Preface

Structure in Protein Chemistry is designed for a senior undergraduate or graduate course covering the structures of proteins and biophysical chemistry. The course created by this textbook is intended to bridge the gap between the research literature and the courses in introductory chemistry and biochemistry that the student has already taken. There are suggested readings at the end of each section. In these selected publications, the concepts just discussed in that section are applied in an experimental setting. There are also more than 4800 citations within the text itself that should direct the student to the scientific literature. The format of the book is intended to resemble that of a biochemical journal to ease the transition. At the completion of the course, the student should be equipped to take charge of his own education by critically reading the biochemical literature on his own. To do this he must be able to understand the experiments performed and be able to reach the same conclusions as do the authors of each publication or to realize that the authors are mistaken in their interpretations. It is my intention to develop in the student the ability to draw his own conclusions from only the experimental results. To this end, there are problems after most of the sections to reinforce the concepts that have just been presented in the text. These problems are usually based on actual experimental results, which are to be evaluated by the student, ideally in the absence of assistance or misdirection from the authors of the publications from which the results were taken.

Refined crystallographic molecular models provide most of our knowledge of the structures of proteins. Their importance and validity are self evident, and they provide the foundation on which almost all of the other experimental observations in the field must rest. They also create, in the imagination of the chemist, a reliable abstract image of what the structure of a protein consists—its atomic details, its folded polypeptide backbone, its α helices and β structure, the packing of its secondary structure, its globular or elongated shape, its irregular surface, its hydration, and the symmetric arrangement of its subunits. This abstract image of a molecule of generic protein is synthesized by her imagination from all of the particular crystallographic molecular models she has viewed. Its fully developed mental existence permits her to understand the molecular basis of all of the other physical and chemical observations that are made of proteins and thus what these observa-

tions actually mean. The abstract image also permits her to understand more clearly the evolution of proteins, the folding of proteins, and the assembly of oligomeric and polymeric proteins. Consequently, crystallographic molecular models of proteins must be discussed as soon as possible and as comprehensibly as possible in any successful presentation of the biophysical chemistry of proteins.

Structure in Protein Chemistry begins with descriptions of how proteins are purified to provide the student with an understanding of where the proteins themselves and their crystals come from. To permit him to recognize intimately the polypeptide that folds to produce the crystallographic map of electron density, the electronic and atomic details of its covalent bonds are then described, and the methods for elucidating its sequence of amino acids and defining its posttranslational modifications are explained. A comprehensive presentation of the methods of crystallography, which permits the student to understand critically its strengths and weaknesses, and a thermodynamic discussion of the properties of noncovalent forces—ionic interactions, hydrogen bonding, and the hydrophobic effect—as they are expressed in aqueous solution are a prelude to an exhaustive description of the atomic details of the structures of proteins as observed in crystallographic molecular models. The resulting understanding of their molecular structures at the atomic level and the noncovalent forces that produce those structures forms the basis for discussions of the evolution of proteins, of the symmetry of the oligomeric and polymeric associations that produce them, and of the chemical, mathematical, and physical basis of the techniques used to study their structures such as image reconstruction, nuclear magnetic resonance spectroscopy, proton exchange, optical spectroscopy, electrophoresis, covalent cross-linking, chemical modification, immunochemistry, hydrodynamics, and the scattering of light, X-radiation, and neutrons. The application of these procedures to the study of the folding of polypeptides and the assembly of oligomers and helical polymers is then described. Finally, biological membranes and the structures of their proteins are discussed.

To present a comprehensive view of the biophysical chemistry of proteins, this text combines concepts of bonding and chemical reactivity, descriptions of macromolecular structure, principles of thermodynamics, and

explanations of biophysical methods and their results. The concepts of bonding and chemical reactivity are presented in standard structural drawings of individual molecules or chemical reactions in which electronic and mechanistic aspects are emphasized as they are in courses in organic chemistry. The descriptions of macromolecular structure are illustrated with stereo images of crystallographic molecular models that are drawn by the author so that details appropriate to the particular points made in the text are emphasized by choosing the appropriate views of the structures. The principles of chemical thermodynamics are applied in relationships among the equilibrium constants and fundamental state functions. The explanations of biophysical methods rely on the mathematical equations defining the physical properties being measured. The results of the experiments themselves are found in graphs and tables derived from the experimental literature. It is this combination of chemical drawings, stereo images, mathematical equations, graphs, and tables that makes this book both unique and comprehensive. It also places severe demands on the student. She must have a firm background in physics, mathematics, analytical chemistry, organic chemistry, and physical chemistry to understand the material. In the broadest sense the intention of the course is to educate protein chemists. A protein chemist should be able to evaluate critically the results of any of the methods applied to the study of proteins.

The foregoing describes both the First Edition and the Second Edition of *Structure in Protein Chemistry* but the Second Edition is a major revision of the first. All of the sections in each of the chapters in the Second Edition of *Structure in Protein Chemistry* have been updated extensively to include the relevant observations and new discoveries in the field that have been made since the First Edition was written.

The significant progress that has been made since that time has required that some sections of the book be completely rewritten. For example, because of the explosion of knowledge in the area of protein folding, the section on the kinetics of folding has been completely redone. Likewise, there has been a dramatic increase in the number of crystallographic molecular models of oligomeric proteins so that examples are now available of all of the point groups for the symmetric assembly of asymmetric objects. As a result, because oligomeric proteins and isometric oligomeric proteins can now be discussed more systematically, the sections covering their structures have also been completely reorganized and rewritten, and stereo drawings of crystallographic molecular models of proteins representing each point group are included.

Completely new sections have also been added to the book. A new section on the structural details of the interactions between proteins and nucleic acids has been added, in part to recognize the significant progress that has been made in this area. The explosion of new

crystallographic molecular models over the last two decades has included many with heterologous oligomeric associations where few were available at the time that the First Edition was being written. Consequently, a new section discussing oligomeric proteins that are constructed heterologously has been added. As part of this section, the major classes of these proteins are discussed, including proteins involved in cellular control, motility, the cytoskeleton, the extracellular matrix, cellular adhesion, and cell-cell interactions. There is also a completely new section on the roles of metallic cations in the structures of proteins.

There are other instances in which major advances have led to extensive additions to the text. Descriptions and drawings of the crystallographic molecular models of representatives of the various classes of integral membrane-bound proteins, which were mostly unavailable for the First Edition, have been added. There is now a comprehensive description of mass spectrometry and its application to the direct sequencing of proteins, the elucidation of the structures of posttranslational modifications, and the determination of the molar masses of proteins. The section on sequencing and modifying DNA has been extensively expanded to include developments in this rapidly advancing area. The number of posttranslational modifications included in the section covering this topic has been significantly increased, a reflection of the new discoveries in this area. In particular, the recently elucidated role of inteins in the posttranslational rearrangements of the polypeptide backbone is described. There is a new discussion of the results of crystallographic molecular models of atomic resolution (Bragg spacing less than 0.1 nm) because many of these have also become available since the First Edition was written. The section on hydrogen bonding in proteins has been significantly improved by including the results of double mutant cycles, a procedure that has been developed since the First Edition was written. How the most widely used algorithms for searching data banks of amino acid sequences work is described. There is a new, detailed discussion on how an icosahedral assembly is expanded by incorporating segments of a hexagonal array, which is the strategy that viruses have used to increase the size of their coats. The use of physical measurements of a protein in solution to adjust its crystallographic molecular model, also a new development, is now discussed in the context of comprehensive descriptions of the techniques that are used to make these adjustments. For example, scattering curves from solutions of a protein are now used to adjust its crystallographic molecular model to the structure that it assumes when it is in solution.

In several instances, descriptions of procedures have been made more comprehensive to improve the student's understanding. The section on nuclear magnetic resonance has been significantly updated to describe the improvements that have been made in this

field since the First Edition, but the physical basis and the techniques of nuclear magnetic resonance spectroscopy itself are now more comprehensively discussed so that a more complete understanding of the method is gained. The limited description of electron paramagnetic resonance spectroscopy in the First Edition has been expanded to create a new section in which examples of its recent use are presented. The use of image reconstruction and cryo-electron microscopy to produce structures of helical polymeric proteins and membrane-bound proteins is more comprehensively discussed than it was in the First Edition.

All of these changes together have created a text that is not only an update but also a significant expansion of the First Edition.

It is a pleasure to thank everyone who has helped me in the preparation of this book. First and foremost I thank my wife Francey. She has entered into the computer in the proper places and the proper order all of the almost impossible to follow changes and insertions that were haphazardly written in pencil and red pen over the typescript of the First Edition or written out in my hand as inserts on sheets of scrap paper, while at the same time correcting my spelling, grammar, and punctuation. Without her assistance, it would have taken me at least an additional year to finish the job less successfully. Daniel Louvard was kind enough to provide me with an office at the Institut Curie and access to its library in the years 1995–1996 and 2000–2001 so that I could pursue the project while away from La Jolla. I would also like to thank Heather Whirlow Cammarn, my copyeditor, who converted the manuscript into the style of the American

Chemical Society and tied up all of the many loose ends with acumen. I would again like to thank all of the reviewers of the First Edition because much of their assistance has been carried into the Second Edition. Russell Doolittle and Harvey Itano read large portions of the manuscript of the First Edition and provided excellent suggestions. Individual sections of the manuscript of the First Edition were reviewed critically by Frank Huennekens, Bruno Zimm, Charles Perrin, Steven Clarke, Ajit Varki, David Matthews, John Edsall, Cyrus Chothia, Arthur Lesk, David DeRosier, Nigel Unwin, Stephen Harrison, Fred Hartman, John Simon, George Fortes, Rachel Klevit, Ken Dill, Robert Baldwin, Howard Shachman, Dennis Haydon, and Guido Guidotti. I would like to thank all of the reviewers of the Second Edition. Individual sections of the manuscript of the Second Edition were reviewed by Larry Cummings, Martin Webb, Iain Nicholl, Jeffrey Carbeck, Lloyd Waxman, Partho Ghosh, Charles Perrin, Kenneth Walsh, Tama Hasson, Steven Clarke, Ajit Varki, Brian Matthews, the late Carl-Ivar Brändén, Dave Matthews, Ken Dill, V. Adrian Parsegian, Michael Page, Malcolm MacArthur, Patrick Argos, Stephen Harrison, William Trogler, Russell Doolittle, Henryk Eisenberg, Pierre Goloubinoff, Robert Fletterick, Georg Schulz, Michael Rossmann, Ron Milligan, Fred Hartman, Donald Engelman, David Johnson, Walter Englander, C. Nick Pace, Franz Schmid, Arshad Desai, Stephen White, and Douglas Rees. Each of them provided detailed criticism, many helpful comments, and reassurance.

Stereo Drawings

Almost all of the stereo drawings of crystallographic molecular models included in *Structure in Protein Chemistry* were produced by the program Molscript created by Per J. Kraulis. If you have the time and enjoy working on a computer, you should learn how to use the program, which is described at <http://www.avatar.se/molscript/doc/molscript.html>. It is now standard practice to publish drawings of crystallographic molecular model in this format. To appreciate the results of crystallographic studies, one must be able to view these images. Although a few individuals can view them effortlessly by crossing their eyes, the rest of us need a stereo viewer. The stereoviewer that I use and have recommended for my students is the PEAK™ Pocket Stereo Viewer with 2× magnification (124 mm legs). Suppliers of this viewer can be found using Google. It has been my experience that a student who has never viewed a stereo drawing before

will usually complain that although everyone else can learn to use one of these viewers, he cannot. It is also my experience that everyone learns to use one. When I have put a question on an examination such Problem 4.5, where one is asked to write down the sequence of the protein by examining a drawing of a crystallographic molecular model that she has never seen before, everyone in the class gets at least 90% of the sequence correct, which would have been impossible unless everyone was able to see the image in stereo. It is essential that anyone interested in the structures of proteins learn to view drawings of crystallographic molecular models in stereo. The drawings in this text have been placed vertically rather than in their usual horizontal orientation and each has been placed on the outside edge of a page. This has been done to allow each image to be spread as flat as possible for the best viewing.

NEWT

There are hundreds of proteins discussed in the text of *Structure in Protein Chemistry*. Each of these proteins is present in many different species of organisms, but usually the details that are being discussed are specific enough that the protein from only one of these many species is described, even though what is described would fit the protein from any one of these species. Furthermore, a particular protein from a particular species is always used in a particular experiment. The names of both the protein being discussed and the species from which it was derived are usually stated in the text. It turns out that protein chemists, because they realize that the same protein from different species of organisms is basically the same, don't really care from what species of organism the protein comes, and a remarkably large collection of species of organisms are used as sources for proteins. Usually, in a particular

investigation, one particular species is chosen as a source for a particular protein for a particular reason known only to the investigator. The practical result of these diverse choices is that the names of hundreds of species of organisms are used in this book. I have chosen to name each of them with the usual Latin names of their genus and species, without explaining what the species are because I wanted to make the point that it doesn't matter where a protein comes from. The names *Escherichia coli* and *Saccharomyces cerevisiae* and the adjectives murine, equine, bovine, canine, and human are probably already familiar to you but very few of the other names will be. Even though there is no need to know, if you would like to know to what the name of a genus and species refer, go to <http://www.ebi.ac.uk/newt/display>, and enter the name of the species.

ExPASy

Hundreds of thousands of proteins from hundreds of different species of organisms have been sequenced. The sequences of their amino acids are tabulated in large data banks. The most easily used of the data banks is the Swiss-Prot/TrEMBL at <http://www.expasy.org/>. You

should become familiar with this site on the web, not only for the sequences it makes available but also for the free programs that are available at the site to analyze those sequences.

Protein Data Bank

The Protein Data Bank at <http://betastaging.rcsb.org/pdb/Welcome.do> contains the atomic coordinates of most of the crystallographic molecular models that have been constructed. At the moment there are 36,000 separate molecular models entered in the data bank. You should look at some of the lists of the full coordinates to get a feeling for what such a file contains. Enter the name of a protein for which there is a stereo drawing in the text of this book, click on the name of one of the molecular

models that are then listed, choose "Download Files", and then choose "PDB File". The atoms are listed by the name of the amino acid, the position of that amino acid in the sequence of the protein, and their locations within that amino acid by using the abbreviations given in Figure 4.14. The list is that of the *x*, *y*, and *z* coordinates of each atom in Ångströms. Each file constitutes the raw data on which the molscript program operates.

Chapter 1

Purification

The living world that teems around us, the world of species, individual organisms, organs, tissues, and cells, can be viewed as the manifestation of a vast fluid array of protein molecules, each appearing and disappearing in the proper place at the proper time. This array of protein molecules is the outcome of a long history. Each protein within the array is itself the product of evolution by natural selection, which has had more than two billion years and much of the surface of the earth to explore, by random, irrational trial and error, strategies with which to accomplish the function of that protein. There are several consequences of this fact. First, chemical principles in addition to those of which we are aware have been discovered and exploited. Second, completely different chemical mechanisms often have been applied haphazardly to achieve similar purposes. Third, there are puzzling features that are inefficient, useless, or meaningless. Fourth, the result of this process does not resemble anything the human mind would have designed, even if it were aware of all of the available chemical strategies. One consequence of these facts is that argument by exclusion is useless because it cannot be assumed that the mechanism by which a biological problem was solved is only one or more of the mechanisms of which we can conceive.

One fruitful approach in our attempt to understand life has been to study, individually or in small groups, the proteins that produce it to gain insight into the role of each one in the overall scheme. An argument could be made that a cell does seem to be no more than the sum of its parts and that a significant understanding of how it accomplishes its purpose can be gained by studying those parts individually. Because the proteins are the parts of a cell that perform almost all of the chemical and structural transformations that occur within it, they have attracted the most attention.

The most dynamic region in a living organism is the cytoplasm of the cells or cell from which it is made. About 20–30% of the total mass of cytoplasm is protein dissolved in a solution the solvent of which is water. The cytoplasm is enclosed within a thin, fragile, continuous membrane. About 60–80% of the dry weight of this membrane is protein dissolved in a solution, the solvent of which is lipid. This membrane is surrounded and supported by a tough protective integument of polysaccharide; polysaccharide and protein; or polysaccharide, lipid, and protein. Organelles, enclosed within their own

membranes, are often scattered through the cytoplasm. In a eukaryotic cell the largest of these is the nucleus, containing most of the nucleic acid in the cell.

The strategy that has been applied most frequently to the study of proteins is to identify a particular biological feature of a living organism and then purify the protein or proteins responsible for it. Typically, when a complex, beautiful, intricately organized biological specimen, such as a tissue or a suspension of cells, is submitted to the first step in any purification procedure, it is immediately sundered beyond recognition and becomes a nondescript jumble of its organelles and broken fragments of its membranes and their integuments suspended in an aqueous solution of proteins, nucleic acids, metabolites, and salts. This event is referred to as homogenization. It is usually accompanied by the dilution of the proteins in the initial specimen by addition of a buffered aqueous solution. Following the homogenization, insoluble fragments are removed by centrifugation to produce a clear solution, the protein concentration of which is 1–10%. This solution contains most of the proteins that were once the living cytoplasm of the specimen. It is from this solution that particular proteins can be isolated. The purification of a protein is the separation of that protein from all of the others in a homogenate. A particular protein must be purified before its molecular structure can be studied.

Usually, the only interest that one has in a particular protein arises from its participation in some process of biological importance. It might be an enzyme responsible for catalyzing a particular reaction; it might be a structural protein creating the macroscopic shape of the cell; it might be a protein that binds a hormone or neurotransmitter; or it might be a protein that binds to DNA and controls its transcription. To distinguish one protein from the others in a complex mixture, an assay for the protein of interest, based on its particular function, is required.

The most widely used procedure for purifying proteins is chromatography. This technique separates molecules of protein by differences in the rate at which they move along a cylinder of a porous solid phase as a liquid phase percolates through it. If the solid phase is properly chosen, each protein travels through the cylinder at a different rate and each emerges in the solution coming out of the cylinder at a different time. In this way, one can be separated from the others. In order to distinguish the

protein of interest from the others as they emerge from the chromatographic column, the assay for that protein is used. As the protein becomes purified, the preparation displays greater and greater activity in the specific assay for a given amount of total protein.

Once the protein has been purified, analytical methods must be used to demonstrate that only one protein is the major component in the final preparation and that this protein is responsible for the biological function of interest. The analytical procedure most suited to this demonstration is electrophoresis. Electrophoresis separates proteins by both their charge and their shape, and if used with discontinuous stable boundaries, electrophoresis can have high resolution.

Once a protein of known function has been purified to homogeneity, it can be crystallized. As in organic chemistry, crystallization is a way of harvesting a particular substance in a highly purified form. Ideally, every protein that was purified would be crystallized and stored in this form, as are organic molecules. In this form, each suspension of crystals would represent a pure chemical compound. In practice, because crystals are often difficult to make and yields in crystallizations are poor, purified proteins are usually left in solution or precipitated for storage. It is these solutions, precipitates, or suspensions of crystals that are the raw material for studies of the structures and functions of the proteins they contain. The purpose of this chapter is to describe how a particular protein is purified from a complex mixture of proteins such as the homogenate of either a tissue or a suspension of cells.

Adsorption to stationary phases and chromatography are the bases for both the purification of proteins and many of the assays used to identify particular proteins, so these processes will be considered first.

Partition into Stationary Phases and Chromatography

The goal of any procedure used to purify a particular substance from a complex mixture is to separate that substance from all of the other components in the mixture. When adsorption or chromatography is used for this purpose, differences in the preferences of solutes in a solution for another phase are exploited. The simplest example of such a strategy is an affinity adsorbent. Suppose a small molecule that could be tightly bound by only one particular protein in a solution was covalently attached to a solid surface. By binding them specifically, this affinity adsorbent would collect molecules of only that one protein on its surface. The rest of the molecules of protein in the solution could be washed away, and the molecules of the desired protein could then be released. Unfortunately, such highly specific adsorbents are not usually available, so small differences in affinity among proteins or among other molecules in a solution for a

separate phase are amplified by the process of chromatography.

When a chemical substance A, which will be referred to as the solute, is added to a vessel containing two immiscible phases and the system is allowed to come to equilibrium, the solute A will distribute between the two phases in a characteristic manner. The solute can be an inorganic ion, a small organic molecule, a protein, a nucleic acid, a polysaccharide, or any other similar substance. The two phases can be, for example, two immiscible liquids, a liquid and a solid, or a gas and a liquid; the only requirement is that those two phases be brought into sufficient contact to permit the **distribution of solute A** between them to reach equilibrium and that they then be separated in some way that does not redistribute the solute. The simplest examples are a two-phase, solvent-solvent extraction or the suspension of some finely divided solid in a liquid followed by its removal from the liquid by filtration.

After the equilibration and separation of the two phases, the moles of solute A in each of them can be determined. In the cases that are generally encountered, at least one of the phases is a fluid that can be freed entirely of the other phase. This fluid will be arbitrarily called the **mobile phase**. In the special case when a protein is solute A, the mobile phase is invariably an aqueous solution of moderate ionic strength buffered at a specific pH. In any situation, however, the molar concentration of solute A in the mobile phase can be readily measured. The second phase, arbitrarily referred to as the **stationary phase**, can be an immiscible liquid, a solid, or a solid in which a liquid is entrapped. Because of the peculiarities of this stationary phase, the best way to express the concentration of solute A that has become physically associated with the stationary phase, $[A]_s$, is in moles (liter of bed)⁻¹, where the volume of the bed is the volume filled by the stationary phase when it has settled.*

Three general types of behavior¹ have been observed in such a partition (Figure 1-1). The simplest behavior, type A, occurs when the concentration of the solute A in the stationary phase increases in direct proportion to its concentration in the mobile phase. This type of behavior is encountered in solvent-solvent extractions or in chromatography by molecular exclusion. In the latter example, it results from the fact that the stationary phase is nothing more than trapped, and thereby immobilized, mobile phase. Behavior of type B (Figure 1-1) is encountered when the stationary phase saturates with solute A. It results from the presence of only a finite number of sites on the stationary phase that are all equivalent in their individual affinities for solute A

* Concentrations in moles per liter of bed are indicated by primed notation. Concentrations in moles per liter of stationary phase or moles per liter of mobile phase are in the usual unprimed notation.

