330
 nucleic acid, association of
 proteins with, 320
 E2 DNA-binding domain
 rotational axes of symmetry, 468
 DNA-directed DNA polymerase
 cloning of DNA, 97
 domains, 388
 fluorescence resonance energy transfer, 608–09
 posttranslational modification, 115
 purification, 30
 DNA-directed RNA polymerase
 cloning of DNA, 97
 covalent modification, 548
 quaternary structure, 407
 DNA ligase (ATP)
 cloning of DNA, 96
 DNA ligase (NAD⁺)
 cloning of DNA, 96
 DNA polymerase β
 nucleic acid, association of
 proteins with, 315
 DNA topoisomerase
 covalent modification, 546
 dodecyl β -D-glucoside
 detergent, 770
 dodecyl β -D-maltoside
 detergent, 770
 dodecyl sulfate gel electrophoresis
 carbonate dehydratase, 422
 catalase, 422
 catalogue of polypeptides, 431
 chymotrypsinogen, 422
 fructose-bisphosphate aldolase, 422
 fumarate hydratase, 422
 glutamate dehydrogenase, 422
 glyceraldehyde-3-phosphate dehydrogenase, 422
 L-lactate dehydrogenase, 422
 micelle of dodecyl sulfate, 421
 myoglobin, 422
 ovalbumin, 422
 phosphorylase, 422
 retardation coefficient, 422
 serum albumin, 422
 stacking, 422
 unfolded polypeptides, 421

- dolichyl-phosphate
 β -D-mannosyltransferase
 fluorescence resonance energy transfer, 609
 purification, 773
 domains, 376–91
 acetylcholine receptor, 779
 acyl carrier protein, 382
 [acyl-carrier-protein]
 S-acyltransferase, 381
 adenylate cyclase, 817
 aggreCAN, 386
 β -alanine– β -alanine ligase, 388
 aminodeoxychorismate synthase, 380
 anchored membrane-bound proteins, 764
 anion carrier, 377
 ankyrin domain, 386
 anthranilate synthase, 380
 antifreeze protein, 384
 AraC protein, 378
 armadillo domain, 386
 aspartate carbamoyltransferase, 379
 aspartate kinase, 378
 aspartate kinase–homoserine dehydrogenase, 381
 aspartate transaminase, 389
 aspartic endopeptidase, 384
 benzoate 4-monooxygenase, 382
 biotin-dependent carboxylase, 382, 388
 btk kinase, 386
 C2 domain, 386
 Ca²⁺-transporting ATPase, 779
 CAD multienzyme complex, 379, 390
 carbamoyl-phosphate synthase, 383
 carbamoyl-phosphate synthase (ammonia), 379
 carbamoyl-phosphate synthase (glutamine hydrolysing), 379
 catalase, 388
 chaperone protein PapD, 390
 cholesterol oxidase, 382
 CLC-0 chloride channel, 389
 coenzymatic domain, 382
 cohesin domain, 386
 collagen VI, 386
 CTP synthase, 380
 cyclic AMP-dependent protein kinase, 382
 cystathionine β -synthase, 378
 3-dehydroquinone dehydratase, 380
 3-dehydroquinone synthase, 380
 dephospho-CoA kinase, 391
 detachable domain, 376
 diaminopimelate epimerase, 383
 differential scanning calorimetry, 388–89
 dihydrofolate reductase, 380
 dihydrofolate reductase–thymidylate synthase, 390
 dihydrolipoyl dehydrogenase, 388
 dihydrolipoyllysine-residue acetyltransferase, 384, 390
 dihydroorotase, 379
 DNA-directed DNA polymerase I, 388
 dot matrix, 384
 dragline silk, 384
 EF hand, 386
 effect on folding, 680
 EGF domain, 386
 endopeptidolytic detachment, 377
 enoyl-[acyl-carrier-protein] reductase, 381
 enzymatic domain, 379–82
 epidermal growth factor receptor, 815
 erythronolide synthase, 381
 evolutionarily shifting domains, 388
 exon shuffling, 386
 extracellular matrix, 386
 Fab fragments, 376
 Factor XII, 386
 fatty-acid synthase, 381
 ferredoxin–NADP⁺ reductase, 376–77, 388
 fibrinogen, 388–89, 717
 fibronectin domain, 386
 functional domain, 382
 fundamental units of protein structure, 390
 galactose oxidase, 382
 gelsolin, 384
 gene fusion, 381
 gene multiplication, 384
 genetic detachment, 377
 glucose oxidase, 382
 glutaminase, 379
 glutamine–fructose-6-phosphate transaminase (isomerizing), 380
 glutamyl endopeptidase, 378
 glutathione reductase, 388–89
 glutathione synthase, 388
 glutathione-disulfide reductase, 382
 GMP synthase, 380
 granulin, 384
 hemagglutinin glycoprotein, 388
 hemocyanin, 384
 hemopexin domain, 386
 hexokinase, 384
 homoserine dehydrogenase, 378
 3-hydroxyacyl-[acyl-carrier-protein] dehydratase, 381
 imidazole glycerol phosphate synthase, 380, 383
 immunoglobulin domain, 386
 immunoglobulin G, 376, 378, 382, 390, 477, 555
 independently folding domain, 389
 independently shifting domains, 388
 indole-3-glycerol-phosphate synthase, 377, 384
 initiation factor IF3, 390
 internal duplication, 383
 internally repeating domain, 382
 kinetics of folding, 709
 kringle, 386, 390
 L-lactate dehydrogenase, 382–83
 laminin γ 1, 390
 leucine-rich repeat, 386
 lysozyme, 388
 mannose-6-phosphate receptor, 385
 methionyl aminopeptidase, 383
 modular domain, 385
 mosaic eukaryotic protein, 385
 multienzyme complex, 379–82
 NADH peroxidase, 388
 nebulin, 384
 operon, 381
 ovotransferrin, 384
 3-oxoacyl-[acyl-carrier-protein] reductase, 381
 3-oxoacyl-[acyl-carrier-protein] synthase, 381
 p120 GTPase activator, 386
 pantetheine-phosphate adenylyltransferase, 391
 peptidylamidoglycolate lyase, 377
 peptidylglycine monooxygenase, 377
 perlecan, 386
 6-phosphofructo-2-kinase/fructose-2,6-bisphosphate 2-phosphatase, 389
 phosphoglycerate kinase, 383
 phosphoinositide phospholipase C δ 1, 386–87
 phospholipase C γ , 386
 1-(5-phosphoribosyl)-5-[(5-phosphoribosylamino)methylidene amino] imidazole-4-carboxamide isomerase, 383
 phosphoribosylamine–glycine ligase, 388, 390

- phosphoribosylanthranilate isomerase, 377, 384
 phosphoribosylformylglycin-amidine cyclo-ligase, 390
 phosphoribosylformylglycin-amidine synthase, 380
 phosphoribosylglycinamide formyltransferase, 390
 3-phosphoshikimate 1-carboxy-vinyltransferase, 380, 382
 placental ribonuclease inhibitor, 384
 plasminogen, 388–89
 pleckstrin domain, 386
 prepromaginin, 384
 protein-tyrosine kinase ZAP-70, 390
 protein-tyrosine-phosphatase, 381
 pyruvate kinase, 382–83
 pyruvate oxidase, 385