Figure 1-1: Partition of a solute between two phases referred to as the stationary phase, S, and the mobile phase, M. The concentration of solute A at equilibrium in the stationary phase in units of moles (liter of bed)⁻¹, $[A]_S$, is presented as a function of its molar concentration in the mobile phase in units of moles (liter of fluid)⁻¹, $[A]_M$, for three types of behavior designated A, B, and C.

and that are distributed over the stationary phase so that they do not interact with each other at saturation. Behavior of this type is encouraged by choosing microscopically uniform stationary phases. It is advantageous because at low concentrations of solute A the partition of solute closely approximates the direct proportionality of behavior of type A. Stationary phases showing this type of behavior are highly uniform ion-exchange resins or uniform, inert matrices to which molecules of a small organic compound displaying an affinity for solute A have been randomly and sparsely attached. In more heterogeneous stationary phases, specific sites with which molecules of solute A associate are composed and distributed in such a way that they have an array of different affinities. This means that the small number of sites with high affinities for solute A are occupied first, followed by those with lower and lower affinities sequentially. This produces behavior of type C (Figure 1-1), which is unpredictable and not uniform. Examples of a stationary phase of this type are crude hydroxylapatite or a matrix to which a polyclonal immunoglobulin has been attached.

All three of these examples are to some extent idealized descriptions of actual behavior. The deviation from ideal behavior that is the most important to the present discussion, however, is that observed during the physical adsorption of molecules of protein onto the surfaces of a solid phase.² In this circumstance, although apparently ideal behavior of type B is observed at short times, the fraction of the adsorbed protein actually in equilibrium with the protein in solution decreases with time as the amount of irreversibly bound protein increases. It is believed that in such instances molecules of protein are denatured at the interface and that the interactions of these denatured molecules with the surface are much stronger than those of the undenatured

molecules. This essentially **irreversible adsorption** of protein to the surfaces of a solid phase probably occurs in any chromatographic separation and is experienced as a less than theoretical yield of the protein collected from the chromatographic system. Often this loss is inconsequential or tolerable. Because this process is a slow one,² a consequential loss of protein due to irreversible adsorption upon chromatography can be decreased by decreasing the time during which the protein is in contact with the solid phase. Such loss of protein can also be avoided by choosing a solid phase such as agarose or polyacrylamide that is less prone to producing interfacial denaturation. It also helps to use the same solid phase repeatedly because the sites at which irreversible adsorption occur become saturated over several uses. This strategy is inappropriate, however, if the sites at which irreversible adsorption occurs are the very sites upon which the desired reversible adsorption occurs, and repeated use gradually poisons the system.

The earliest use of distributions of solutes between two phases was **selective adsorption**. Selective adsorption is a technique in which conditions are sought that promote the almost complete confinement of the substance of interest to one phase while other, unwanted substances distribute into the other phase and can thus be discarded. When a protein is being isolated in this way, the ionic strength, pH, temperature, and choice of stationary phase is varied until conditions are found that permit the protein of interest to distribute almost completely into one of the two phases while the maximum amount of the other, undesired proteins distribute into the other. An example of this strategy is one of the steps in the purification of the protein fumarate hydratase.³ Calcium phosphate gel was added to a crude mixture of proteins containing fumarate hydratase dissolved in 0.1 M sodium acetate, pH 5.2. All of the fumarate hydratase (>95%) associated tightly with the calcium phosphate gel. After the gel was washed, the adsorbed fumarate hydratase was then eluted in 97% yield with 5% $(\text{NH}_4)_2\text{SO}_4$ and 0.1 M sodium phosphate, pH 7.3, even though only 20% of the original protein remained in the final solution.

Selective adsorption is a rather unsophisticated use of the distribution of a solute between a mobile and a stationary phase. It can be remarkably improved upon by operating at concentrations of solutes low enough that $[A]_S$ is directly proportional to the molar concentration of A in the mobile phase (behavior of type A) and by causing the mobile phase to move slowly through or across the stationary phase. This process is known as chromatography.

Chromatography is the process by which solutes are separated from one another on the basis of differences in the rate at which they pass across a bed of stationary phase through which a liquid mobile phase is continuously flowing. A chromatographic system is designed so that the mobile phase passes by the

stationary phase in such a way that the contact between the two phases is maximized and equilibration of the solute between them is encouraged. Examples are **paper chromatography**, in which the liquid mobile phase moves down the paper while flowing among the cellulose fibers that form the stationary phase; **thin-layer chromatography**, in which the liquid mobile phase creeps up a thin layer of the solid, dry stationary phase drawn by the capillary force arising from its movement between finely divided particles; **column chromatography**, in which the fluid mobile phase percolates through a finely divided, solid stationary phase compacted in a cylinder; and **gas-liquid chromatography**, a type of column chromatography in which a gas containing the solutes is passed through a finely divided solid phase coated with a liquid of low volatility. All of these are examples of zonal chromatography.

Zonal chromatography is chromatography in which the mixture of solutes to be separated is introduced in a thin zone at one end of the bed of stationary phase and the mobile phase is then set in motion. The molecules of solute in the mixture meander through the system, drawn forward by the movement of the mobile phase but retarded by the stationary phase in which each spends a certain fraction of its time. The fraction of the time each solute spends in the stationary phase is determined by its affinity for the stationary phase, and this is determined by its bulk distribution behavior (Figure 1-1). Since the molecules of each solute spend a different fraction of their time in the immobility of the stationary phase, each solute moves through the system at a different rate and the components of the mixture are isolated one from the other into separate zones, which are also referred to as **peaks** or **bands**. The separated solutes are collected either by dividing the stationary phase itself and extracting them, as in paper chromatography, thin-layer chromatography, or countercurrent distribution chromatography, or by continuously collecting the mobile phase as it emerges at the opposite end of the bed of the chromatographic system, as in column chromatography or gas-liquid chromatography. Any visual display of the distribution over the field of the chromatographic system of one or more of the substances being separated is referred to as a **chromatogram**.

The important properties of the chromatogram are the relative mobilities of the solutes, the widths of the peaks of the concentrations of the solutes at their half heights, and the resolution of those peaks one from the other. The **relative mobility**, $R_{f,A}$, of a particular solute A is either (1) the distance that the peak of its distribution has traveled through the system divided by the distance traveled by the mobile phase or (2) the total volume of the mobile phase in the bed of the system, referred to as the **void volume**, V_0 , divided by the total volume that has passed through the system before the peak of the distribution of solute A emerges, referred to as its **elution volume**, $V_{e,A}$. Definitions 1 and 2 are two different ways to

define the same parameter. The **width** of the distribution of solute A at **half height**, $w_{1/2,A}$, is the width, in units of distance for definition 1 or volume for definition 2, between the two points at which the concentration of solute A is half its maximum concentration at the peak. The **resolution**, R_{AB} , between two solutes is a measure of the completeness with which they are separated, a property that increases as the difference in their relative mobility increases and decreases as their widths at half height increase. The larger the differences in the various $R_{f,i}$ and the smaller the various $w_{1/2,i}$, the more successful will be the separation of the different solutes i . Expressions for $R_{f,A}$, $w_{1/2,A}$, and R_{AB} as functions of parameters that can be manipulated are of value in the understanding and design of chromatographic separations.

There are two approaches to describing the phenomenon of chromatography in theoretical terms.⁴ It can be treated as the continuous process that it is, and differential equations can be formulated to describe the differential changes in solute positions and concentrations with time. These differential equations, however, do not have simple solutions, nor do they lead to an intuitive understanding of the process. The alternative approach is based on the concept of the theoretical plate, which was developed originally to describe the separation performed by a fractional distillation column.^{5,6} Although this is a discontinuous model for a continuous process, the treatment is formulated in terms of an easily understood mechanism and does provide, in at least one case, that of countercurrent distribution chromatography, an exact solution to the problem. Martin and Synge⁷ were the first to apply this model to the process of chromatography.

Suppose that a chromatographic separation always operates at concentrations of solute A such that the amount associated with the stationary phase and the mobile phase in the chromatographic system is a linear function of its concentration in the mobile phase (behavior of type A, Figure 1-1). If so, at equilibrium

$$[A]'_S = \alpha'_A [A]'_M \quad (1-1)$$

where $[A]'_M$ is the concentration of solute A in the mobile phase in units of moles (liter of bed)⁻¹, where the **volume of the bed**, V_T , is the volume filled by the stationary and mobile phases together as they are packed into the chromatographic system; and where α'_A is a **partition coefficient**. The units for $[A]'_S$ are, as defined earlier, moles (liter of bed)⁻¹.

The bed of the chromatographic system is formally divided into a series of equivalent theoretical plates. A set of **theoretical plates** is a set of contiguous compartments of equal volume formed by a set of evenly spaced planes passing through the bed normal to the direction in which the mobile phase flows. The **height equivalent to a theoretical plate**, h , is the distance the mobile phase must

move, at the rate of normal flow, past the stationary phase until the concentration of solute in the fluid emerging from the theoretical plate is equal to the concentration the solute would have had if the fluid entering the theoretical plate had come into equilibrium with the stationary phase that fills the theoretical plate. For example, if the fluid entering the upstream boundary of the theoretical plate had a concentration of solute A equal to $[A]_{M,ent}'$ and the stationary phase already had solute A immobilized within it at a concentration of $[A]_{S,im}'$, the formal downstream boundary of the theoretical plate would occur at the point where the concentration of the solute in the mobile phase, $[A]_{M,lv}'$, had reached a value

$$[A]_{M,lv}' = \frac{[A]_{M,ent}' + [A]_{S,im}'}{1 + \alpha'_A} \quad (1-2)$$

where all concentrations are expressed in moles (liter of bed)⁻¹.

With this definition, the continuous process of zonal chromatography is equivalent to the following discontinuous sequence of events. A number of moles of solute A equal to $m_{TOT,A}$ is added to the first theoretical plate and allowed to come to equilibrium between the stationary and mobile phases. The entire mobile phase of each plate in the system is then moved to its neighbor downstream, and mobile phase containing no solute is added to the first plate. After the new situation is allowed to come to equilibrium, the same transfers of mobile phases are made. The cycle of equilibrium and transfer is repeated n times. A machine⁸ that performs **chromatography by countercurrent distribution** mechanically proceeds through this exact sequence of transfers. The theoretical plates in the countercurrent machine are individual glass vials, the mobile phases are equal volumes of an aqueous solution, the stationary phases are equal volumes of an immiscible organic solvent, and the steps of equilibration and transfer are discrete. Normally, however, this sequence of events is a theoretical simplification only formally equivalent to what actually happens.

At the conclusion of n steps, the downstream boundary of the mobile phase will have moved through the chromatographic system a distance d_M where

$$d_M = nh \quad (1-3)$$

the number of steps times the height of a theoretical plate. It can be shown^{7,9} that after n steps the mean of the distribution of solute A, and hence the peak of its distribution, will have moved a distance d_A where

$$d_A = \frac{nh}{1 + \alpha'_A} \quad (1-4)$$

while the width of its distribution at half height will be

$$w_{1/2,A} = \frac{h\sqrt{n}[\sqrt{8(\ln 2)\alpha'_A}]}{1 + \alpha'_A} \quad (1-5)$$

In thin-layer chromatography and paper chromatography, the flow of mobile phase up the thin layer or down the paper is stopped before the downstream boundary of the mobile phase reaches the end of the stationary phase. The number of steps n that have occurred is defined by the fact that the boundary has moved a distance nh from the origin at which the solutes were applied. If the relative mobility of solute A is defined as the distance solute A has moved, d_A , divided by the distance the boundary has moved, d_M , then

$$R_{f,A} = \frac{nh}{nh(1 + \alpha'_A)} = \frac{1}{1 + \alpha'_A} \quad (1-6)$$

By combining Equations 1-3, 1-5, and 1-6

$$w_{1/2,A} = \sqrt{d_M} h \left[\sqrt{8(\ln 2) R_{f,A} (1 - R_{f,A})} \right] \quad (1-7)$$

The distance that solute A has moved through a given chromatographic system, d_A , is directly proportional to the number of theoretical plates through which the mobile phase has moved (Equation 1-4), but the width of its distribution, $w_{1/2,A}$, is proportional to the square root of the number of theoretical plates through which the mobile phase has moved (Equation 1-5). As a result, as the chromatography progresses, solutes separate from each other more rapidly than they spread, and it is this property that permits chromatography to perform separations. This property can be quantified as the resolution between any two solutes.

If the resolution, R_{AB} , between the distribution of solute A and the distribution of solute B is defined as

$$R_{AB} = \frac{2|d_A - d_B|}{w_{1/2,A} + w_{1/2,B}} \quad (1-8)$$

then by assuming that h is the same for both solutes and combining Equations 1-3 through 1-5

$$R_{AB} = \sqrt{\frac{d_M}{h}} \left\{ \frac{2|\alpha'_A - \alpha'_B|}{\sqrt{8(\ln 2)} [\sqrt{\alpha'_A(1 + \alpha'_B)} + \sqrt{\alpha'_B(1 + \alpha'_A)}]} \right\} \quad (1-9)$$

Because α'_A and α'_B are fixed properties of the stationary phase, the solvent, and the solutes, this equation demon-

strates that resolution is increased either by decreasing the height of a theoretical plate or by running the chromatography over a greater distance.

In column chromatography the effluent emerging from the end of the column is collected and the concentration of solute A in this effluent is monitored as a function of the total volume that has emerged since the chromatogram was begun. If the column of stationary phase contains p theoretical plates, the effluent collected and monitored is, by definition, the mobile phase entering plate $p + 1$. As mobile phase emerges from the end of the system, the concentration of solute A that it contains increases, reaches a maximum, and then declines. This results from the approach of the peak of the distribution of solute A to plate $p + 1$, its arrival at plate $p + 1$, and its passage beyond plate $p + 1$. The volume at which the maximum passes through plate $p + 1$ is the elution volume of solute A, $V_{e,A}$. It corresponds to the volume of mobile phase that must pass through the system to bring the maximum of the distribution of solute A into plate $p + 1$. Because it takes p steps for a volume equal to the void volume V_0 to emerge from the column but the peak of the distribution of solute A will have entered only theoretical plate $p(1 + \alpha'_A)^{-1}$ after p steps, the peak of the distribution of solute A will enter plate $p + 1$ only after a volume equal to $V_0(1 + \alpha'_A)$ has passed through the system. It follows that

$$V_{e,A} = V_0(1 + \alpha'_A) \quad (1-10)$$

and

$$R_{f,A} \equiv \frac{V_0}{V_{e,A}} = \frac{1}{1 + \alpha'_A} \quad (1-11)$$

This is the fundamental equation governing column chromatography. It connects the volume at which the solute A emerges from the end of the chromatographic column with its bulk partition coefficient for the material composing the stationary phase. The relationship between the relative mobility $R_{f,A}$ and the partition coefficient α'_A is identical to that governing thin-layer chromatography and paper chromatography (Equation 1-6). This is reassuring because it is reasonable that the same process occurs in all types of chromatography. The validity of this equation was verified experimentally by Martin and Synge.⁷

The width of the peak of concentration at half height, in units of eluted volume, can be shown to be a function of the number of theoretical plates:^{4,7,10,11}

$$w_{1/2,A} = \frac{\sqrt{8(\ln 2)}}{\sqrt{p}} V_{e,A} \quad (1-12)$$

If the resolution between the distribution of solute A and the distribution of solute B is defined as

$$R_{AB} \equiv \frac{2|V_{e,A} - V_{e,B}|}{w_{1/2,A} + w_{1/2,B}} \quad (1-13)$$

then

$$R_{AB} = \frac{\sqrt{8(\ln 2)}}{\sqrt{p}} \left(\frac{2|\alpha'_A - \alpha'_B|}{2 + \alpha'_A + \alpha'_B} \right) \quad (1-14)$$

If the solvent, ionic strength, temperature, and pH of the mobile phase and the volume and chemical structure of the stationary phase remain the same so that the values of α' are unchanged, the resolution of the separation can be improved by increasing the number of theoretical plates, p , that the column contains. The most obvious way to accomplish this is to increase the length of the chromatographic column, but this can become both cumbersome and expensive.

Because the height of a theoretical plate, h , is defined as the distance of passage required for equilibrium to be reached, h decreases and p increases as the **flow rate** of the chromatographic column is decreased, at least until diffusion between the plates becomes a significant factor. In most cases, however, diffusion is severely hindered by the structure of the stationary phase itself and almost never becomes important, and the slower the flow, the better the resolution. This is particularly important in the chromatography of proteins, especially when they are unfolded, because their slow rates of diffusion significantly decrease rates of equilibration with the stationary phase.

The height of the theoretical plate decreases as the **diameter of the particles** in a solid stationary phase decreases,⁷ and it is advantageous to use particles of solid phase that are as small as possible. The small size of the particles increases the surface area available for equilibration and decreases the distances over which the solute molecules must diffuse. The realization of this fact has led to the recent development of the **high-pressure liquid chromatography** foreseen by Martin and Synge.⁷ In such systems, the high pressure is inconsequential to the process of separation but is required to force the liquid mobile phase through the small, finely divided solid particles of the stationary phase at a realistic rate. The particles themselves are spherical in shape and of uniform diameter to promote uniform flow of as rapid a rate as possible over the bed. Because the smaller particles of the solid phase decrease the height of a theoretical plate, more theoretical plates can exist in a given length of bed. This advantage can be exploited either to increase the resolution or to decrease the length of the chromatographic column or both.

Because high pressures are used to increase the rate of flow through a shorter column, the major advantage of high-pressure liquid chromatography is the **speed** with which the chromatograms can be run. For example, when peptides are separated on chromatography by cation exchange with sulfonated polystyrene,¹² at low pressure (<500 psi), the chromatography takes about 25 h; when peptides are separated by reverse-phase adsorption chromatography,¹³ at high pressure (>1000 psi), the chromatography takes only 1 h, even though the resolution in each case is about the same. With reverse-phase adsorption chromatography, the solvents used are also more transparent to ultraviolet light, so peptides can be followed simply by their absorbance with a continuous-flow spectrophotometer.

Improvements in the size, uniformity, and rigidity of the particles of the stationary phase have permitted similar increases in the rate at which chromatography of proteins can be performed. These developments are referred to commercially as fast protein liquid chromatography. In both high-pressure liquid chromatography and fast protein liquid chromatography, the principles remain the same as before, often the solid phases remain the same as before, and the technological improvements of the original techniques are based on previously noted predictions of the original theory.

The discontinuous model presented here for chromatography has been developed for regions of the partition curves (Figure 1-1) where solute A distributes with a constant partition coefficient, α'_A . It turns out that the most usual deviation from such ideal behavior is for the stationary phase to display saturation (curves B and C, Figure 1-1). The more prominent this behavior becomes, the poorer the resolution of the chromatogram becomes.⁴ As a rule, uniform stationary phases of high capacity, by promoting the linearity of the partition function, provide the highest resolution.

The fact that, unless the number of theoretical plates is increased, peak height decreases in almost inverse proportion to α'_A (Equations 1-11 and 1-12) precludes the use of conditions where the solute has a high **affinity for the stationary phase**. Usually, conditions such as solvent, temperature, ionic strength, and pH of the mobile phase and the chemical structure of the stationary phase are manipulated to bring the values of α'_A for the solutes to be separated into a useful range, usually between 1 and 10. A variation in one of these properties of the mobile phase, however, can also be incorporated into the chromatography itself.

To this point, only isocratic zonal chromatography has been described. **Isocratic zonal chromatography** is chromatography in which the mobile phase introduced continuously into the chromatographic system remains of constant composition. It is possible, however, to vary continuously and monotonically the composition of the mobile phase entering a column. This systematic variation produces a **gradient** of one or more properties of the

mobile phase. For example, the ionic strength of the entering mobile phase can be increased continuously over time so that it is a linear function of the volume introduced into the system. Mechanical devices are available to produce linear gradients or gradients that are exponential or logarithmic or some other function of the volume by mixing two or more solutions that differ in the property to be varied. When a gradient of pH is required, the situation becomes somewhat more complicated because the pH of a solution is usually controlled with a buffer. Not only is the pH a logarithmic function of the concentrations of the conjugate acid and base of the buffer, but changing the concentrations of conjugate acid and base often affects the ionic strength. There is no requirement, however, that the gradient be some particular function of a particular property; the only requirement is that the property be varied continuously and monotonically.

The method of **gradient chromatography** is an important tool because it permits the partition coefficient of solute A, α'_A , to be decreased during the chromatographic run. This often is essential because if the partition coefficient for a particular solute is too large, it emerges from the system with such a large elution volume, $V_{e,A}$, that the width of its band is unacceptably large. To produce satisfactory chromatography, the partition coefficient must be less than 10 in most situations, but frequently the values of the partition coefficient of solutes in a complicated mixture can spread over a large range for one particular mobile phase of constant composition. By using a gradient formulated so that all of the partition coefficients for the solutes decrease continuously, even those solutes with the highest affinity for the stationary phase eventually have low enough partition coefficients to emerge from the system within a reasonable time. Usually, a gradient of ionic strength, cosolvent, or pH is employed. It is constructed in such a way that the chosen property continuously changes in a direction that will cause the solutes to have smaller and smaller affinities for the stationary phase and elute earlier than they would under isocratic conditions. For example, if a solute is being adsorbed to a nonpolar stationary phase, a gradient that increases in the concentration of a miscible nonpolar solvent in water is used to decrease gradually the affinity of the solute for the stationary phase.

The stationary phase in a chromatographic system is the **chromatographic medium**. The solid matrix composing a chromatographic medium is almost always a polymer. Both natural polymers, for example, cellulose, and unnatural polymers, for example, polymers of polystyrene cross-linked with divinylbenzene, are used. The basic polymer is often cross-linked appropriately to increase its rigidity and manufactured in the form of small spherical beads of uniform size to improve flow rates. For chromatography of small molecules such as metabolites or peptides, beads of polystyrene or silica gel are used; for chromatography of proteins, cellulose or

beads of dextran, allyldextran, polyethers, agarose, or polymethacrylate are used.* Each of these intentionally inert polymeric matrices is then modified chemically. The type of modification performed determines the molecular property used by the chromatographic system to separate the solutes.

Media for **chromatography by adsorption** are solid phases with which the solutes physically associate by noncovalent forces. Certain amorphous or heterogeneous solids such as hydroxylapatite and silica gel have long been used as chromatographic media for chromatography by adsorption. Amorphous hydroxylapatite has been used extensively in protein purification. Unfortunately, it is prone to significant irreversible adsorption,² and it is heterogeneous and saturates readily, which causes it to have nonlinear distribution behavior. All of these properties limit its resolution. Although it separates nonpolar solutes successfully, silica gel has the unfortunate property of strongly adsorbing hydrogen-bonding solutes, which precludes its use with most biological substances. **Reverse-phase chromatographic media**, however, have found wide use in protein chemistry in the separation of small molecules such as peptides and metabolites. Such media are composed of spherical beads of silica gel that have been heavily alkylated with hydrocarbons of uniform length, for example, octadecyl or octyl groups. This blocks the sites of hydrogen bonding and creates an apolar surface on the beads that adsorbs apolar functional groups on the otherwise polar solutes. Such a chromatographic medium, however, shows little affinity for completely polar solutes unless a significant portion of the silica gel has lost its apolar coating.

Beaded, cross-linked dextran, agarose, or polymethacrylate are covalently modified to produce chromatographic media for the chromatography of proteins by adsorption. The functional groups that are attached to these hydrophilic matrices during the covalent modification are hydrophobic groups such as phenyl, methyl, butyl, propyl, or *tert*-butyl groups. These hydrophobic groups associate directly with hydrophobic groups on the surface of a molecule of protein that are the side chains of the amino acids valine, leucine, isoleucine, and phenylalanine.

In media for chromatography by adsorption, the affinity of the molecules of the solute for the stationary phase arises from their direct physical attachment to the molecular surface of the stationary phase. These transient associations are noncovalent in nature and can be considered as hydrophobic contacts or hydrogen bonding—designations that imply direct molecular contact

between solid phase and solute. It is this molecular contact that distinguishes chromatography by adsorption from chromatography by ion exchange.

Media for **chromatography by ion exchange** are solids formed from all of the usual neutral polymers to which charged organic functional groups have been covalently attached (Figure 1–2). **Anion-exchange media**, or basic media, are solid phases to which functional groups of positive charge at neutral pH have been covalently attached, and **cation-exchange media**, or acidic media, are solid phases to which functional groups of negative charge at neutral pH have been attached. A distinction can be made between weakly basic or acidic and strongly basic or acidic ion-exchange media based on whether the fixed charges can or cannot be neutralized, respectively, by variation of the pH within the ranges normally employed for chromatography. This is an important distinction because the density of charge, and hence the capacity of the medium, can be changed by changing the pH when weakly basic or weakly acidic ion-exchange media are used but not when strongly basic or strongly acidic ion-exchange media are used. Examples of weakly basic functional groups are tertiary amines such as those on [2-(diethylamino)ethyl]cellulose (DEAE-cellulose); examples of strongly basic functional groups are quarternary ammonium cations such as those on *N,N*-diethyl-*N*-(2-hydroxypropyl)ammonioethyl agarose (QAE agarose) or trimethylammonioethyl polymethacrylate; examples of weakly acidic functional groups are carboxylates, such as those on carboxymethyl cellulose, or phosphates, such as those on phosphocellulose; and examples of strongly acidic functional groups are sulfonates, such as those on sulfonated polystyrene (Figure 1–2) or sulfonated polymethacrylate.

The fixed charges on the stationary phase are responsible for the tendency of ionic solutes of an opposite charge to associate with it. A **counterion** is a mobile ion that is dissolved in the surrounding solution and has a charge opposite in sign to the fixed charges on the stationary phase; a **co-ion** is a mobile ion that is dissolved in the surrounding solution and has a charge of like sign to the fixed charges on the stationary phase. Solutes containing simple univalent ionic functional groups do not form physical contacts with the isolated univalent fixed charges of opposite sign that are attached to the stationary phase when chromatography by ion exchange is performed in aqueous solution. Rather, such charged solutes (for example, nucleotides, amino acids, or proteins) can be considered to be trapped as mobile counterions surrounding the covalently fixed charges in an ionic double layer.¹⁴ The two layers in an **ionic double layer** are a layer of covalently fixed charges on the surface of the polymer forming the stationary phase and a layer of solution, adjacent to that surface, that is enriched in counterions and depleted of co-ions. The molecular surface of the layer of fixed charge is considered to be the boundary between the layers of the double layer.

* The commercial forms of these beaded, cross-linked polymers each have their own uninformative names, but it is possible to learn their compositions if one is perseverant. Although one or the other chromatographic medium may have the same composition, each manufacturer claims unique benefits for his product.

Figure 1-2: Covalent modifications that produce media for ion exchange. Media derived from polystyrene and cellulose are presented.

The enrichment of counterions, which in this case are the solutes being separated, in the layer of solution results from the requirement for maintaining electroneutrality. The layer of solution contains solutes of both net positive and net negative charge but has an excess of solutes of net charge opposite to the charge of the functional groups in the layer of covalently fixed charges and is depleted in solutes of opposite charge. The layer of covalently fixed charges is usually considered to be localized in a geometric surface representing the molecular surface of the polymer, and the layer of solution enriched in the respective counterions is considered to have the properties of a space charge extending into the surrounding solvent.¹⁴

The reason that the diffuse space charge extends a significant distance into the solution beyond this boundary is that the positive and negative charges in the solution are on mobile, dissolved cations and anions, and the enthalpic tendency of the counterions to gather at the charged surface of the boundary and the tendency of the co-ions to avoid the charged surface of the boundary is counterbalanced by the entropic tendency for each of them to diffuse randomly throughout the surrounding

solution. Because the imbalance in charge that defines the ionic double layer falls off exponentially, the layer of solution in which the imbalance in charge occurs theoretically has no outer boundary. It is, however, arbitrarily assigned a thickness that is approximately that distance, from the surface of fixed charges, at which the space charge has decreased by a factor of $\exp(-1)$. Under the normal conditions of chromatography, the thickness of the layer of solution in the double layer would be less than 10 nm.¹⁴ It can be assumed that the boundary that separates the stationary phase from the mobile phase during the chromatography, namely the outside surface of the bead, lies at a much greater distance than this from the molecular surface of the charged strands of polymer within the bead because flow occurs around beads of dimensions at least a thousand times larger. Therefore, the entire ionic double layer must be within the chromatographic stationary phase.

If this assumption is made, the **distribution of counterions** between the stationary phase and the mobile phase becomes formally equivalent to the distribution of permeant counterions across a permeable membrane when a charged, impermeant macromole-

cule is present on only one side of the membrane. In the case of chromatography by ion exchange, the charged polymer of the bead is formally equivalent to the trapped, charged macromolecule. If this is the case, the sum of the fixed charges and the dissolved mobile charges of the same sign in the stationary phase must equal the sum of the dissolved mobile charges of the opposite sign in the stationary phase. It follows that the concentration within the stationary phase of any solute of charge opposite to the fixed charges must always be greater than its concentration within the mobile phase, and it is this bias that can produce significant values of α'_i . This bias can be treated by the Donnan formalism.¹⁵

Consider the situation of an anion-exchange medium of univalent fixed positive charges, N^+ [an example would be *N,N*-diethyl-*N*-(2-hydroxypropyl) aminoethyl] cellulose, Figure 1-2], and a univalent anionic solute, A^- (an example would be AMP^-), in the presence of a dissolved univalent salt, K^+Cl^- , referred to as the electrolyte. Assume that the original stationary phase was the chloride salt of N^+ and that the solute before it was added to the stationary phase was the potassium salt of A^- . All concentrations are expressed in terms of moles (liter of phase)⁻¹, hence the unprimed values. From the requirement for electroneutrality

$$[K^+]_S + [N^+]_S = [Cl^-]_S + [A^-]_S \quad (1-15)$$

$$[K^+]_M = [Cl^-]_M + [A^-]_M \quad (1-16)$$

where the subscripts refer to the stationary and mobile phases. Since the electrolytes are at equilibrium within the theoretical plate

$$[K^+]_M [Cl^-]_M = [K^+]_S [Cl^-]_S \quad (1-17)$$

$$[K^+]_M [A^-]_M = [K^+]_S [A^-]_S \quad (1-18)$$

In the particular circumstance where the concentration of solute A^- is significantly less than the concentration of Cl^- so that $[A^-]$ becomes negligible in both Equations 1-15 and 1-16 and the concentration of fixed charges in the stationary phase, $[N^+]_S$, is so large that $[K^+]_S$ in Equation 1-15 becomes negligible, then

$$\alpha_{A^-} \equiv \frac{[A^-]_S}{[A^-]_M} \equiv \frac{[N^+]_S}{[K^+]_M} \quad (1-19)$$

where α_{A^-} is defined somewhat differently from the partition coefficient described so far. Instead of units of concentration in moles (liter of bed)⁻¹, the units of

concentration are moles (liter of stationary phase)⁻¹ and moles (liter of mobile phase)⁻¹.

Equation 1-19 predicts that the partition coefficient, α_{A^-} , for solute A should be inversely proportional to the concentration of K^+ in the mobile phase. Because the internal volumes of the stationary phases in chromatography by ion exchange are fairly small and the capacities of most media are large even in terms of equivalents (liter of bed)⁻¹, the situation in which $[K^+]_S = [N^+]_S$ is probably rarely approached, and Equation 1-19 should govern most concentrations of salt employed. The effect of adding a univalent salt to the mobile phase is to decrease the value of the partition coefficient for the anion A^- between the cationic stationary phase and the aqueous mobile phase. In this way, the value of α_{A^-} can be adjusted by varying the concentration of electrolyte to optimize an isocratic separation, or a gradient of the electrolyte can be used to vary α_{A^-} continuously. If the concentration of electrolyte is low, α_{A^-} will be large and the mobility of A^- will be negligible. Therefore, a charged solute can be gathered tightly at the origin of the chromatographic system from a large volume of a dilute solution at low ionic strength, and chromatography can then be initiated by increasing the concentration of the electrolyte.

In a weakly basic or acidic ion-exchange medium, the **titration of the charges** that occurs upon adding acid or base, respectively, occurs over a broad range of pH because of electrostatic repulsion among the fixed cations or anions. This permits the density of charge on the medium ($[N^+]_S$ or $[O^-]_S$) to be continuously decreased by incorporating a gradient of pH into the entering mobile phase. For example, if the stationary phase has fixed, protonated tertiary ammonium cations, a gradient of increasing pH would decrease $[R_3NH^+]_S$ as it progresses. The decrease in the density of charge ($[N^+]_S$ or $[O^-]_S$) produces a decrease in α_{A^-} or α_{A^+} (Equation 1-19), causing the solutes to emerge sooner than they would under isocratic conditions. When the solutes themselves are weak acids or bases, however, their ionization may also vary as the gradient of pH progresses, but in the opposite sense to the stationary phase; their effective charge will be increasing as the gradient progresses.

There is no question that Equation 1-19, although intuitively informative, does not describe real ion-exchange processes. At face value it predicts that α_{A^-} should be a function only of the charge density on the stationary phase and the concentration of electrolyte, and this is often not the case. Even simple solutes upon ion exchange display affinities for the supporting polymeric matrix or the functional groups on the fixed charges that sometimes differ greatly from this expectation. The reason for these deviations is almost certainly due to the fact that solutes, brought to high concentration within the double layer by ion exchange, adsorb physically to these constituents, and as a result chromatography by adsorption is superimposed upon the basic process of chromatography by ion exchange. The

clearest example of this is found in the separation of amino acids on sulfonated polystyrene (Figure 1-3).^{16,17} Even though the solutes in the series alanine, valine, leucine, and phenylalanine have almost identical acid dissociation constants, and hence ionic charge, they are cleanly separated. There is little doubt that the separation observed in this series is due to chromatography by adsorption performed by the styrene-divinylbenzene copolymer of the matrix.¹⁶ An ion-exchange medium can also participate in adsorbing simple cations or anions by chelation, such as occurs in the binding of alkali metal cations to polygalacturonic acid.¹⁸

A molecule of protein is a macromolecular poly-electrolyte, the effective charge of which is a function of

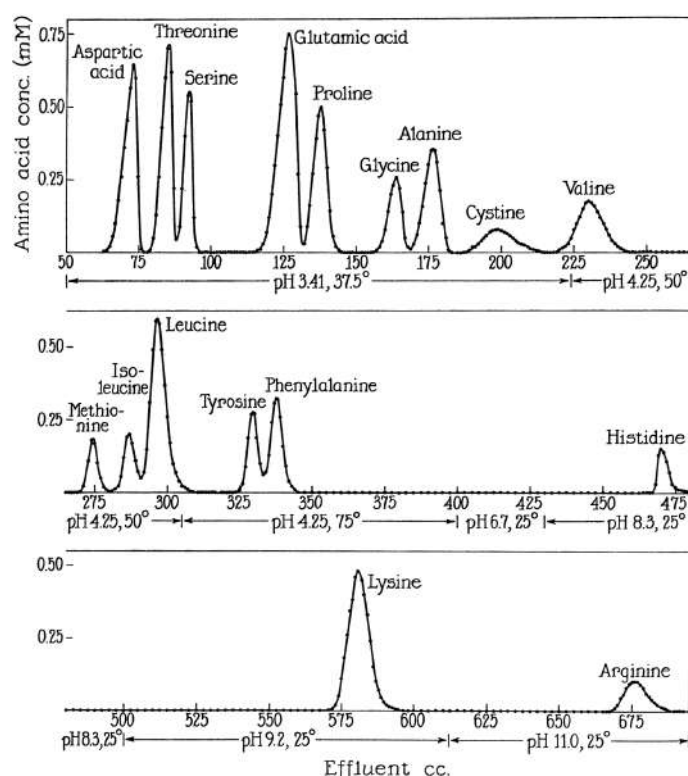

Figure 1-3: Separation of amino acids on chromatography by cation exchange.¹⁶ A mixture of amino acids in the ratios typical of those found in a protein was submitted to chromatography on a column (0.90 cm × 100 cm) of sulfonated polystyrene (Figure 1-2) in the sodium form. The values of the pH and temperatures of the buffered mobile phases are noted below the horizontal axes, which register the volume of the mobile phase that has passed through the column (in centimeters³) since initiation of the chromatography. Changes from one mobile phase to the next were made discontinuously at the times noted. Individual fractions of the effluent emerging from the bottom of the column were collected and assayed for their concentration of amino acid (millimolar). The relative mobility, R_f , of each amino acid in the initial isocratic separation at pH 3.41 would be the void volume of the column divided by the volume at which its peak of concentration emerged from the column. The width at half height, $w_{1/2}$, of each peak is its width in milliliters at a level of concentration half that of the concentration at its peak. Reprinted with permission from ref 16. Copyright 1951 *Journal of Biological Chemistry*.

pH and varies over a wide range. If the pH is changed, the partition coefficients of proteins upon ion exchange vary, and gradients of pH as well as gradients of ionic strength are used in their chromatography. In the case of poly-electrolytes of this type, interactions between the solute and the stationary phase may also lead to direct adsorption. Although simple univalent ions when they are at normal concentrations almost certainly do not physically associate with each other in aqueous solution, poly-electrolytes of opposite charge, such as proteins and ion-exchange media, sometimes do. This results from a **cooperative association** of the opposite charges on the two polymers that arises from the fact that the charges on the ion-exchange medium are covalently fixed and those of the opposite sign on the protein are also covalently fixed. It is always possible that there is a population of sites on the ion-exchange medium where the distribution of charge complements the distribution of charge on the protein, a possibility that will produce physical adsorption. This, however, is probably a rare phenomenon; most of the time the molecules of protein are simply trapped inside the ion-exchange medium as mobile counterions in the ionic double layer.

Media for **chromatography by molecular exclusion*** separate molecules on the basis of differences in their size and shape. The beaded solids used as stationary phases are tangled webs of hydrophilic, linear polymers—dextran, agarose, polyacrylamide, polyether, or polymethacrylate—cross-linked among themselves randomly along their length. These matrices can be produced in two ways. First, polysaccharides such as agarose and dextran spontaneously imbibe water and swell when the dry solid is exposed to an aqueous solution. The degree to which the linear polymers are cross-linked among themselves determines how much water they will imbibe at saturation. This is designated as their water regain, W_r , in milliliters (gram of polysaccharide)⁻¹. This in turn determines the fraction of the volume of the stationary phase occupied by solid polymer, f_{poly} :

$$f_{\text{poly}} = \frac{V_{\text{poly}}}{V_{\text{H}_2\text{O}} + V_{\text{poly}}} = \frac{\bar{v}_{\text{poly}}}{W_r + \bar{v}_{\text{poly}}} \quad (1-20)$$

where V_{poly} is the volume occupied by polysaccharide, $V_{\text{H}_2\text{O}}$ is the volume occupied by water, and \bar{v}_{poly} is the partial specific volume of the polysaccharide in milliliters gram⁻¹. Second, polyacrylamide does not swell readily but can be polymerized from acrylamide monomers and a small amount of the cross-linker N,N' -methylenebis(acrylamide), both dissolved at a certain concentration in an aqueous solution. This produces a rigid gel that can be fragmented. The majority of

* This method is also called size exclusion, gel filtration, and gel permeation.

the volume inside the beads of any of these stationary phases for chromatography by molecular exclusion is occupied by water. When water is within the tangled web of the bead, however, it is no longer mobile but stationary. The mobile phase percolates around the beads and flow occurs only in the interstices among the beads. The void volume, V_0 , is the volume of this space outside of the beads.

The larger the molecule of solute, the less of the open space inside the beads of the stationary phase is available to it. If solute A is too large, it cannot enter the beads at all, and its peak emerges from the system at the void volume, V_0 . Therefore, the elution position on the chromatogram of the completely excluded molecules marks the position of V_0 . A small molecule (in theory, water itself or something equivalent to it) can enter the entire open space in each bead, and its elution position marks V_i , the **included volume**. Unlike with most other chromatographic separations, there is an end to a molecular exclusion chromatogram because no solute can see a larger volume than V_i . The only useful separation that occurs in such a system is of those solutes that emerge between V_0 and V_i , because all solutes larger than a certain size travel together at V_0 and all solutes smaller than a certain size travel together at V_i (Figure 1–4). Between V_0 and V_i on the chromatogram, the larger solutes are the first to emerge.

Because the fluid contained within the beads is identical in composition to the mobile phase percolating around the beads and because a polymer that theoretically has no affinity for the solutes being separated has been chosen, the partition coefficient for solute A, α'_A , between stationary and mobile phases is the ratio of the volume within the stationary phase that solute A can

Figure 1–4: Chromatography by molecular exclusion. As in Figure 1–3, the concentration of solute in the fluid emerging from the chromatographic system is plotted as a function of the volume that has emerged. All molecules larger than a certain size move at the void volume, V_0 ; all molecules below a certain size travel at the included volume, V_i ; and solutes A and B travel at their elution volumes, $V_{e,A}$ and $V_{e,B}$, respectively, and are separated from each other because a molecule of solute A is larger than a molecule of solute B.

enter, which is its elution volume minus the void volume, divided by the volume of the mobile phase within the bed, which is, by definition, the void volume V_0 . Parameters other than the partition coefficient, however, are usually used to define the behavior of a solute on chromatography by molecular exclusion. If V_T is the total volume of the bed of the chromatographic system, then the volume of the bed occupied by the stationary phase is $V_0 - V_T$. The fraction of the volume of the stationary phase that is available to solute A is designated $K_{av,A}$:

$$K_{av,A} \equiv \frac{V_{e,A} - V_0}{V_T - V_0} = \frac{\alpha'_A}{\frac{V_T}{V_0} - 1} \quad (1-21)$$

Another parameter is often used to describe the elution during chromatography by molecular exclusion. This is the fraction of the volume within the stationary phase available to a small reference solute, solute R, that is also available to solute A, and it is designated $K_{D,A}$ so that

$$K_{D,A} \equiv \frac{V_{e,A} - V_0}{V_{e,R} - V_0} \quad (1-22)$$

where $V_{e,R}$ is the volume at which solute R elutes. If the reference solute were able to enter the entire aqueous phase within the stationary phase, V_i , then $V_{e,R}$ would be equal to V_i and $K_{D,A}$ would equal $K_{av}(1 - f_{poly})^{-1}$. The difficulty with this definition is that it depends on the identity of the reference solute.

Problem 1–1: Assume that the total volume of mobile phase in the column described in Figure 1–3 is 45 cm³. Calculate α'_i for aspartic acid, threonine, glutamic acid, proline, glycine, alanine, and valine. Calculate the number of theoretical plates in the column used for the separation shown in Figure 1–3 from the peaks for threonine, serine, proline, glycine, alanine, and valine.

Problem 1–2: List the following amino acids in order of their elution from a column of sulfonated polystyrene.

homoserine

Assay

Homogenization of a biological specimen produces a complex mixture of proteins. Before any one of these proteins can be purified, there must be a way to identify it; an assay serves this purpose. An **assay** is any connection between a specific biological phenomenon and a solution containing the protein responsible for this phenomenon. During a purification, separations of high resolution are performed that produce large numbers of separate samples, and the need to locate the protein of interest within these separated fractions requires that they be individually assayed (see points in Figure 1–3). This fact puts a premium on the speed and efficiency of the assay used.

One of the most common types of assay is one that monitors a **chemical reaction catalyzed by an enzyme**. One of the phenomena that occurs in living organisms is the conversion of fumarate to malate

catalyzed by the enzyme fumarate hydratase.*

When the homogenate from a porcine heart, which contains fumarate hydratase, is added to a solution of fumarate, which is otherwise quite stable, the fumarate begins to disappear and malate appears.³ Because fumarate has significant absorbance at 300 nm (A_{300}), the

decrease in A_{300} with time can be followed to assay the enzyme.

The goal of any assay is to produce a signal that is directly **proportional to the molar concentration** of the particular protein being assayed. A necessary and sufficient condition for this to be the case is that the quantity measured, for example, the rate of decrease in A_{300} in the first few minutes, be directly proportional to the amount of sample added. This proportionality must be demonstrated directly by examining the magnitude of the signal used in the assay as a function of the amount of sample added.^{19–21} The range over which this direct proportionality between the measurement and the added sample occurs must be known. Because the assay should always be performed within this range, it must be fairly broad to avoid the problem of having to assay every sample at a series of different dilutions to find the range. It is also helpful if the quantity measured, such as A_{300} in the case of fumarate hydratase, changes as a linear function of time within the interval chosen to monitor the reaction.

The rate at which an enzyme converts a reactant into a product usually changes as the **pH** of the solution changes. It is always a good idea to measure the enzymatic activity as a function of the pH of the solution to find the pH at which the rate of the reaction is at its maximum and then use that pH in the routine assay.²²

A **coenzyme** is a molecule that is not a protein but nevertheless must be added to the assay of an enzyme for the reaction it catalyzes to occur. Because the coenzyme is not converted during the enzymatic reaction into a product, it is not a reactant. Coenzymes are used by proteins to provide chemical capabilities that cannot be provided by the side chains of its amino acids alone. Examples of coenzymes are pyridoxal phosphate, thiamin pyrophosphate, flavin adenine dinucleotide, biotin, lipoic acid, heme, chlorophyll, and ubiquinone. If an enzyme catalyzes a reaction requiring a coenzyme, that coenzyme usually must be added to the assay. Often the nature of the reaction is such that the coenzyme required is obvious. For example, most enzymes that catalyze transaminations require pyridoxal phosphate. Often, however, the requirement for a coenzyme is not obvious.

2-Hydroxyphytanoyl-CoA lyase catalyzes the reaction

The enzymatic activity could be readily assayed in the homogenate from a rat liver but disappeared as the purification proceeded. It was found that if thiamin pyrophosphate was added to the assays, however, the activity did not disappear.²³ This result demonstrates that thiamin pyrophosphate is a coenzyme for 2-hydroxyphytanoyl-CoA lyase. There was enough of it in the initial homogenate to satisfy the enzyme, but it was lost as the purification proceeded. It might have been argued that

* In this section and in the rest of the book, enzymes are named according to the recommendations of the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (us.expasy.org/enzyme/).

this coenzymatic requirement should have been expected because the enzyme catalyzes a cleavage immediately adjacent to an acyl carbon, but such arguments are usually after the fact. Often the requirement for a coenzyme is not obvious and is both difficult and frustrating to discover.

It also often happens that, as with a coenzyme, a **metallic cation**, such as Mg^{2+} , Ca^{2+} , Zn^{2+} , Cu^{2+} , Fe^{2+} , or K^+ , is required by a protein to perform its function and must be added to the assay. Although there are often obvious choices, such as Mg^{2+} for enzymes having phosphoesters as reactants, the requirement for a particular metal is often unpredicted.

The most unambiguous assay of the reaction catalyzed by an enzyme is one in which the reactants and products are **chromatographically separated** after the reaction and the quantities of each are determined. The introduction of rapid, automated, high-pressure liquid chromatographic systems with associated monitoring systems of high sensitivity has made this approach convenient and efficient. If **radioactive reactants** are available that can be turned into radioactive products, reactants and products from a large number of assays can be separated in arrays of simple, inexpensive chromatographic systems and their respective quantities can be determined by scintillation counting.

Examples of assays in which reactants and products are chromatographically separated have been used for the purifications of the proteins geranyltransferase, cyclosporin synthase, methylamine-glutamate *N*-methyltransferase, and lysine *N*-methyltransferase. Geranyltransferase catalyzes the reaction

A sample of protein to be assayed for this enzymatic activity can be mixed with geranyl diphosphate and $[1\text{-}^{14}\text{C}]\text{isopentenyl diphosphate}$ and incubated for a set time. The reaction can then be terminated by adding alkaline phosphatase to hydrolyze rapidly the various diphosphates. After extraction, the resulting $[1\text{-}^{14}\text{C}]\text{farnesol}$ and $[1\text{-}^{14}\text{C}]\text{isopentenol}$ in each sample can be separated on small plates by thin-layer chromatography and separately quantified.²⁴ That the product was entirely the expected (*E,E*) isomer of $[1\text{-}^{14}\text{C}]\text{farnesol}$ was demonstrated by gas-liquid chromatography.

Cyclosporin synthase catalyzes the reaction

If the reaction is run with *S*-adenosyl[*methyl*- ^{14}C]methionine, the $[^{14}\text{C}]\text{cyclosporin}$ produced can be isolated, after extraction, by thin-layer chromatography.²⁵

Methylamine-glutamate *N*-methyltransferase catalyzes the reaction

The $[^{14}\text{C}]\text{methylammonium cation}$ and the $[^{14}\text{C}]\text{methyl-L-glutamate}$ can be separated by isocratic chromatography by cation exchange.²⁶ L-Lysine, *N*^ε-methyl-L-lysine, and *N*^ε,*N*^ε-dimethyl-L-lysine are converted in the presence of *S*-adenosyl[*methyl*- ^3H]methionine into mixtures of *N*^ε-[^3H]methyl-L-lysine, *N*^ε,*N*^ε-[^3H]dimethyl-L-lysine, and *N*^ε,*N*^ε,*N*^ε-[^3H]trimethyl-L-lysine by lysine *N*-methyltransferase. After removal of unreacted *S*-adenosyl[*methyl*- ^3H]methionine with activated charcoal, the three radioactive products can be separated by thin-layer chromatography and quantified individually.²⁷

As in the previous example, where unreacted *S*-adenosyl[*methyl*- ^3H]methionine was removed by adsorption to activated charcoal, the chemical transformation performed by an enzyme often produces a product that can be exclusively **transferred to a separable phase**. For example, tryptophan-tRNA ligase catalyzes the reaction

The L- $[^{14}\text{C}]\text{tryptophan-tRNA}^{\text{Trp}}$ can be isolated from the assay solution as a precipitate, free of L- $[^{14}\text{C}]\text{tryptophan}$, by treatment with acid and filtration through filters of glass fiber.²⁸ The $[^{14}\text{C}]\text{CO}_2$ released from L- $[1\text{-}^{14}\text{C}]\text{glutamate}$ by glutamate decarboxylase²⁹ or from 4-hydroxyphenyl[$1\text{-}^{14}\text{C}]\text{pyruvate}$ by 4-hydroxyphenylpyruvate dioxygenase³⁰ can be released as a gas from the assay solutions by treatment with acid and collected in a separate well containing a strong base. The enzyme encoded by the *murG* gene of *Escherichia coli* catalyzes the addition of the *N*-acetylglucosamine from UDP-*N*-acetylglucosamine to the 4' position of the muramoyl group in 1'-*O*-β-[3(*R*)-3,7-dimethylhept-6-enyl]-1'-diphospho-2'-*N*-acetylmuramoyl-L-alanyl-D-γ-glutamyl-6-carboxy-L-lysyl-D-alanyl-D-alanine. A derivative of the heptenyldiphospho-*N*-acetylmuramoyl pentapeptide to which a molecule of biotin has been covalently attached can be used in an assay for this enzyme³¹ along with UDP-*N*- $[^{14}\text{C}]\text{acetylglucosamine}$. The resulting biotinylated β(1,4)-*N*- $[^{14}\text{C}]\text{acetylglucosaminylheptenyldiphospho-}N\text{-acetylmuramoyl pentapeptide}$ can be separated cleanly and quantitatively from the remaining UDP-*N*- $[^{14}\text{C}]\text{acetylglucosamine}$ by adsorbing it to a solid phase on which has been attached covalently the protein

avidin, which binds the biotin in the product with high affinity.

A special case of assays that depend on transferring a product or a reactant to a separate phase are those used to monitor the binding of a small molecule to a protein. Certain proteins, known loosely as **receptors**, often do not catalyze a chemical reaction but respond to specific small molecules, referred to as **agonists**, by binding them and then undergoing a change in structure. Receptors are assayed by their ability to bind either these agonists or similar molecules that also bind but do not elicit the response, referred to as **antagonists**. In such **binding assays**, the receptor and a suitable radioactive agonist or antagonist are mixed together, the binding is allowed to come to equilibrium, and the receptor–agonist or receptor–antagonist complex is separated from unbound agonist or antagonist, respectively. Because receptors are usually proteins dissolved in membranes, the separation of bound from unbound ligand often takes advantage of the large size of the fragments of membrane produced by homogenization, which can be separated from the rest of the solution by filtration or centrifugation. After the separation, the amount of bound radioactivity is then determined by scintillation counting.

Chemically stable agonists or antagonists of high affinity for a receptor are required to ensure that the binding is at saturation so that all receptors are counted and to prevent dissociation of receptor and agonist or receptor and antagonist during the separation of bound and free radioactivity. These reagents are often produced by the synthesis of analogues of the natural compounds. For example, [^3H]dihydroalprenolol is a radioactive synthetic compound that binds tightly (dissociation constant = 2 nM)³² to the β -adrenergic receptor, which physiologically responds to epinephrine. Its binding has been used as an assay during the purification of this receptor.³³ Often a synthetic compound the binding of which to a receptor is strong has been obtained during a search for pharmaceutically useful agents. An example of this kind of product is prazosin, which was developed as a drug specific for α_1 -adrenergic receptors and the binding of which (dissociation constant = 1 nM) could be used as an assay during the purification of the α_1 -adrenergic receptor.³⁴ Often the naturally occurring agonist has an affinity great enough that it can be used in an assay during the purification of the receptor. For this purpose, it is synthesized in a radioactive form. Examples would be the use of the binding of ^{125}I -epidermal growth factor³⁵ (dissociation constant = 20 nM) and the binding of [$1,2\text{-}^3\text{H}_2$]progesterone³⁶ (dissociation constant = 1 nM) as assays for their receptors.

In all binding assays for receptors, the difficulty is to separate the complex between the receptor and the agonist from the unbound agonist without losing the bound agonist through the dissociation of the complex. It is often possible to sediment the complex in a preparative ultracentrifuge.³⁷ This strategy is particularly useful for

weakly bound agonists that dissociate rapidly after the unbound agonist is removed, because during sedimentation the concentration of unbound agonist does not change so the amount of bound agonist does not either. The small amount of unbound agonist in the pellet can be estimated and a correction made to obtain an accurate measurement of the bound agonist. With agonists and antagonists that bind tightly, the complex can be separated rapidly with little loss of bound radioactivity on rapid chromatography by molecular exclusion on small, disposable columns.³⁸

Binding assays have also been developed for proteins that associate with specific nucleotide sequences in DNA,³⁹ such as promoters or other regulatory elements. A short fragment of DNA labeled with [^{32}P]phosphate at one end and containing the sequence of interest is used as a reagent. When such a fragment is digested with deoxyribonuclease I and the products are then separated by electrophoresis, a characteristic pattern of shorter segments of DNA of various lengths is obtained as a result of random cleavage by the nuclease of the phosphodiester bonds along the double-stranded DNA. The presence of a protein that binds specifically to a particular nucleotide sequence in a short fragment of end-labeled DNA results in prevention of cleavage of the DNA by the nuclease at that site. The fragments resulting from cleavages in this region disappear from the display, and this **footprint** demonstrates that the **DNA-binding protein** is present. Such an assay can be used to determine the relative concentration of the DNA-binding protein by examining the patterns produced as a series of dilutions is performed in the solution of the protein added to the end-labeled DNA.

An enzyme that catalyzes a physical or chemical transformation of DNA can often be assayed by separating the product of the transformation from the reactant by electrophoresis. Deoxyribonucleic acid primase/helicase from T7 bacteriophage catalyzes the unwinding of double-stranded DNA. Double-stranded DNA, one of the strands of which has been labeled with [^{32}P]phosphate at its 5' end, is mixed with a sample of protein to be assayed for this activity, and after a few seconds the reaction is quenched with dodecyl sulfate. The ^{32}P -labeled single-stranded DNA produced by the unwinding can be separated from the ^{32}P -labeled double-stranded DNA by electrophoresis.⁴⁰

Up to this point, with the exception of that for fumarate hydratase, the assays described have been discontinuous ones. The reaction is allowed to proceed for a certain interval, it is quenched in some way, and the amount of product formed is then measured, usually by dissecting the final, quenched solution. Because less manipulation is required and because the result is immediate, **continuous assays** in which the product of the live enzyme is monitored as it is formed are more convenient. As in the assay for fumarate hydratase, the continuous **change in absorbance** of a reactant or

product is often followed. The reaction catalyzed by 2-methyleneglutarate mutase

can be assayed⁴¹ by monitoring the change in absorbance of the solution if the 2-methylene-3-methylsuccinate is converted immediately as it is produced into 2,3-dimethylmaleate with the enzyme methylitaconate Δ -isomerase. 2,3-Dimethylmaleate absorbs most strongly at 230 nm, but in the assay for the enzyme, absorbance changes between 240 and 256 nm were monitored in order to avoid interference from the absorbance of nucleic acids and protein in the samples.

Because the enzymatic activity in the initial homogenate and at early steps in the purification of a protein is usually quite low, large amounts of these heterogeneous mixtures of protein and nucleic acid often must be added to the assay and their intrinsic absorbance can be appreciable. This problem precludes the use of absorbance changes at wavelengths below 240 nm for continuous assays based on absorbance because all proteins absorb too strongly in this range. A crude mixture of protein and nucleic acid also has a significant and rather uniform absorbance between 240 and 290 nm so the change in absorbance being monitored in the assay must be great enough to overcome this **interference**, as it is in the assay for 2-methyleneglutarate mutase (between $\Delta\epsilon_{240} = 3700 \text{ M}^{-1} \text{ cm}^{-1}$ and $\Delta\epsilon_{256} = 660 \text{ M}^{-1} \text{ cm}^{-1}$ for the production of 2,3-dimethylmaleate).⁴¹

In any type of enzymatic assay, the proteins and nucleic acids in the early, crude mixtures can interfere in other, unexpected ways with many otherwise useful assays. In particular, contaminating proteins may catalyze the transformation of either the reactants or the products of the enzyme being assayed. The reaction catalyzed by protocatechuate 3,4-dioxygenase

could be followed by the increase in A_{290} as the reaction proceeded.⁴² In crude homogenates, however, the 3-carboxy-*cis,cis*-muconate was converted by a contaminating enzyme into 3-carboxy-*cis,cis*-muconolactone, and absorbances had to be corrected for this further transformation until the contaminating enzyme had been lost at an intermediate step in the purification.

Even though an enzyme normally produces a product the absorbance of which is no different from that of the reactant, it is sometimes possible to design a **synthetic reactant** in such a way that its absorbance does change upon its conversion in a continuous assay. Medium-chain acyl-CoA dehydrogenase catalyzes the reaction

involving no change in absorbance. If synthetic 4-thiaoctanoyl-SCoA is used as a reactant instead of octanoyl-SCoA, the 4-thia-*trans*-2-octenoyl-SCoA produced, because it is a vinylthioether, absorbs strongly at 312 nm ($\epsilon_{312} = 22,000 \text{ M}^{-1} \text{ cm}^{-1}$).⁴³

Enzymes that operate at **lipid-water interfaces** are often difficult to monitor with a continuous assay because of the requirement that lipid and water be present together, which can lead to cloudy suspensions that interfere with spectrometry. Triacylglycerol lipase catalyzes the reaction

Both the triacylglycerol and the diacylglycerol are fats or oils. If the triacylglycerol is presented to the enzyme on the surface of a droplet of oil in an oil drop tensiometer, the change in surface tension of the droplet resulting from the hydrolysis of the triacylglycerol can be monitored continuously.⁴⁴ It is also possible, however, to produce a clear emulsion of water-filled micelles suspended in an organic solvent. If the lipase is incorporated into the aqueous phase of these "reverse" micelles and the triacylglycerol is dissolved in the organic solvent, the shift in the wavelength of the absorbance of the C=O stretch from 1751 to 1715 cm^{-1} occurring upon hydrolysis of the triacylglycerol at the interface between water and oil can be monitored in an infrared spectrophotometer.⁴⁵ Infrared spectrometry is useful in this instance because it is much less affected by light scattering than is visible or ultraviolet spectrometry.

In the assay for 2-methyleneglutarate mutase (Equation 1-29), the 2-methylene-3-methylsuccinate is converted immediately and continuously upon its production into 2,3-dimethylmaleate by another enzyme, methylitaconate Δ -isomerase, that has been added intentionally to the solution. This is an example of a coupled continuous assay. A **coupled assay** is an assay in which one or more purified enzymes, usually commercially available, and any reactants required by those additional enzymes are added to transform the immediate product of the enzyme of interest by a subsequent enzymatic reaction or reactions that produce a change in absorbance or fluorescence, the rate of which is directly proportional to the rate at which the product is produced. The other enzymes and their reactants must be added at high enough concentrations that the complete transformation of the initial product is effectively immediate, and the initial product is converted continuously as it is formed. Another example of a coupled assay is that used to follow the ATPase reaction

catalyzed by myosin subfragment 1.⁴⁶ Both the reactant 2-amino-6-mercapto-7-methylpurine ribonucleoside and the enzyme purine-nucleoside phosphorylase are added to the solution in addition to MgATP and the ATPase. The inorganic phosphate produced is immediately and continuously used by the phosphorylase to cleave the purine ribonucleoside to ribose-1-phosphate and 2-amino-6-mercapto-7-methylpurine that, unlike the ribonucleoside, absorbs strongly at 360 nm ($\Delta\epsilon_{360} = 11,000 \text{ M}^{-1} \text{ cm}^{-1}$). This coupled continuous assay is useful for monitoring any one of the many enzymes that have **inorganic phosphate** as one of their products.

Of all of the changes of absorbance that are employed in continuous enzymatic assays, none is more heavily used than the decrease in A_{340} of **dihydronicotinamide adenine dinucleotide** (NADH; $\epsilon_{340} = 6220 \text{ M}^{-1} \text{ cm}^{-1}$)⁴⁷ or its phosphate (NADPH; $\epsilon_{340} = 6100 \text{ M}^{-1} \text{ cm}^{-1}$), when it is oxidized to nicotinamide adenine dinucleotide (NAD^+) or to its phosphate (NADP^+), respectively, or the increase in A_{340} that occurs in the reverse reaction. There is a large class of enzymes, known as **dehydrogenases**, that use the oxidation–reduction pairs of either NAD^+ and NADH or NADP^+ and NADPH, and they can be assayed directly and continuously. For example, 3-hydroxyacyl-CoA dehydrogenase catalyzes the reaction

The loss of NADH can be followed at 340 nm.⁴⁸ To insure that only 3-hydroxyacyl-CoA dehydrogenase is being assayed, a control in the absence of S-acetoacetylpanthetheine is run.

In the opposite sense, the increase in A_{340} can be used to follow the reaction catalyzed by glyceraldehyde-3-phosphate dehydrogenase (phosphorylating):⁴⁹

The absorbance change produced by a particular dehydrogenase can also be used in a coupled, continuous assay to monitor enzymatically catalyzed reactions that do not involve NADH. Examples of such coupled assays have been used for the purifications of pyruvate carboxylase, phosphomevalonate kinase, and imidazoleglycerol-phosphate dehydratase. The oxaloacetate produced by pyruvate carboxylase

can be monitored by adding NADH and excess malate dehydrogenase:⁵⁰

Phosphomevalonate kinase catalyzes the reaction

The MgADP can be monitored continuously as it is produced by adding phosphoenolpyruvate, NADH, and an excess of both pyruvate kinase and L-lactate dehydrogenase:⁵¹

This coupled assay is widely used for enzymes that produce **MgADP**.

The 3-(imidazol-4-yl)-2-oxopropyl phosphate produced by imidazoleglycerol-phosphate dehydratase

during its assay⁵² is consumed as it is produced by histidinol-phosphate transaminase:

The unfavorable equilibrium of Reaction 1–42 is pulled in the direction written by the exergonic hydrolysis catalyzed by histidinol-phosphatase

The 2-oxoglutarate produced by the transaminase (Equation 1–42) is converted back to L-glutamate by glutamate dehydrogenase:

to produce the decrease in A_{340} . Similar coupled assays are used to monitor other transaminases.

One of the more subtle uses of a coupled assay based on the A_{340} of NADH is the one devised⁵³ for hydroxymethylglutaryl-CoA lyase:

This coupled assay takes advantage of the fact that the equilibrium of the malate dehydrogenase reaction (Equation 1-37) lies in the direction of NAD^+ and (S)-malate so that if NAD^+ , malate, and malate dehydrogenase are mixed together, little oxaloacetate and NADH are formed. With this in mind, it can be seen that if (S)-malate, NAD^+ , and excesses of citrate (*si*) synthase and malate dehydrogenase are present during the progress of the reaction catalyzed by hydroxymethylglutaryl-CoA lyase, the conversion of the acetyl-CoA into citrate by citrate (*si*) synthase

consumes oxaloacetate and pulls the unfavorable equilibrium of the malate dehydrogenase reaction in the direction of NADH production, and hence an increase in the A_{340} of the solution is observed.

The two or more enzymatic steps in a coupled assay are sometimes disconnected rather than allowed to proceed simultaneously. An example would be an assay⁵⁴ for ribose-phosphate diphosphokinase:

The reaction is quenched by boiling, and the amount of 5-phospho- α -D-ribose 1-diphosphate that has accumulated is determined by adding orotate, orotate phosphoribosyltransferase, and orotidine-5'-phosphate decarboxylase:

The decrease in A_{295} due to the loss of orotate is proportional to the 5-phospho- α -D-ribose 1-diphosphate originally present in the quenched samples. The decarboxylation has been incorporated in the assay to draw the reactions to completion.

Colorimetric assays are assays in which a reagent is added that reacts chemically rather than enzymatically with a product of the enzymatic reaction being monitored to produce a change in absorbance, often observed visually as a dramatic change in the color of the solution. Monophenol monooxygenase catalyzes the reaction

When 3-methyl-2-benzothiazolinonehydrazone has been added to the solution of the assay,²¹ the L-dopaquinone reacts rapidly and quantitatively with it to produce a dark pink color ($\epsilon = 29,000 \text{ M}^{-1} \text{ cm}^{-1}$), the appearance of which can be monitored continuously. As is medium-chain acyl-CoA dehydrogenase (Equation 1-31), (S)-pantolactone dehydrogenase, which catalyzes the oxidation

is a member of a large class of enzymes that catalyze oxidation-reduction reactions and then transfer the electrons involved either to or from small proteins or natural compounds the role of which is to receive or provide electrons. These natural donors or acceptors can often be replaced by synthetic donors or acceptors. (S)-Pantolactone dehydrogenase accepts phenazine methosulfate as an oxidant in place of the acceptor it uses naturally, and reduced phenazine methosulfate readily oxidizes nitrotetrazolium blue. When both of these compounds are present in the assay, the appearance of diformazan, which is the product of the oxidation of nitrotetrazolium blue, can be followed by its strong absorbance ($\epsilon_{570} = 40,200 \text{ M}^{-1} \text{ cm}^{-1}$).⁵⁵ It is possible to monitor the production of coenzyme A by citrate (*si*) synthase (Equation 1-46) continuously⁵⁶ by the addition of 5,5'-dithiobis(2-nitrobenzoate). This reagent reacts with the thiol of the coenzyme A as it is formed to release the bright yellow 2-nitro-5-thiolatobenzoate dianion. This assay is useful for monitoring any enzyme that produces **coenzyme A**.

The colorimetric assays described so far are continuous assays in which the chemistry of the colorimetric reagent is compatible with the aqueous solution and neutral pH required to avoid denaturation and inactivation of the protein being assayed. This is usually not the case with colorimetric reagents. In the instances in which it is not, the assay must be **quenched** after a convenient interval before the colorimetry is performed. 2-Hydroxy-6-ketono-2,4-diene-1,9-dioic acid 5,6-hydrolase produces succinate as one of its two products. The production of succinate is coupled in the assay²² to the reaction catalyzed by succinate-CoA ligase (ADP-forming):

After 15 min, the solution is heated to 100 °C to quench the enzymatic reaction and the inorganic phosphate is

assayed by its reaction with Malachite green in the presence of citrate, which produces strong absorbance at 600 nm. Phosphate produced during an enzymatic reaction can also be determined colorimetrically by the addition of ammonium molybdate in dilute sulfuric acid and a strong reductant, which together produce a blue color proportional in magnitude to the phosphate present.⁵⁷ Glutamine–pyruvate transaminase will also catalyze the reaction

The glycine produced and the L-glutamine remaining will react with *o*-phthalaldehyde and a thiol, after the enzymatic conversion has been terminated, to produce complexes that absorb in the near ultraviolet.⁵⁸ The glycine complex, however, absorbs at a higher wavelength ($\lambda_{\text{max}} = 330 \text{ nm}$). Galactonate dehydratase catalyzes the reaction

After the reaction is quenched, the ketonic product is reacted with semicarbazide⁵⁹ to produce a semicarbazone that absorbs at 250 nm.⁵⁹ Selenocysteine lyase catalyzes the reaction

where RSH is a mercaptan such as 2-mercaptoethanol. After the enzymatic reaction is stopped, the H_2Se can be assayed colorimetrically by its reaction with lead acetate, a reaction that yields a yellow color.⁶⁰

Biological assays are assays in which the ability to evoke a complex biological response by samples added to cells or whole organisms is determined. For example, the assay for a protein referred to as the Hurler corrective factor measures the ability of this protein to prevent the accumulation of sulfated mucopolysaccharide in lysosomes of intact cells. It is this accumulation that causes Hurler's syndrome. Samples are added to a series of petri dishes on which fibroblasts from a patient with Hurler's syndrome have been grown and $^{35}\text{S}]\text{SO}_4$ is added. After several days, the accumulation of ^{35}S -sulfated mucopolysaccharide is assessed by washing the cells and submitting them to scintillation counting.⁶¹ In this particular assay, the decrease in accumulation of radioactivity was not directly proportional to the amount of sample added, and this problem was overcome by constructing a dose–response curve.

A biological assay was also used for the maturation-promoting factor, which is a protein involved in controlling the cell cycle.⁶² Samples containing this protein could be assayed for its activity by injecting sequentially

diluted aliquots into individual oocytes from the frog *Xenopus laevis* and scoring the cells for the disappearance of geminal vesicles.⁶³ With the use of this assay, the protein could be followed during a purification procedure⁶³ and the remarkable fluctuation of its concentration during the cell cycle could be documented.⁶²

The success of a particular assay is usually judged on the bases of its accuracy, sensitivity, and selectivity. For following the distribution of a protein during its purification, the accuracy of an assay is not critical—all that is needed is a way to decide whether or not it is present in a particular fraction—but for kinetic studies of the reaction catalyzed by an enzyme, accuracy is often critical.⁶⁴ If only small amounts of a protein are present, the sensitivity of an assay is also often critical.⁶⁵ It is usually to increase the sensitivity of an assay that radioactive reactants are used so that the small amounts of product produced or ligand bound can be identified. Fluorescence is often used for the same purpose. For example, continuous assays monitoring the absorbance of NADH can detect its production at $10 \text{ nmol min}^{-1} \text{ mL}^{-1}$ but those monitoring its fluorescence can detect its production at $0.1 \text{ nmol min}^{-1} \text{ mL}^{-1}$. When following the increase in a particular product produced from a particular reactant or the binding of a particular ligand, an assay is usually selective for a particular protein, but sufficient selectivity is often difficult to achieve. It was only when agonists and antagonists of high affinity and high selectivity were synthesized that the various receptors for epinephrine could be separately identified and purified. A suspension of cellular membranes displays a rather high level of adenosine triphosphatase activity arising from a number of different proteins. It was only when that portion of this activity for which sodium/potassium-exchanging ATPase was responsible could be clearly distinguished⁶⁶ that it became possible to purify the enzyme.⁶⁷

Purification of a Protein

The **homogenization** of a biological specimen produces a clarified solution of protein and nucleic acid. Animal tissues can be diced, blended, and then processed with a homogenizer to produce a turbid suspension that is then clarified by centrifugation. Plant tissues, because their cells are surrounded by strong cell walls, must be homogenized more forcefully.⁶⁸ If the protein of interest is located in one of the organelles within a plant or animal cell, that organelle is often isolated from the homogenate and then separately fragmented. For example, a protein required for the activation of transcription was purified from an extract of nuclei that had been isolated from a homogenate of HeLa cells,⁶⁹ and 2-hydroxyphytanoyl-CoA lyase was purified from sonicated peroxisomes that had been isolated from a homogenate of rat liver.²³ Bacteria, because they are small, single cells surrounded by a tough integument, are particularly difficult to homogenize. Sonication or passage through a French pressure cell is usually required.

If the source that has been chosen is a plant or an animal, different organs and different species are scanned with the assay to find a source in which the particular protein is present at the highest relative concentration. If the source is a bacterium, various strategies are employed to increase the concentration of the protein of interest. For example, the *Xanthobacter* from which cyclohexane monooxygenase was purified were grown on cyclohexane as the sole carbon source because this enzyme is one of those in the pathway that catabolizes cyclohexane.⁷⁰

The goal of the **purification** of a protein from the clear solution produced by centrifugation of a homogenate is to isolate that protein, whose presence and relative molar concentration can be followed by a specific assay, from all of the other proteins present. To do this, advantage is taken of the properties that distinguish a molecule of one protein from a molecule of another. Proteins are macromolecules of molar mass 10,000–10,000,000 g mol⁻¹. Unless the molecules of a protein have been posttranslationally modified hetero-

geneously by processes such as glycosylation, phosphorylation, endopeptidolytic digestion, or acetylation, each molecule of a given protein has the same covalent structure, the same distribution of polar and nonpolar functional groups over its surface, and the same shape as every other molecule of the same protein. Different proteins are distinguished from each other by differences in these properties.

A molecule of protein can be a **globular macromolecule**, the shape of which resembles a hollow metal sphere that has been dented at random, or it can be a **fibrous macromolecule**, the shape of which is elongated, often dramatically, in one dimension, irregular, and either rigid or flexible. The diameters of globular proteins vary from 2 to 10 nm; the lengths of fibrous proteins can be as great as 300 nm. Positively and negatively charged functional groups are distributed in a characteristic array over the surface of each molecule of a particular protein. In addition to guanidinium ions from the arginines, these charged functional groups are carboxylate ions from the glutamates and aspartates, ammonium ions from the lysines, and imidazolium cations from the histidines, each of which can be neutralized by lowering or raising the pH. As a result, the net charge on a molecule of protein varies with the pH and can be negative or positive within normal physiological ranges. Patches of nonpolar functional groups are distributed in a characteristic array over the surface of each molecule of protein. The affinity of these patches for nonpolar solid phases can be exploited to separate molecules of one protein from those of another. Chromatography is used to separate molecules of protein by differences in their size, their shape, their charge as a function of pH, and the unique distribution of polar and nonpolar groups on their surfaces.

The strategy for the purification of a protein is tailored to the particular problems faced in each instance. Usually it includes a series of steps, each involving a fractionation of the solution by chromatography or adsorption. Each step produces a series of fractions, from two to several hundred, each contained in a volume of aqueous solution. Those fractions containing the protein of interest are identified by the assay, they are pooled together, and the protein in the pool is submitted to the next step of fractionation. The three requirements for the successful purification of a protein are an assay for the protein, the ability to minimize or prevent the loss of the protein through endopeptidolytic degradation or denaturation, and a source of the protein of sufficient abundance.

The progress of the purification of a protein is usually evaluated by examination of both the total activity recovered, which is a measure of the yield of the particular protein being purified at each step, and the specific activity, which is a measure of the enrichment of the protein of interest relative to the other proteins present (Table 1-1). The assay provides a numerical value for the amount of biological activity in a milliliter of the solution

Table 1–1: Purification of Aryl-acylamidase from *Nocardia globerule*⁷¹

purification step	total protein (mg)	total activity ($\mu\text{mol min}^{-1}$)	specific activity ($\mu\text{mol min}^{-1} \text{mg}^{-1}$)	yield of activity (%)	enrichment (x -fold)

being assayed. For an enzymatic assay, this value is the number of micromoles of reactant that would be converted to product every minute if one milliliter of the solution had been added to the assay. The **total activity** present after any step in the purification is the activity milliliter^{–1} multiplied by the total number of milliliters in the pool of fractions. The **yield of activity** is the percentage of the initial total activity remaining after each step. Although the yield of activity usually decreases as the purification proceeds, sometimes it increases, for example if an inhibitor of the activity is removed during a step.⁷²

The **concentration of protein**, in units of milligrams milliliter^{–1}, in the pool of fractions is also assayed. The most accurate method for making this determination⁷³ is quantitative amino acid analysis (Figure 1–3), but this procedure is too tedious and time-consuming for routine assays. The Biuret colorimetric assay⁷⁴ is the most accurate rapid method, but its low sensitivity often requires that an unreasonable portion of a precious sample be sacrificed. The Lowry⁷⁵ colorimetric method, because of its sensitivity, is the most widely used method for determining the concentration of protein in a sample, but it suffers from the drawbacks that many solutes other than protein also produce color and that different proteins give different yields of color. For example, it was shown that the concentration of protein in samples of purified hydrogenase I from *Clostridium pasteurianum*, which had been accurately quantified by quantitative amino acid analysis, was overestimated by the Lowry procedure by a factor of 1.37 ± 0.03 .⁷⁶ The least quantitative but most convenient and rapid methods for assessing the concentration of protein are the colorimetric method of Bradford⁷⁷ and the absorbance of the solution at 280 nm. The **specific activity** of a pool of fractions from a step in the procedure for purifying the protein is the amount of biological activity displayed by a milligram of the proteins in that solution—the activity milliliter^{–1} divided by the amount of protein milliliter^{–1}. For an enzyme, the units of specific activity are (micromoles

of reactant converted) minute^{–1} (milligram of protein)^{–1}. The **enrichment** in the protein of interest during a particular series of steps is the increase in its specific activity relative to its initial specific activity in the homogenate.

There is a **conventional order** in which the various steps of the purification are carried out. This order is usually determined by the amount of material a certain procedure can accommodate, because the amounts that must be processed, if the samples have been concentrated after each step, always decrease as the purification proceeds because of the decrease in the total amount of protein. Precipitations can be carried out on large volumes and are usually the first step in a purification. If appropriate, selective adsorption is used in the next step because it is an efficient method for handling large samples and the media are usually inexpensive. Chromatography by ion exchange is usually used before chromatography by adsorption because the media used for the former are usually less expensive and have higher capacity. Chromatography by molecular exclusion is usually used as a late step because it is most successful when the samples, and hence the amount of protein, are as small as possible.

The purification of aryl-acylamidase

from *Nocardia globerule* (Table 1–1) illustrates this systematic strategy. In each step of the purification the specific enzymatic activity increases as extraneous proteins are separated from the desired protein, and the yield of enzymatic activity after each step is high. Nevertheless, because there are so many steps, the overall yield is only 8%, but an 8% yield is high for the purification of a protein. In this example, chromatography by molecular exclusion on Superose is used in the last step when total amounts of protein are small so that the samples can be concentrated to the small volumes required by this pro-

cedure. Chromatography by anion exchange (DEAE-Sephacel), however, can be used early in the purification because large volumes at low concentration of electrolyte can be passed through the ion-exchange medium to concentrate the protein on the top of the column. The chromatography itself is then initiated by increasing the concentration of electrolyte.

The **precipitation of proteins** from an aqueous solution that is effected by the addition of a high concentration of another solute has a long history. Originally, such precipitations were observed upon the addition of certain salts to solutions of proteins. This observation led to the terms **salting out**, to describe a precipitation caused by a salt, and **salting in**, to describe the dissolution of a precipitate caused by a salt. For example, sulfate ion salts out, and thiocyanate ion and guanidinium ion salt in. A systematic study of the effect of salts on the solubility of proteins led to the **Hofmeister series**,⁷⁸⁻⁸⁰ an ordering of various ions on the basis of their ability to salt out or salt in.* Similar effects, however, are observed with nonionic solutes as well, somewhat confounding the words chosen. Urea salts in, and poly(ethylene glycol) salts out.

It has been shown that these capacities of solutes, both ionic and nonionic, to affect the solubility of a protein can be ascribed to differences in **preferential solvation**.⁸³⁻⁸⁵ The preferential solvation of a particular protein by a particular solute can be defined by the equation

$$\text{preferential solvation} \equiv \frac{\left(\frac{\partial m_s}{\partial m_p} \right)_{T, \mu_{H_2O}, \mu_s}}{\gamma_s} \quad (1-57)$$

where m_s is the grams of that solute in the solution for every gram of water, m_p is grams of that protein in the solution for every gram of water, γ_s is the concentration of the solute in the solution in grams milliliter⁻¹, T is the temperature, and μ_{H_2O} and μ_s indicate that both the chemical potential of the water and the chemical potential of the solute must remain constant as the grams of protein, ∂m_p , change. Solutes that display negative values of preferential solvation salt out and solutes that display positive values of preferential solvation salt in, and the magnitude of their values of preferential solvation correlates with the potency of their ability to salt out or salt in.

A negative value for preferential solvation, indicating salting out, states that grams of solute, ∂m_s , must be

removed from the solution whenever grams of anhydrous protein, ∂m_p , are added to maintain constant chemical potential. The usual reason⁸³ given for the observation of negative preferential solvation is that, in an aqueous solution, the layer of water surrounding the protein has properties distinct from those of the rest of the water in the solution and a salting-out solute is preferentially excluded from that layer of solvation. The reason grams of solute must be removed to maintain a constant chemical potential is that water is removed from the bulk solution to form this layer of hydration and solute must be removed from the overall solution to keep its concentration the same in the bulk solution surrounding the hydrated protein.

A positive value for the preferential solvation of a particular solute states that the grams of that solute in the solution must be increased when the grams of protein are increased in order to maintain constant chemical potential. Therefore, the solute prefers to interact with the protein rather than with water; for example, it has a higher solubility in the layer of water around the protein or it simply binds to the protein. Positive preferential solvations mean that the protein becomes more soluble as the solute is added to the solution. Such salting-in is displayed by urea, potassium thiocyanate, and guanidinium chloride. At concentrations of 1 M, the value of the preferential solvation of bovine serum albumin by potassium thiocyanate⁸³ is +0.07 mL g⁻¹ and that of bovine serum albumin by guanidinium chloride⁸⁴ is +0.26 mL g⁻¹. The ability of urea to increase the solubility of proteins is frequently used during their purification. For example, the proteins that form intermediate filaments, which are naturally occurring, insoluble polymeric aggregates of protein, are purified from the solution that is obtained by dissolving the filaments in 7 M urea.⁸⁶ The advantage of using urea is that because it is a neutral molecule, it has no effect on chromatography by ion exchange.

It is for precipitation, however, that preferential solvation is usually exploited during purification of a protein. Assume that a solution is at saturation in the concentration of a particular protein; in other words, the chemical potential of that protein in the saturated solution is equal to the chemical potential of that protein in its precipitate. If a solute with negative value of preferential solvation is added to the saturated solution of protein, some of the protein must precipitate to maintain a constant chemical potential. In reality, what happens is that as more and more of the solute is added, the chemical potential of the protein decreases until it equals that of its precipitate and then it begins to precipitate. The more negative the value of preferential solvation for the solute being added, the more rapidly does the concentration of protein reach and then surpass saturation. At 1 M concentration, the value for the preferential solvation of bovine serum albumin by sodium sulfate⁸³ is -0.52 mL g⁻¹. As a comparison, the preferential solvation

* The effects of salts on many properties of proteins, such as their enzymatic activity⁸¹ and their specific associations with each other,⁸² are often governed by the Hofmeister series.⁸⁰

of bovine serum albumin by NaCl, a salt that shows weak salting-out, is -0.26 mL g^{-1} at a concentration of 1 M. Although sodium sulfate has been used to precipitate proteins during purifications, ammonium sulfate is preferred because it is more soluble than sodium sulfate and it is also lethal to fungi or bacteria that would otherwise be happy to use the precipitated protein as a source of food. A protein as a precipitate in a concentrated solution of ammonium sulfate at 4°C is usually stable for decades. Traditionally, the concentration of ammonium sulfate used to precipitate a protein is expressed as the percentage that the final concentration in the solution is of the concentration of ammonium sulfate at saturation (0.52 g mL^{-1} at 4°C).

Ammonium sulfate at high concentrations causes most proteins to precipitate from solution. In the example of aryl-acylamidase (Table 1–1), the enzyme was precipitated between 25% and 60% ammonium sulfate. No purification was observed in this instance; the step was used to concentrate the protein and rapidly remove it from all of the other metabolites in the clarified homogenate. Usually, however, an attempt is made to obtain some purification. Each protein precipitates in a given range of ammonium sulfate concentration. Extraneous proteins that precipitate at lower concentrations can be removed first, and then the protein being purified can be precipitated by raising the concentration of ammonium sulfate and thus be separated from proteins that remain soluble at the higher concentration. For example, formate–tetrahydrofolate ligase was purified 10-fold by bringing the solution of ammonium sulfate to 50% of saturation to precipitate other proteins, then increasing the concentration of ammonium sulfate to 70% of saturation to precipitate the synthase while leaving yet other proteins in the supernatant.⁶⁸ Purification by ammonium sulfate precipitation is usually not so large as in this example, but the procedure is a mild one, usually of high yield. Precipitation with ammonium sulfate can be used to concentrate rapidly and gently a solution of protein between later steps in a purification (Table 1–1).

Poly(ethylene glycol) has also been used to precipitate proteins selectively and reversibly. It is easy to imagine why a large hydrophilic polymer such as poly(ethylene glycol) would be excluded from the layer of water surrounding a protein and thus have a negative value for preferential solvation. Tryptophan 5-mono-oxygenase can be purified 5-fold after precipitation with poly(ethylene glycol) and redissolution in aqueous buffer.⁸⁷ **Trimethylamine oxide**, a naturally occurring solute in the serum of fish,⁸⁸ is also able to precipitate proteins.⁸⁹

Several other types of precipitation are used during the purification of a protein. At the pH at which a given protein bears no net charge, known as its isoelectric pH, it is least soluble in water. If the pH is adjusted to this value and the salts in the solution are removed by

dialysis, the protein will often precipitate, while other proteins, which have different isoelectric points, do not. Such an **isoelectric precipitation** has been used in the purification of aspartate carbamoyltransferase⁹⁰ and in the purification of fibrinogen.⁹¹ One traditional method of concentrating protein and removing it from other molecules in a homogenate is to precipitate it by adding acetone.⁹² The resulting dry **acetone powder** can be extracted with a buffered aqueous solution, and if one is lucky, the protein of interest will dissolve. Because their DNA is not contained in nuclei, when bacterial cells are fragmented by homogenization, the DNA is released as an intractable, gelatinous mass. Before the solution can be processed further, the DNA must be precipitated with **streptomycin sulfate**⁹³ or the DNA must be hydrolyzed to small fragments that are not gelatinous by adding nucleases to the solution.

Isoelectric precipitation and precipitations with poly(ethylene glycol) and ammonium sulfate are reversible, and the protein is readily redissolved by decreasing the concentration of precipitant or changing the pH. In contrast, precipitation by acid or heat is usually not reversible. In these situations advantage is taken of the ability of the protein of interest to remain in solution while other proteins precipitate irreversibly. An example of the use of **precipitation with heat** occurs in the purification of 6-phosphofructokinase, and during this step a 2.5-fold increase in specific activity was recorded.⁹⁴ These techniques are quite harsh and can lead to degradation of the protein being purified by endopeptidases or to chemical alterations such as deamidation of glutamine and asparagine side chains⁹⁵ even though little loss of enzymatic activity is recorded.

Proteins are separated chromatographically by exploiting differences among them in particular properties. Different proteins have different sizes and shapes and can be separated on chromatography by molecular exclusion. Different proteins also have different charges at a given pH and can be separated on **chromatography by ion exchange**. In the case of chromatography by ion exchange, a pH is chosen at which the protein to be purified has a net charge opposite to the fixed charge on the chromatographic medium so that it will participate in ion exchange with the stationary phase as the chromatography progresses. The elution of bound protein is usually performed with a gradient of increasing concentration of a simple monovalent salt such as KCl. If a gradient of pH is used, the change in pH is usually in the direction that would decrease the magnitude of the net charge on the protein. Because the value of α' is changing continuously, the use of a gradient always produces chromatographic separations of much lower resolution than those performed isocratically without a gradient. The advantage of a gradient, however, is that it bypasses the problem of finding conditions of pH and ionic strength at which the value of α' for the protein being purified is in a usable range. Because molecules of pro-

tein are multivalent ions, their values of α' change rapidly as the ionic strength is varied, and such a search is often tedious and fruitless.

Glyceraldehyde-3-phosphate dehydrogenase (GDH), phosphoglycerate mutase (PGM), and phosphoglycerate kinase (PGK) in the ammonium sulfate precipitate from a clarified homogenate could be separated on **chromatography by molecular exclusion** (Figure 1–5A).⁹⁶

Each of the three enzymes migrates with a characteristic elution volume, V_e , and the glyceraldehyde-3-phosphate dehydrogenase is cleanly separated from the other two enzymes by molecular exclusion chromatography on a column of Sephadex G-150. The fractions containing the activities of phosphoglycerate mutase and phosphoglycerate kinase were combined and submitted directly to ion-exchange chromatography on DEAE-cellulose devel-

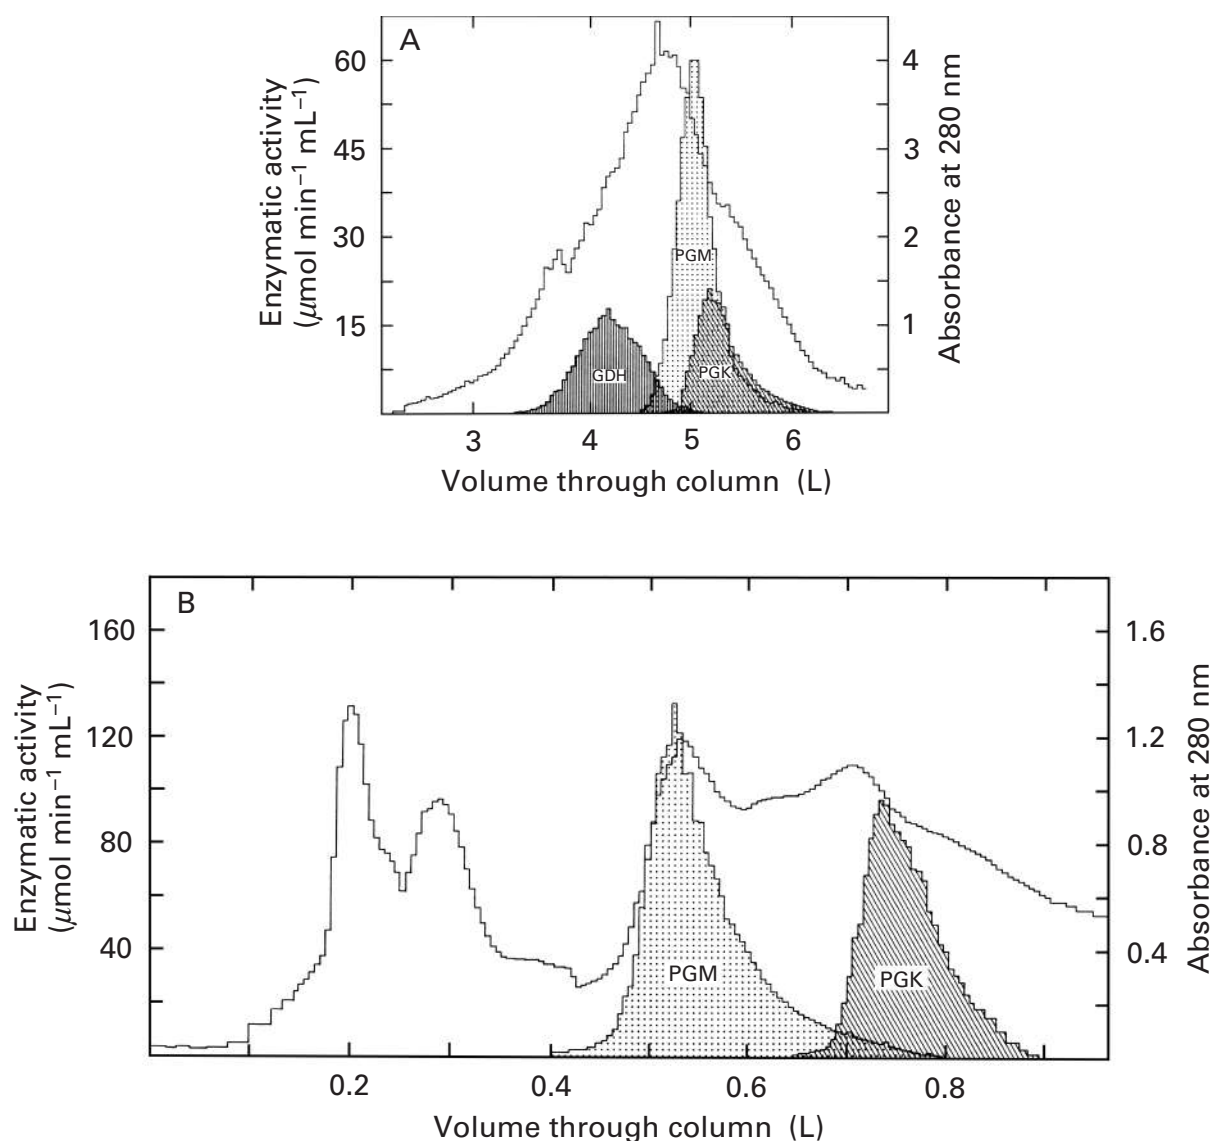

Figure 1–5: Chromatography by molecular exclusion (A) and chromatography by anion exchange (B) of proteins in a homogenate from the bacterium *E. coli*.⁹⁶ The clarified homogenate was submitted to precipitation with ammonium sulfate (30–45%). The precipitate (7.2 g of protein) was redissolved in a minimum volume (120 mL) of aqueous buffer and submitted to zonal chromatography on a column (10 cm \times 120 cm) of cross-linked dextran (Sephadex G-150). (A) Fractions were assayed for protein (absorbance at 280 nm) and enzymatic activity (micromoles minute⁻¹ milliliter⁻¹) of glyceraldehyde-3-phosphate dehydrogenase (GDH), phosphoglycerate mutase (PGM), and phosphoglycerate kinase (PGK), respectively. The proteins contained in the fractions from 4.9 to 5.8 L in the chromatogram in panel A were combined and submitted to chromatography by anion exchange. (B) The ionic strength of the buffer used for the chromatography by molecular exclusion was low enough that the sample (900 mL) could be passed directly through the column (2.2 cm \times 25 cm) of diethylaminoethyl- (DEAE-) cellulose while the proteins gathered at the top of the medium for ion exchange. Chromatography was then initiated with a gradient of NaCl (0–0.15 M in the same buffer at pH 8). Fractions were again assayed for protein and enzymatic activity. Reprinted with permission from ref 96. Copyright 1971 *Journal of Biological Chemistry*.

oped with a gradient of sodium chloride (Figure 1-5B). In this step the phosphoglycerate mutase was cleanly separated from the phosphoglycerate kinase. These examples illustrate the use of column chromatography, monitored by enzymatic assay, to separate proteins.

An example of the use of a sequence of steps of column chromatography to purify a particular protein is found in the purification of α -ketoisocaproate oxygenase from rat liver (Figure 1-6).⁹⁷ Aside from an initial ammonium sulfate precipitation, only three consecutive steps, chromatography by ion exchange (Figure 1-6A), chromatography by adsorption (Figure 1-6B), and chromatography by molecular exclusion (Figure 1-6C), were necessary to purify the enzyme to homogeneity.

Because the resolution of chromatography by ion exchange run with a gradient and the resolution of chromatography by molecular exclusion are not great (Figures 1-5 and 1-6), the increase in specific activity seen in each of the chromatographic steps is usually around 5-fold. Extreme examples of purification, such as the 100-fold purification of 3-deoxy-7-phosphoheptulonate synthase on phosphocellulose⁹⁸ or the 100-fold purification of methylcrotonyl-CoA carboxylase on DEAE-cellulose,⁹⁹ are rare. For reasons that are not obvious, however, it has recently been discovered that the magnitude of the purification on chromatography by adsorption is often significantly greater than that

observed on chromatography by ion exchange or molecular exclusion.

Traditionally, hydroxylapatite, because of its physical properties, has been used mainly for selective adsorption of proteins, but recently much more effective, beaded forms of hydroxylapatite that can be used for chromatography by adsorption have become available. Nitric-oxide reductase could be purified 100-fold by chromatography on one of these media,¹⁰⁰ and acetyl-CoA hydrolase, 60-fold.¹⁰¹ The media most widely used, however, for **chromatography by adsorption** (Table 1-2) are produced by synthetically coupling defined organic functional groups or molecules or chelated metal ions¹⁰⁵ to beaded hydrophilic matrices, usually cross-linked agarose or polymethacrylate. Although the intention in the syntheses in which organic molecules are covalently attached to the polymer has often been to produce a chromatographic medium with a specific affinity for one particular protein or class of proteins, most of these products have turned out to be simple adsorption media with useful and unexpected affinities for proteins in general.¹⁰⁶ Ironically, this makes them more valuable than they were originally intended to be.

Successful purification of a minor component from a complex mixture requires that the set of distribution coefficients, α'_i , for the components present assume a new and randomly permuted sequence of magnitudes as each new chromatographic medium is used. If it were possible to do so, a series of chromatographic steps would be designed so that all of the components that had similar values of α'_i in the preceding step, and that were not separated, have different values of α'_i in the next step and are separated. The availability of a collection of microscopically uniform adsorption media with peculiar and unexpected affinities for proteins in general assists in this strategy. The purification achieved on these media is often dramatic (Table 1-2). There are two methods, how-

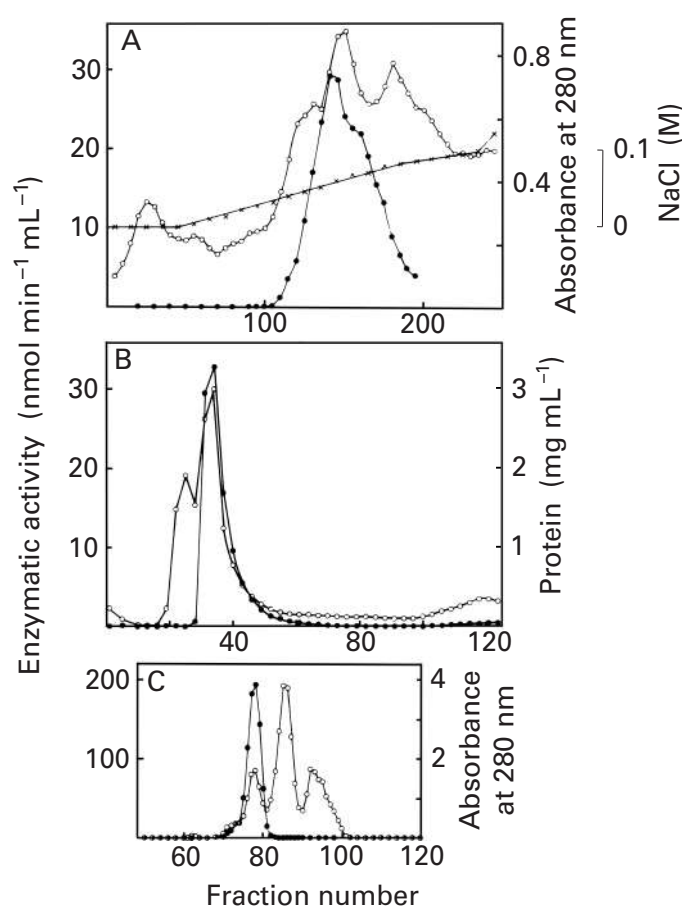

Figure 1-6: Column chromatography of α -ketoisocaproate oxygenase from rat liver.⁹⁷ An ammonium sulfate (45–75%) precipitate (35 g of protein) of the clarified homogenate was redissolved, dialyzed to remove salt, and applied to a column (5 cm \times 80 cm) of DEAE-cellulose (A). The chromatogram was developed with a gradient of NaCl (\times) from 0 to 0.1 M. Fractions containing enzymatic activity (4 g of protein) were pooled, concentrated, brought to 2.5 M NaCl, and applied to a column (4 cm \times 40 cm) of cross-linked agarose to which phenyl groups had been covalently attached. The proteins were eluted with a gradient between 2.5 M NaCl and buffer without added NaCl (B). The fractions containing enzymatic activity (500 mg of protein) were pooled, concentrated, and applied to a column (5 cm \times 80 cm) of allyldextran cross-linked with *N,N'*-methylenebis(acrylamide) for chromatography by molecular exclusion (C). In each panel, α -ketoisocaproate oxygenase activity (nanomoles of CO_2 released minute⁻¹ milliliter⁻¹; \times) is presented as a function of fraction number. The total protein in each fraction (\circ) was also monitored by absorbance at 280 nm. The final yield was 70 mg of protein in the peak of enzymatic activity. Reprinted with permission from ref 97. ^aIn all cases cited, cross-linked agarose (Figure 1–7) was used as the polymeric support to which the organic molecules were covalently attached. ^bIn ether linkage to agarose. ^cThese solutes are detergents. ^dAffinity elution. ^eEnrichment during each step.

ever, that do not rely on chromatography and that often produce even greater degrees of purification. They are based on the selective elution from or selective adsorption to a stationary phase and can be referred to as affinity elution or affinity adsorption, respectively.

When a protein is purified by **affinity elution**, it is first adsorbed to a stationary phase, such as a chromatographic medium; and after all unabsorbed proteins have been washed away, a compound that binds with high specificity to the protein of interest and leads to its elution is added (as for example in the second step of the purification of isocitrate dehydrogenase, Table 1–2). The presence of this compound can sometimes cause only that protein to which it binds to elute from the stationary phase. For example, when (carboxymethyl)cellulose is added to a crude, clarified homogenate from liver at pH 6, all of the fructose 1,6-bisphosphatase is adsorbed along with many other proteins. When the (carboxymethyl)cellulose is collected, washed well with 5 mM sodium malonate, pH 6, and then rinsed with 0.06 mM fructose 1,6-bisphosphate in 5 mM sodium malonate, pH 6, only the fructose 1,6-bisphosphatase elutes in the rinse. In one step the enzyme can be purified 400-fold, to homogeneity.¹⁰⁷ Transketolase, after initial purification by DEAE-cellulose from homogenates of human leukocytes, will adsorb tightly to the top of a small column (16 mL) of (carboxymethyl)cellulose when a dilute solution (90 mL) of the protein dissolved at low ionic strength is passed over the column. After the column has been washed extensively, the transketolase is eluted with buffer to which xylulose 5-phosphate (0.2 mM) and ribose 5-phosphate (0.3 mM) have been added. The transketolase is purified 40-fold to homogeneity.¹⁰⁸ Protein kinase N, bound to a methylenesulfonate cation-exchange medium, can be eluted specifically with ATP (0.1 mM) for a purification of 2500-fold.¹⁰⁹

Although it requires much more effort, affinity adsorption is more widely used than affinity elution and has been successful in a number of instances. The basic

idea in **affinity adsorption** is to synthesize a stationary phase to which has been covalently attached a chemical compound that binds specifically and with high affinity to the protein being purified. The compound synthetically attached to the stationary phase is usually an analog or a derivative of a reactant or product in the reaction catalyzed by an enzyme, an inhibitor of the enzyme, an allosteric activator of the enzyme, or an agonist or antagonist of a receptor. This compound, when covalently attached to the stationary phase, is referred to as an immobilized ligand for the protein. Cross-linked agarose^{110,111} is the stationary phase to which the immobilized ligand is usually attached.

One of the original examples of this technique¹¹² can serve to illustrate the strategy. Micrococcal nuclease is an enzyme from *Staphylococcus aureus* that can hydrolyze the phosphodiester of either single-stranded RNA or double-stranded DNA to produce as its final products 3'-phosphomononucleotides or dinucleotides. Thymidine 3',5'-bisphosphate is a specific inhibitor of the nuclease that binds to it tightly. A *p*-aminophenyl derivative of this inhibitor was synthesized and attached covalently to agarose through its aniline nitrogen to produce a stationary phase displaying the thymidine 3',5'-bisphosphate (Figure 1–7).¹¹² When a crude supernatant containing micrococcal nuclease was passed over this affinity medium, none of the nuclease emerged but almost all of the protein did. The nuclease could then be eluted nonspecifically with dilute acetic acid in greater than 90% yield. It was completely purified in this one step.

Since this early report, the technical aspects of affinity adsorption have been exhaustively explored. The main difficulty to which many of these investigations have been directed is positioning the ligand far enough from the polymeric matrix of the agarose to minimize steric hindrance and thus interact effectively with the protein.^{113,114} This problem may explain many of the failed attempts to use the technique of affinity adsorp-

Figure 1-7: Synthetic strategy used to couple deoxythymidine 3',5'-bisphosphate covalently to agarose activated with cyanogen bromide (BrCN).¹¹² The cyanylation occurs randomly on the agarose.

tion. Several long, hydrophilic connecting links, usually referred to as **spacers**, that serve the purpose of the *p*-aminophenyl in the original example (Figure 1-7) have been developed to solve this problem. Often a long hydrophilic spacer is created during the set of reactions used to attach the ligand to the solid phase (Figure 1-8).³⁴ Many different strategies for attaching ligands of various structures to the stationary phase have been developed.

The cases in which affinity adsorption has been successful in the purification of proteins provide a provocative collection of examples (Table 1-3). Because purifications of 100-fold in one step are not unusual, this approach has obvious advantages over the traditional strategy that combines chromatography by ion exchange, chromatography by molecular exclusion (Table 1-1), and chromatography by adsorption (Table 1-2), where several steps are required to achieve the same degree of purification. Affinity adsorption, how-

ever, often requires a greater investment than assembling a sequence of simple chromatographic steps and has a higher risk of failure. Often the affinity adsorbent produces only a modest purification of 10-fold or less under conditions that suggest that the process occurring is either nonspecific ion exchange¹³⁹ or simple adsorption¹⁴⁰ or affinity elution from a nonspecific stationary phase.¹⁴¹ Often the desired protein adsorbs so tightly to the affinity medium that it can be eluted only in low yield.¹⁴²

The central, defining feature of affinity adsorption is the design of the stationary phase, but the conditions used for **elution** of the bound protein are also characteristic. Often they are merely the application of a mobile phase of extreme pH or ionic strength such as in the original example of micrococcal nuclease. The ideal approach, however, is to combine affinity adsorption with affinity elution to gain an advantage in each of the

Figure 1-8: Use of a hydrophilic spacer to connect a specific ligand to a polymeric support.³⁴ N,N -Di-(3-aminopropyl)amine was attached to agarose by activating the polysaccharide with cyanogen bromide (Figure 1-7). 1-(4-Amino-6,7-dimethoxy-2-quinazolinyl)piperazine, which is a portion of prazosin, a specific antagonist for α_1 -adrenergic receptors, was succinylated and then attached to the aliphatic amine by activation of the resulting carboxylic acid with 1-[(N,N -dimethylamino)propyl]-3-ethylcarbodiimide. This produced a spacer of 14 atoms connecting an oxygen of the polysaccharide with the nitrogen of the ligand. The spacer is hydrophilic by virtue of the O -alkyl- N -alkyl urea, the amine, and the two N -alkyl amides. This affinity medium was used to purify α_1 -adrenergic receptor.

two steps, and the protein is often eluted with a solution of the soluble ligand from which the immobilized ligand was derived (Table 1-3, Figure 1-9).¹²⁷

Affinity adsorption has also been used to purify proteins that bind to particular nucleotide sequences in DNA.¹⁴³ The spacer holding the DNA recognized by the protein away from the surface of the agarose can be produced by polymerizing short fragments of DNA containing the target sequence to produce a long repeating double strand of DNA and then attaching this long repeating polymer to the agarose through one of its ends. The DNA closest to the surface of the agarose acts as a spacer for the more peripheral segments. Such an affinity adsorbent was used to purify the promoter-specific transcription factor Sp1.³⁹ This protein binds to the nucleotide sequence GGGGCGGGGC in double-stranded DNA, and its concentration in a particular solution can be assayed by observing its footprint on DNA

Figure 1-9: Affinity adsorption and affinity elution used in combination to purify 5-formyltetrahydrofolate cyclo-ligase.¹²⁷ (A) A crude extract (7.3 g of protein in 2 L) from the bacterium *Lactobacillus casei* was passed over a column (4 cm \times 18 cm) of agarose to which 5-formyltetrahydropteroylglutamate had been attached. After the affinity adsorbent had been washed with 2 L of buffer until no more protein emerged, the bound enzyme was eluted with a solution of 5-formyltetrahydrofolate, a reactant in the enzymatic reaction. (B) A purified fraction (0.7 mg of protein in 40 mL from a later step in the procedure) was passed over a column (2 cm \times 13 cm) of agarose to which ATP had been covalently attached. After the affinity adsorbent had been washed with 100 mL of buffer, the bound enzyme was eluted with a solution of ATP, another reactant in the enzymatic reaction. Protein concentration (milligrams milliliter⁻¹; \circ) and enzymatic activity (nanomoles minute⁻¹ milliliter⁻¹; \bullet) were measured for each fraction collected from each column. containing this specific sequence. An extract of nuclei from HeLa cells was purified on chromatography by molecular exclusion, chromatography by adsorption on heparin bound to agarose, chromatography by cation exchange on sulfated dextran, and affinity adsorption on agarose to which the specific DNA was attached. In the last step, the protein was eluted with a high concentration (0.5 M) of KCl. The first three steps produced 100-fold purification with a 20% yield, and the last step alone produced a further 100-fold purification with a 50% yield.

The inhibition of the DNA polymerase from herpes simplex virus by the antiviral agent 9-[O-(2-hydroxyethyl) hydroxymethyl]guanosine (acyclovir) results from the formation of a tight complex between the polymerase, a duplex of DNA containing a template and a primer into which 9-[O-(2-hydroxyethyl)hydroxymethyl]guanosine has been incorporated at the 3' end of the primer of DNA as it is being elongated, and the triphosphate of the next nucleotide encoded by the template. When a duplex of template and primer into which 9-[O-(2-hydroxyethyl)hydroxymethyl]guanosine had been incorporated was covalently attached to cross-linked agarose, the resulting affinity adsorbent bound the polymerase strongly, but only when GTP, the next nucleotide encoded by the template strand, was present in the solution. A homogenate was passed over the adsorbent in the absence of GTP to adsorb proteins binding nonspecifically to DNA. The unbound proteins from this first step were then added to the adsorbent in the presence of GTP, and the DNA polymerase was bound strongly. The column was rinsed with high salt and brought to low ionic strength, the GTP was removed to eliminate the binding with high affinity, and the DNA polymerase was then eluted with a gradient of NaCl.¹⁴⁴

It is sometimes the case that during a step of the purification the activity of the enzyme of interest disappears, which can be discouraging. A common reason for such disappearance is digestion of the protein of interest by endopeptidases in the homogenate.^{145,146} A more interesting reason, however, for loss of enzymatic activity is that the function being assayed requires more than one protein and that these proteins are separated from each other during a step in the purification. The removal of mismatched uracil bases from double-stranded DNA is conveniently assayed by following the replacement by [α -³²P]dCTP of a mismatched uracil in the center of a short segment of double-stranded DNA.¹⁴⁷ Although the homogenate from HeLa cells displayed significant activity in this assay, that activity disappeared upon fractionation by sulfopropyl-agarose. It could be regained by combining two of the fractions produced by this step.¹⁴⁷ The active protein in one of these two fractions was then purified to homogeneity by use of the assay supplemented with the other fraction. The ability of this other fraction to support the enzymatic activity in the presence of the purified protein was lost upon its fractionation by phenyl-agarose. When two of the fractions from this step

were combined, activity returned. The single proteins in each of these two fractions were then purified separately, in each case by use of assays supplemented with the other two necessary components. In the end, the three distinct proteins that together perform the reaction were each purified to homogeneity.¹⁴⁸ Only when all three are mixed together is enzymatic activity observed.

The goal of purification is to obtain the protein of interest isolated from all of the other proteins that were originally in the homogenate derived from the biological specimen. That this has been achieved is often suggested by the **coelution** of the protein present and the biological or enzymatic activity in the last chromatographic step of the purification (Figures 1–6 and 1–10).¹⁴⁹ This is only an indication of purity, and the absolute purity of the final preparation must always be demonstrated independently by electrophoresis.

Figure 1–10: Chromatography by molecular exclusion of malate synthase.¹⁴⁹ A solution (280 mg of protein in 7 mL) of malate synthase, from the penultimate step in the purification procedure from *Saccharomyces cerevisiae*, was loaded onto a column (1.8 L) of cross-linked dextran. The fractions (7 mL) collected from the bottom of the column were assayed for absorbance at 280 nm (○) and enzymatic activity (nanomoles minute⁻¹ milliliter⁻¹; △) and specific activity (□) was calculated by dividing enzymatic activity (milliliter)⁻¹ by the absorbance at 280 nm. Problem 1–8: Sugars such as lactose have negative values of preferential solvation. Unlike the preferential solvation of most salts, which are affected by activity coefficients, the preferential solvation of lactose is invari-

ant with its concentration. The preferential solvation of bovine serum albumin by lactose⁸⁵ is -0.35 mL g^{-1} . What molar concentration of lactose should have an effect on the solubility of bovine serum albumin equal to a 1 M concentration of Na_2SO_4 ? What is the percent saturation of a 1 M solution of $(\text{NH}_4)_2\text{SO}_4$? Why isn't lactose used to precipitate protein?

Problem 1-9: Calculate the number of theoretical plates in the column used for the separation displayed in Figure 1-5A from the width of the peak of phosphoglycerate mutase. Use the number of theoretical plates to calculate the width the peak of glyceraldehyde-3-phosphate dehydrogenase should have. Why might its peak be wider than the width calculated?

Problem 1-10: Calculate the number of theoretical plates in the column used in Figure 1-6C.

Problem 1-11: The table below describes the purification of glutamyl-tRNA reductase. Calculate, in the proper units, the total enzymatic activity, the yield, the total protein, the specific activity, and the cumulative enrichment at each step.

Problem 1-12: Alprenolol (Al) binds tightly and specifically to β -adrenergic receptor (βAR), which is a protein in the plasma membranes of certain animal cells. The dissociation constant for this binding is the equilibrium constant defined by the equation

$$K_d = \frac{[\text{Al}][\beta\text{AR}]}{[\text{Al} \cdot \beta\text{AR}]}$$

where all concentrations are in moles (liter)⁻¹. They are the concentration of free alprenolol, [Al], the concentration of uncomplexed β -adrenergic receptor, [βAR], and the concentration of the complex between the alprenolol and β -adrenergic receptor, [Al \cdot βAR]. The value for K_d is 8 nM.

Alprenolol was covalently attached to agarose to produce an affinity adsorbent for the purification of β -adrenergic receptor. The final concentration of the alprenolol covalently bound to the solid phase, $[\text{Al}_B]_{\text{TOT}}'$, was 2 mM in units of millimoles (liter of bed)⁻¹. All molar concentrations designated with primes are in moles (liter of bed)⁻¹. Assume that the dissociation constant between covalently bound alprenolol and β -adrenergic receptor is the same as that for unbound alprenolol (8 nM).

Consider what happens when a solution containing β -adrenergic receptor is added to a chromatographic column containing the affinity adsorbent. If, as is reasonable, $[\beta\text{AR}]' \ll [\text{Al}_B]_{\text{TOT}}'$, where $[\text{Al}_B]_{\text{TOT}}'$ is the molar concentration of covalently bound alprenolol (2 mM), then $[\text{Al}_B]_{\text{TOT}}' = [\text{Al}_B]'$, the molar concentration of covalently attached alprenolol to which β -adrenergic receptor is not bound; and from the equation for K_d

$$\frac{[\text{Al}_B]_{\text{TOT}}'}{K_d} = \frac{[\text{Al}_B \cdot \beta\text{AR}]'}{[\beta\text{AR}]'} \cong \alpha'_{\beta\text{AR}}$$

where α' is the partition coefficient for β -adrenergic receptor between the mobile phase, βAR , and its complex with alprenolol covalently bound to the stationary phase, $\text{Al}_B \cdot \beta\text{AR}$.

- (A) If the chromatographic column has a volume of mobile phase, V_0 , of 2.0 mL, calculate the elution volume, $V_{e,\beta\text{AR}}$, of β -adrenergic receptor.

One way to decrease the elution volume of β -adrenergic receptor would be to add free alprenolol to the mobile phase at a particular molar concentration $[\text{Al}_M]'$ in moles (liter of bed)⁻¹. Again, if $[\beta\text{AR}]' \ll [\text{Al}_B]_{\text{TOT}}'$, then

$$\alpha'_{\beta\text{AR}} \cong \frac{[\text{Al}_B \cdot \beta\text{AR}]'}{[\beta\text{AR}]' + [\text{Al}_M \cdot \beta\text{AR}]'}$$

- (B) Derive an equation for $\alpha'_{\beta\text{AR}}$ in terms of $[\text{Al}_M]_{\text{TOT}}'$, $[\text{Al}_B]_{\text{TOT}}'$, and K_d , if

Molecular Charge

Before electrophoresis can be understood, the property of a molecule of protein that permits its electrophoresis to occur, namely, its molecular charge, must be understood. The **mean net molecular charge number*** of a molecule of protein i , \bar{Z}_i [mean number of elementary charges (molecule of protein)⁻¹], is the difference between the number of its many positive elementary charges and the number of its many negative elementary charges averaged over time. These individual elementary charges are those of adsorbed ions from the solution; those of any tightly bound coenzymes, inorganic anions, and metallic cations; and those of the covalent post-translational modifications of the protein as well as the more obvious positive elementary charges of the guanidinium, ammonium, and imidazolium cations and the negative elementary charges of the carboxylates, thiolates, and phenolates that are the side chains of the amino acids incorporated into the covalent molecular structure of the protein itself.

Each of the charged side chains of the amino acids is the conjugate acid or conjugate base of a weak neutral base or weak neutral acid, respectively (Table 2-2), and the degree to which each is ionized is a function of the pH of the solution. The **mean net proton charge number** of protein i , $\bar{Z}_{H,i}$, is the difference, averaged over time at a particular pH, between the number of all the positive elementary charges and the number of all the negative elementary charges on a molecule of that protein that arise from ions or functional groups that remain affixed to the protein, covalently or noncovalently, in pure water in the

absence of any other dissolved electrolytes in the solution. Because the rates of protonic equilibria are extremely rapid, all molecules of a protein i , even though each has a different number of elementary charges at any instant, will have the same mean net proton charge number, $\bar{Z}_{H,i}$, if the fluctuations of charge are averaged over a time as long as a second.

The change in the mean net proton charge number on a protein as a function of pH is measured by performing a simple **acid-base titration** (Figure 1-11).^{150,151} The number of moles of protons or hydroxide ions necessary to adjust an unbuffered solution containing a known molar concentration of protein i to a given final pH from a given initial pH is measured. The number of moles of protons or hydroxide ions necessary to adjust an identical unbuffered solution, lacking the protein, to the same final pH from the same initial pH is then measured. The solution containing the protein will always consume more moles of protons or hydroxide ions than the control, and this additional amount can be converted into the equivalents of positive charge gained by the protein upon association of the excess protons or the equivalents of positive charge lost upon dissociation of the protons and their combination with the excess hydroxide ions, respectively, as the pH of the solution is changed from the initial value to the final value. In order to anchor this titration curve at some absolute number of net elementary charges on the protein rather than equivalents of elementary charge relative to those on the protein at some arbitrary initial pH, three distinct properties of a protein, which are often confused with each other, must be understood and clearly distinguished. These properties are the isoionic point, the point of zero net proton charge, and the isoelectric point.

The **isoionic point**, $pH_{isoionic,i}$ of protein i is the pH of a solution containing only water and protein i including all of its tightly bound ions, coenzymes, and post-translational modifications.¹⁵⁰ A solution containing only water and protein i , an isoionic solution, is usually obtained by passing a solution of protein i over a mixed-bed ion-exchange medium to remove all salts, and the pH of the resulting solution is then measured.¹⁵¹ Since the only cations and anions in such a solution, other than the ions bound tightly or covalently to the protein, are protons and hydroxide ions

$$(\bar{Z}_{H,isoionic,i}) [\text{protein } i] + [H^+]_{isoionic} = [OH^-]_{isoionic} \quad (1-58)$$

where $[\text{protein } i]$ is the molar concentration of the protein, $\bar{Z}_{H,isoionic,i}$ is the mean net proton charge number on the protein at its isoionic point, and $[H^+]_{isoionic}$ and $[OH^-]_{isoionic}$ are the molar concentrations of protons and hydroxide ions in this isoionic solution. This equation can be combined with the expression for the ionization

* The charge number of an ion, a molecule, or a functional group should be distinguished from its charge. The charge number is the number of elementary charges borne by the ion, the molecule, or the functional group. The charge is the number of coulombs borne by the ion, the molecule, or the functional group. The charge on an ion, a molecule, or a functional group is the elementary charge (1.602×10^{-19} C) multiplied by its charge number. Chemists are accustomed to refer to the number of elementary charges borne by an ion, a molecule, or a functional group, its charge number, as its "charge". This habit involves no misunderstanding so long as the actual charge on the ion, the molecule, or the functional group is never involved in the discussion. Unfortunately, the property that determines its electrophoretic mobility is the charge on the molecule, not its charge number, so in this instance the distinction between charge number and charge must be clear.

of water ($K_w = [H^+][OH^-]$) and the definition of pH ($[H^+] = 10^{-pH}$) to give

$$\bar{Z}_{H, \text{isoionic}, i} = \frac{K_w - 10^{-2 \text{pH}_{\text{isoionic}, i}}}{[\text{protein } i] 10^{-\text{pH}_{\text{isoionic}, i}}} \quad (1-59)$$

Equation 1-59 can be used to calculate the mean net proton charge number on the protein i at its isoionic point, and this provides a measurement of the absolute mean net proton charge number on the protein i at one pH in the absence of electrolytes. It is this direct measurement of the mean number of charges on the protein at a given pH in the absence of electrolyte that is usually used to anchor the titration curve of a protein (Figure 1-11).¹⁵¹

The **point of zero net proton charge** is the pH at which the mean net proton charge number on protein i is zero. The isoionic point, $\text{pH}_{\text{isoionic}, i}$ is formally distinguished from the point of zero net proton charge because at the isoionic point the protein does bear a mean net proton charge. It is clear from Equation 1-58, however, that if $[\text{protein } i]$ is significant and $\text{pH}_{\text{isoionic}, i}$ is between pH 5 and 9, there is little difference between the isoionic point and the point of zero net proton charge. This is not the case, however, for acidic or basic proteins.

Figure 1-11: Net mean proton charge number on ribonuclease as a function of pH. Solutions of ribonuclease at ionic strengths 0.01 M (●), 0.03 M (●), and 0.15 M (○), produced with KCl, were titrated with either KOH or HCl.¹⁵¹ The changes in pH as a function of the equivalents of acid or base added (mole of protein)⁻¹ were recorded. The isoionic point was determined by passing a solution of the protein over a mixed-bed medium for ion exchange to remove all electrolytes except the protein, H^+ , and OH^- . The point of zero net proton charge was then calculated with Equation 1-59. The absolute mean net proton charge number, $\bar{Z}_{H, \text{RNase}}$, is presented as a function of pH. Reprinted with permission from ref 151. Copyright 1956 American Chemical Society.

It is its point of zero net proton charge that is routinely **estimated from the sequence** of a protein. If it is assumed that the protein bears no unknown tightly bound ions or coenzymes and has no unknown post-translational modifications and if it is assumed that each side chain of each type of amino acid has its ideal, unperturbed value of pK_a (Table 2-2), then it is possible to estimate the point of zero net proton charge of the protein from its composition of amino acids and any known tightly bound ions, coenzymes, and posttranslational modifications (Problem 1-15). Such estimates of points of zero net proton charge are commonly performed by simple algorithms available at data banks on the internet. Such calculations are usually rather inaccurate estimates of the actual points of zero net proton charge because the values for the pK_a of the amino acids are seldom the same in the native protein as their ideal, unperturbed values, which are accurate estimates only when the amino acid is in an unfolded polypeptide and does not have an immediate neighbor with an ionized side chain. For example, Glutamate 89 of β -lactoglobulin is buried within the protein at low pH and does not titrate with the rest of the glutamates but becomes exposed during a change that occurs in the structure of the protein above pH 7 and titrates as the structural change progresses.¹⁵² In addition, there often are unknown tightly bound ions or post-translational modifications. Finally, the point of zero net proton charge is often between pH 6 and 8, where small shifts in the titration curve lead to large changes in the point of zero net proton charge (Figure 1-11). The result of one of these algorithmic estimates of the point of zero net proton charge is usually referred to, erroneously, as the isoelectric point of the protein.

The **isoelectric point** of protein i , pI_i , is the pH at which, under a given set of conditions, the mean net molecular charge number of protein i , \bar{Z}_i , is zero.⁷⁸ The mean net proton charge number on protein i , $\bar{Z}_{H, i}$, differs from the mean net molecular charge number on protein i , \bar{Z}_i , because proteins have a tendency to bind weakly the ions of electrolytes in the solution, even ones as simple as halides¹⁵³ and alkali metal ions.¹⁵⁴ This binding occurs even at the point of zero net proton charge and is reflected as a decrease or increase in $\text{pH}_{\text{isoionic}, i}$ as a neutral salt is added to an isoionic solution.¹⁵⁰ For example, if protein i in an isoionic solution binds more of the anions than the cations of a neutral salt that has been added, the increase in its negative charge will indirectly cause it to take up more protons, increasing $\text{pH}_{\text{isoionic}, i}$. The reverse effect on the isoionic point is observed when the cations are preferentially bound.

This binding of small simple ions, such as halides and alkali metal cations, to proteins results from **chelation**. Two or more fixed charges or dipoles on the protein, of opposite sign to the bound ion, have to be properly oriented to perform such chelation. Consequently, the number of each type of ion bound at the isoionic point is a unique and unpredictable property of each protein. In

deoxyhemoglobin, a site at which chloride binds to the protein has been identified, and it sits between two functional groups, an ammonium cation of the amino terminus and a guanidinium cation of an arginine, that both bear a positive charge and chelate the chloride.¹⁵⁵ In tryptophanase, a site at which potassium ion binds to the protein is formed from the oxygen of a carboxylate and three acyl oxygens from the backbone of the polypeptide that together chelate the ion.¹⁵⁶ In plasminogen activator inhibitor 1, a site at which a chloride ion binds is surrounded by two ammonium cations of two lysines and two NH groups of two amides from the backbone of the polypeptide that all chelate the ion.¹⁵⁷ In exotoxin A from *Pseudomonas aeruginosa*, a site at which a chloride ion binds is formed from two guanidinium cations of two arginines, and a site at which a sodium ion binds is formed by two acyl oxygens from the polypeptide backbone.¹⁵⁸

Although there is no relation between the number of ions bound and the charge on the protein at a particular pH, proteins with high densities of negative charge seem to bind cations more readily than those with low densities of negative charge.¹⁵⁴ This tendency presumably results from the increase in the probability of proper juxtaposition for chelation with the increase in the density of negative charge. As the pH is lowered from the point of zero net proton charge, the density of positive charge on a protein increases only marginally; rather, the density of negative charge decreases as carboxylates are neutralized. It has been observed that the number of bound anions increases as the pH is lowered,¹⁵³ which results from the decrease in electrostatic repulsion, due to these carboxylates, that at neutral pH inhibits the chelation of dissolved anions by the fixed positive charges on the protein. For reasons that are not well understood but may include the differences in ionic radii, proteins seem to bind halides more readily than they do alkali metal ions.

The mean net molecular charge number, \bar{Z}_i , on protein i in a solution containing simple neutral salts such as $(\text{NH}_4)_2\text{SO}_4$, NaCl, or KCl is the sum of the mean net proton charge number and the net charge number contributed by these loosely bound ions:

$$\bar{Z}_i = \bar{Z}_{\text{H},i} + \sum_{j=1}^m \bar{v}_j z_j \quad (1-60)$$

where \bar{v}_j is the mean number of ions of species j and charge number z_j bound by the protein. It is this net charge on protein i that determines its behavior on chromatography by ion exchange or electrophoresis. In turn, electrophoresis is the usual method for determining the isoelectric point of a protein.

Problem 1–13: The commercially available anion-exchange medium DEAE-Bio-Gel A is a beaded polymer formed from the naturally occurring polysaccharide agarose (Figure 1–7) to which are attached 2-(diethylamino)ethyl groups (Figure 1–2). In a column poured with DEAE-Bio-Gel A, the concentration of covalently attached tertiary ammonium cations is 20 mmol (L of bed)^{–1}. The bed of such an ion-exchange resin can be divided theoretically into two compartments that can be referred to as the stationary compartment and the mobile compartment. The stationary compartment, which is the volume within the beads, surrounds the covalently attached tertiary ammonium cations and includes enough of the surrounding volume that the compartment is electroneutral. The mobile compartment, which is the volume surrounding the beads, is the remainder of the volume that is accessible to the protein being submitted to the chromatography.

An isoionic solution of bovine serum albumin at 50 mg mL^{–1} has a pH of 5.48. This solution is adjusted to the desired pH with KOH to produce a potassium salt of bovine serum albumin, K_nBSA. Samples of this polyanionic form of bovine serum albumin are submitted to chromatography by anion exchange on a column 4.5 cm in diameter and 40 cm in length of DEAE-Bio-Gel A in the chloride form. The solution within the DEAE-Bio-Gel A itself has been adjusted with HCl to the same pH as that of the solution of protein and equilibrated with an unbuffered solution of KCl. No buffer has to be used because the bovine serum albumin and the diethyl aminoethyl groups on the agarose provide adequate buffering.

The movement of the bovine serum albumin through the chromatographic system will be determined by its partition coefficient between the stationary compartment and the mobile compartment

$$\alpha'_{\text{BSA}} = \frac{[\text{BSA}^{n-}]'_s}{[\text{BSA}^{n-}]'_m}$$

where the superscript $n-$ refers to the mean net molecular charge number on the bovine serum albumin at the chosen pH, and as in Equation 1–1, the primes on the concentrations indicate that they are in units of moles (liter of bed)^{–1}. The free energies of transfer of the ions between the stationary compartment and the mobile compartment, however, are governed by the actual molar concentrations of the bovine serum albumin in the two compartments (indicated by the unprimed brackets as usual) according to the partition coefficient

$$\alpha_{\text{BSA}} = \frac{[\text{BSA}^{n-}]_s}{[\text{BSA}^{n-}]_m}$$

(A) Show that

$$\alpha_{\text{BSA}} = \alpha'_{\text{BSA}} \left(\frac{1-f_s}{f_s} \right)$$

where f_s is the fraction of the total accessible volume of the bed, V_T , that is the volume of the stationary compartment, V_s . Note that by definition the sum of V_s and the volume of the mobile compartment, V_M , is V_T .

The ideal distribution of bovine serum between the mobile and stationary compartments in the DEAE-Bio-Gel A is governed by equations equivalent to Equations 1–15 to 1–18 that describe the conservation of charge in the two compartments and the equivalence of the ideal activities of the various dissolved salts in the system.

(B) Write four equations equivalent to Equations 1–15 to 1–18 for the special case of bovine serum albumin on DEAE-Bio-Gel A. Use the explicit abbreviations K^+ , Cl^- , BSA^{n-} , and $DEAE^+$. Remember that for the potassium salt of a multivalent anion, K_nA , where the charge number on anion A is $n-$, the ideal activity of the salt in a solution is

$$a_{K_nA} = [K^+]^n [A^{n-}]$$

In this equation, n does not have to be an integer.

(C) Unlike the derivation in the book, assume that only the concentration of bovine serum albumin, not $[K^+]_s$, is negligible and show that

$$[K^+]_s = \frac{\sqrt{[DEAE^+]_s^2 + 4[K^+]_M^2} - [DEAE^+]_s}{2}$$

that

$$\alpha_{\text{BSA}} = \left(\frac{\sqrt{[DEAE^+]_s^2 + 4[K^+]_M^2} + [DEAE^+]_s}{2[K^+]_M} \right)^n$$

that

$$\alpha'_{\text{BSA}} = \left(\frac{f_s}{1-f_s} \right) \left(\frac{\sqrt{[DEAE^+]_s'^2 + 4f_s^2[K^+]_M^2} + [DEAE^+]_s'}{2f_s[K^+]_M} \right)^n$$

that

$$\frac{(\alpha_{\text{BSA}})^{2/n} - 1}{(\alpha_{\text{BSA}})^{1/n}} = \frac{[DEAE^+]_s}{[K^+]_M}$$

and that

$$\frac{\left[\alpha'_{\text{BSA}} \left(\frac{1-f_s}{f_s} \right) \right]^{2/n} - 1}{\left[\alpha'_{\text{BSA}} \left(\frac{1-f_s}{f_s} \right) \right]^{1/n}} = \frac{[DEAE^+]_s'}{f_s[K^+]_M}$$

where $[DEAE]'$ is the concentration of covalently attached tertiary ammonium cations: 20 mmol (L of bed)⁻¹.

(D) The titration curve of bovine serum albumin¹⁵⁹ is such that the value of the partial derivative $(\partial \bar{Z}_{H,BSA} / \partial pH)_{T,Ic}$ has a constant value over the region from pH 5.5 to 7.0 of -5.9 .

Assume that, under the conditions of the experiment, bovine serum albumin does not bind either K^+ or Cl^- . What is the mean net molecular charge number on the bovine serum albumin at pH 6.00, and what is the mean net molecular charge number on the bovine serum albumin at pH 7.00?

(E) Before solutions containing the potassium salts of bovine serum albumin are run, a sample of the isoionic solution of bovine serum albumin at 50 mg mL⁻¹ is adjusted to pH 5.0 with HCl and run on the column of DEAE-Bio-Gel A equilibrated at pH 5.0 and eluted with 0.04 M KCl. The elution volume of the bovine serum albumin in this run is 537 mL. What parameter of the ion-exchange column is measured by this experiment?

(F) A sample of the isoionic solution of bovine serum albumin at 50 mg mL⁻¹ is adjusted to pH 6.00 with KOH and run on the column of DEAE-Bio-Gel A equilibrated at pH 6.00 and eluted with 85 mM KCl. The elution volume of the bovine serum albumin on this run is 3.38 L. What is the value of α_{BSA} under these conditions?

(G) Show that the value of f_s for the DEAE-Bio-Gel A in the column is 0.060.

(H) A sample of the isoionic solution of bovine serum albumin at 50 mg mL⁻¹ is adjusted to pH 7.00 with KOH and run on the column of DEAE-Bio-Gel A equilibrated at pH 7.00. What concentration of KCl must be used to have the elution volume of the bovine serum albumin be 3.00 L?

(I) Explain which of the assumptions, either implicit or explicit, relied upon in the preceding development are most certainly oversimplifications and explain why each of them is an oversimplification.

Problem 1–14: At a protein concentration of 3×10^{-4} M, the isoionic pH of ribonuclease¹⁵¹ is 9.60. Calculate $\bar{Z}_{H,\text{isoionic,RNase}}$.

Problem 1–15: Assume that the side chains of the acidic and basic amino acids in a native properly folded protein all have the same values for their acid dissociation constants that they do in the unfolded polypeptide (Table 2–2). Let f be the fraction of a particular acidic or basic amino acid that is ionized at a given pH.

- (A) Show that for a particular type of amino acid the conjugate base of which is anionic, such as aspartate, glutamate, cysteine, tyrosine, or a carboxy terminus,

$$f_{\text{anionic}} = \frac{1}{1 + 10^{(\text{p}K_a - \text{pH})}}$$

where the $\text{p}K_a$ is the one found in Table 2–2. Show that for a particular type of amino acid the conjugate acid of which is cationic, such as histidine, lysine, arginine, or an amino terminus,

$$f_{\text{cationic}} = \frac{1}{1 + 10^{(\text{pH} - \text{p}K_a)}}$$

where the $\text{p}K_a$ is the one found in Table 2–2 for that amino acid.

In a molecule of fructose-bisphosphate aldolase from rabbit skeletal muscle, there are four identical polypeptides, each containing one amino terminus, 14 aspartates, 24 glutamates, 11 histidines, eight cysteines, 12 tyrosines, 26 lysines, 15 arginines, and one carboxy terminus. There are no bound coenzymes or posttranslational modifications. The $\text{p}K_a$ of a carboxy terminus is 3.3, and that of an amino terminus is 8.0.

- (B) Calculate the mean net proton charge number on a molecule of fructose-bisphosphate aldolase at pH 8 and at pH 9. (If you are adept at using a computer, go to part E first).
- (C) Estimate the point of zero net proton charge for fructose-bisphosphate aldolase.
- (D) What is the value of the point of zero net proton charge for fructose-bisphosphate aldolase according to the experiments in Figure 1–16?
- (E) Write a program or program a spreadsheet to calculate the mean net proton charge number on fructose-bisphosphate aldolase at any pH.
- (F) Use the program to draw a titration curve of fructose-bisphosphate aldolase.

Problem 1–16: A particular protein is modified within the cells where it is normally located by the covalent attachment of inorganic phosphate in the form of phosphate esters. Anywhere between zero and seven phosphates can be attached to the protein under normal circumstances. The isoelectric points of these eight dif-

ferent forms of the protein are 4.32, 4.29, 4.26, 4.23, 4.20, 4.17, 4.14, and 4.11, respectively. At these values of pH, each phosphate ester would have a charge number of -1.00 so an additional equivalent of negative charge is added to the protein when an additional phosphate is added.

- (A) Explain why the isoelectric point of the protein decreases as each phosphate is added.
- (B) What amino acid side chains are titrating in this range of pH? (See Table 2–2).
- (C) Assume that the aspartates and glutamates of the protein have the same $\text{p}K_a$ (4.2). The decrease in the mean net proton charge number on a protein as the pH is lowered, if only the glutamates and aspartates are titrating, should be

$$\Delta \bar{Z}_H = n_{\text{E+D}} \left[\frac{1}{1 + 10^{(4.2 - \text{pH}_f)}} - \frac{1}{1 + 10^{(4.2 - \text{pH}_i)}} \right]$$

where $n_{\text{E+D}}$ is the total number of glutamates plus aspartates in the protein, pH_f is the final pH, and pH_i is the initial pH. What is the total number of glutamates plus aspartates in the protein?

Electrophoresis

When a molecule of protein i at a given pH in an aqueous solution of electrolytes is placed in an electric field, it will experience a force, F_{el} , in the direction x such that

$$F_{\text{el}} = Q_i E_x = e_a \bar{Z}_i E_x \quad (1-61)$$

where Q_i is the mean charge on protein i (coulombs), e_a is the elementary charge (1.602×10^{-19} C), \bar{Z}_i is the mean net molecular charge number of the molecule of protein i under these circumstances, and E_x is the electrical field (volts centimeter $^{-1}$) or gradient of the electrical potential ($\partial V / \partial x$) in the x direction. The units of force (grams centimeter second $^{-2}$) follow from the fact that one volt is one joule coulomb $^{-1}$ (10^7 gram centimeter 2 second $^{-2}$ coulomb $^{-1}$). Electrophoresis is usually run in an apparatus designed so that $(\partial V / \partial y)$ and $(\partial V / \partial z)$ are zero, and the force F_{el} will cause the molecule of protein i to move only in the x direction.

For the moment, it will be assumed that only the molecule of protein i and its physically bound ions move. As the molecule of protein i moves, a frictional force, F_{fric} , exerted by the surrounding stationary liquid is experienced by the molecule. The frictional force is proportional to the velocity of movement of the molecule

$$F_{\text{fric}} = -f_i \left(\frac{\partial x_i}{\partial t} \right)_E \quad (1-62)$$

where the constant of proportionality, f_i , is the **frictional coefficient** (grams second⁻¹) of the molecule of protein, one of its physical properties.

At this point a digression is necessary to explain the frictional coefficient before continuing with a discussion of electrophoresis. The most direct way to determine the frictional coefficient of a molecule of protein is from its diffusion coefficient, D . The **diffusion coefficient** is a measure of the net tendency of any population of identical molecules to spread from a region of high concentration to a region of low concentration; the driving force behind this movement is not a function of any intrinsic feature of the individual molecules such as their charge number or their mass. The diffusion coefficient D_i (centimeters² second⁻¹) of any substance i in solution is defined by Fick's law

$$J_{x,i} = -D_i \left(\frac{\partial c_i}{\partial x} \right)_t \quad (1-63)$$

where $J_{x,i}$ is the flux (moles centimeter⁻² second⁻¹) of substance i through a planar surface of unit area, c_i is the concentration (moles centimeter⁻³) of the substance i at any point, and x is the distance (centimeters) along an axis normal to the planar surface. The greater $(\partial c_i / \partial x)_t$, the greater the diffusive force, and the greater the net flux. The diffusion coefficient of substance i , D_i , is simply the constant of this proportionality. It can be shown that

$$f_i = \frac{k_B T}{D_i} \quad (1-64)$$

where k_B is Boltzmann's constant (1.38×10^{-16} g cm² s⁻² K⁻¹) and T is the temperature (kelvins).

The diffusion coefficient of a protein is most unambiguously measured by creating a sharp boundary between two solutions, one of which contains the protein at a given initial concentration and the other of which is otherwise identical to the first but does not contain the protein (Figure 1-12).¹⁶⁰ At any time after initiating the experiment, $(\partial c_i / \partial x)_t$, where x is normal to the original boundary, will be a Gaussian function. The width of this function will increase with time as diffusion spreads the boundary, and

$$D = \frac{1}{4\pi t} \left(\frac{A}{H} \right)^2 \quad (1-65)$$

where A is the area (concentration) of the curve of $(\partial c_i / \partial x)_t$ against x and H is its maximum height (concentration centimeter⁻¹). At the present time, however, the diffusion coefficients of proteins are usually measured by dynamic light scattering^{161,162} or by pulsed field gradient nuclear magnetic resonance.^{163,164}

Figure 1-12: Measurement of a diffusion coefficient.¹⁶⁰ (A) Spreading of a boundary of concentration at the interface formed between two solutions, one containing the solute and the other not containing the solute. A solution containing the solute is brought in contact with a solution otherwise identical, but lacking the solute, to form an interface at the origin of the horizontal axis. At the initial time the function of the concentration (c) is discontinuous at the interface at the origin of the horizontal axis, but as time progresses (t_1 and t_2) the solute diffuses in the direction x normal to the interface into the vacant solution and a gradient of concentration develops. (B) The first derivative of the function of concentration with respect to distance in the direction x $[(\partial c / \partial x)_t]$ at any instant is a Gaussian function (curves labelled t_1 and t_2), the width of which increases and the height of which decreases with time, t . Reprinted with permission from ref 160. Copyright 1961 John Wiley.

The frictional coefficients of spheres or ellipsoids of revolution can be calculated. For a sphere

$$f = 6\pi\eta r \quad (1-66)$$

where η is the viscosity (pascal seconds, where a pascal is a kilogram second⁻² meter⁻²) of the solution and r is the radius (centimeters) of the sphere. This equation has led to the formalism of the **effective sphere** or Stokes' sphere representing protein i , the radius of which, a_i , is defined as

$$a_i \equiv \frac{k_B T}{6\pi\eta D_i} \quad (1-67)$$

This radius, a_i , is simply the radius of a sphere the diffusion coefficient of which is the same as the diffusion coefficient of protein i . It is usually referred to as the **Stokes' radius** of the protein.

It is now possible to return from the digression defining the frictional coefficient to the molecule of protein in the electric field. When the electric field is turned on, a steady state⁴ is rapidly reached in which $F_{el} = -F_{fric}$ and which is characterized by a constant terminal velocity $(\partial x_i / \partial t)_E$ of the molecules of protein i in the direction of the electric field. At steady state, because $F_{el} = -F_{fric}$

$$\left(\frac{\partial x_i}{\partial t} \right)_E = \frac{e_a \bar{Z}_i E_x}{f_i} \quad (1-68)$$

Although electrophoresis is usually carried out in an apparatus in which the current passes through a complicated path, the region of the apparatus over which the proteins are actually separated, the **electrophoretic field**, is uniform in its dimensions and in its specific conductance so that E_x is constant over its length. The **free electrophoretic mobility**, u_i° (centimeters² volt⁻¹ second⁻¹) of protein i is defined as

$$u_i^\circ \equiv \frac{(\partial x_i / \partial t)_E}{(\partial V / \partial x)_t} = \frac{d_i l}{Vt} \quad (1-69)$$

where d_i is the distance (centimeters) moved by protein i in time t (seconds) when a particular voltage V is applied to an electrophoretic field of length l . This definition causes the electrophoretic mobility to be only a function of the molecule of protein and the medium through which it is moving.

It follows that, if the assumptions that have been made were correct, the relationship governing electrophoresis would be

$$u_i^\circ = \frac{e_a \bar{Z}_i}{f_i} \quad (1-70)$$

This relationship, however, is an incomplete description of electrophoresis and fails to explain actual behavior.¹⁶⁵ Equation 1-70 states that electrophoretic mobility will be affected by ionic strength only insofar as \bar{Z}_i is affected by ionic strength. In general, \bar{Z}_i increases gradually but not impressively with ionic strength, as ionic shielding permits the molecule of protein i to bear a greater net charge (Figure 1-11), yet it is observed that electrophoretic mobility declines precipitously as ionic strength is increased (Figure 1-13).¹⁶⁵

The inadequacy of Equation 1-70 is due to the erroneous assumption that the only participant responding to the electric field is the molecule of protein and its directly bound ions. This would be true if the molecule of protein were dissolved in pure water with no added electrolyte. In fact, the value for the extrapolation of the experimental curve in Figure 1-13 to zero ionic strength does seem to agree with that calculated from Equation 1-70 (the upper line in the graph). An actual solution of protein, however, must at the very least contain counterions to balance its charge, and in order to perform the electrophoresis, additional electrolyte must be added to the solution as well.

When a charged particle such as a molecule of protein is dissolved in a solution of water containing electrolyte, the solution surrounding the molecule of protein has a net charge of opposite sign due to the existence of an **ionic double layer**.¹⁴ In the present

Figure 1-13: Free electrophoretic mobility (u_{ovalb}°) of the protein ovalbumin at pH 7.1 as a function of the square root of the ionic strength of the solution, $I_c^{1/2}$.¹⁶⁵ The upper curve is the behavior of the ideal electrophoretic mobility calculated with Equation 1-70; the points (x) are the observed mobilities. The line through the points is the behavior of the electrophoretic mobility calculated with Equation 1-79. Reprinted with permission from ref 165. Copyright 1940 Royal Society of Chemistry.

case, one layer of the ionic double layer is the layer of fixed charges on or near the surface of a molecule of the protein that produces its mean net charge, and the other layer is the layer of solution surrounding that molecule of the protein. This outer layer of the double layer is enriched in counterions opposite in sign to the net charge on the protein and depleted in co-ions of like sign. A region of solution large enough to contain the entire ionic double layer must be electrically neutral, and consequently, the outer layer of the ionic double layer must have a net charge, which is the difference between the charge carried by the counterions and the charge carried by the co-ions, equal in magnitude but opposite in sign to that of the protein. The distribution of that charge within the outer layer of the ionic double layer is a function of the ionic strength of the solution.

If a molecule of protein i were the sphere of its Stokes radius a_i (centimeters), if that sphere had a uniform density of elementary charges on its surface producing a mean net molecular charge number, \bar{Z}_i , and if that sphere were dissolved in a solution of monovalent electrolyte the positive and negative ions of which were both spherical and both had the same radius a_j , then the

radial distribution of electrostatic potential, $\phi(r)$, in volts, through the outer layer of the ionic double layer would be approximated by

$$[\phi(r)]_{r > (a_i + a_j)} = -\frac{e_a}{\epsilon_r r} \left\{ \frac{\bar{Z}_i \exp [\kappa(a_i + a_j - r)]}{1 + \kappa(a_i + a_j)} \right\} \quad (1-71)$$

where r is the distance (centimeters) from the center of the sphere, ϵ_r is the relative permittivity* of the solvent (dimensionless), and e_a is the elementary charge. The term $(a_i + a_j)$ takes account of the fact that an ion cannot approach the sphere of charge closer than its finite radius a_j permits.

By Coulomb's law

$$1 \text{ coulomb}^2 = 10^{-2} c^2 \text{ gram centimeter} = 8.928 \times 10^{18} \text{ gram centimeter}^3 \text{ second}^{-2} \quad (1-72)$$

where c is the speed of light in a vacuum. Consequently,

$$1 \frac{\text{coulomb}}{\text{centimeter}} = 8.298 \times 10^{11} \text{ V} \quad (1-73)$$

The parameter κ (centimeters⁻¹) in Equation 1-71 is defined by the relationship

$$\kappa^2 \equiv \frac{4\pi e_a^2}{\epsilon_r k_B T} \sum_{j=1}^m n_j z_j^2 \quad (1-74)$$

where z_j is the charge number of the ion of species j composing the electrolyte and n_j is the number of ions j for each cubic centimeter of the solution. The units on e_a^2 can be directly converted (Equation 1-72) from coulombs² to gram centimeter³ second⁻².

The term $\sum n_j z_j^2$ is related to the **ionic strength**, I_c (moles liter⁻¹), defined as

$$I_c \equiv \frac{1}{2} \sum_{j=1}^m [J] z_j^2 \quad (1-75)$$

where $[J]$ is the molar concentration (moles liter⁻¹) of the ion of species j , by the relationship

$$\sum_{j=1}^m n_j z_j^2 = 2I_c N_A \quad (1-76)$$

where N_A is Avogadro's number, and

$$\kappa^2 = \frac{8\pi e_a^2 N_A}{\epsilon_r k_B T} I_c \quad (1-77)$$

The term within the brackets on the right side of Equation 1-71 can be considered to be the **effective charge number** of the sphere, and this effective charge number is a function of the distance r from its center. If there were no electrolytes in the solution so that $\kappa = 0$, the potential would decrease radially only as the inverse of the distance, r , as expected for a sphere of charge in a medium of uniform relative permittivity, ϵ_r , and the full charge number, \bar{Z}_i , would contribute to the potential at all values of r . If κ does not equal zero, however, the effective charge number decreases as r increases due to the presence of the outer layer of the ionic double layer. Because the term κ has the dimensions of centimeters⁻¹, its inverse, κ^{-1} , is used as a measure of the **thickness of the double layer**.¹⁴ Equations 1-71 and 1-77 define the dimensions of the double layer and state that the thickness of the double layer will decrease as ionic strength is increased. As the thickness of the ionic double layer decreases, the layer of counterions tightens around the molecule of protein.

Consequently, there are two distributions of charge that respond to the electric field, the one on the molecule of protein and its bound ions with a total charge number of \bar{Z}_i and the one within the outer layer of the ionic double layer the distribution of whose charge is defined by Equation 1-71 and the total charge number of which is $-\bar{Z}_i$. The protein is drawn in one direction by the electric field; the outer layer of double layer, in the other. The effect of this electrostatic force on the outer layer of solution surrounding the protein applied in a direction opposite to that on the molecule of protein (Equation 1-70) causes the outer layer to move in a direction opposite to that in which the protein is caused to move. The consequence of this retrograde movement is to increase the drag of the solution on each molecule of the protein, and this effect can be described in terms of an increase in the effective frictional coefficient of each molecule.¹⁶⁶ As the outer layer moves one way and the molecule of protein, the reason for the existence of the double layer in the first place, moves in the other, the outer layer continuously dissolves behind the molecule of protein and re-forms around it in front so that the movement of the protein is continuously impeded. Because the thickness of the outer layer of the double layer decreases as the ionic strength of the solution increases, its velocity in the direction opposite to that of the protein increases as the ionic strength increases. The result is an increase in its drag on the molecule of protein, and thereby a decrease

* The relative permittivity or **dielectric constant** of a substance is its permittivity relative to the permittivity of the vacuum.

in the electrophoretic mobility of the protein as the ionic strength increases.*

On the basis of these assumptions, an equation has been derived^{165,167-169} to describe the electrophoretic mobility of protein i if its shape is approximately that of a sphere:

$$u_i^\circ = \frac{e_a \bar{Z}_i}{f_i} \left(\frac{1 + \kappa a_j}{1 + \kappa a_j + \kappa a_i} \right) f(\kappa a_i) \quad (1-78)$$

where $f(\kappa a_i)$, Henry's function, is a function in κa_i for which there is no exact expression¹⁶⁸ but which can be expressed graphically (Figure 1-14).¹⁶⁰ The value of this function varies between 1.0 and 1.5. It can be seen that when $\kappa a_j < 1$, as is usually the case for a solution of protein,

Figure 1-14: Graphic presentation of Henry's function.¹⁶⁰ Reprinted with permission from ref 160. Copyright 1961 John Wiley.

* There is another way to describe the effect of the double layer on electrophoresis. An assumption is made that there exists a discrete surface of shear that defines a boundary between the stationary solution and both the moving molecule of protein and the solution moving with it. The charge within the surface of shear, Q , which includes both the charge of protein i , $e_a \bar{Z}_i$, and the sum of the charges of the enclosed mobile ions, $e_a \bar{Z}_j$, creates a potential at that surface. The potential at the surface of shear is the zeta potential, ζ . If this assumption were a realistic one, then

$$u_i^\circ = \frac{D_i \zeta}{4\pi\eta}$$

The problem is that the relationship between \bar{Z}_i and ζ is a complex one. It is possible to calculate ζ for a molecule of protein from its electrophoretic mobility, but ζ provides little information about that molecule of protein because it includes the potential resulting from both the mobile ions and the molecule of protein itself.

$$u_i^\circ \cong \frac{e_a \bar{Z}_i}{f_i} \left(\frac{1}{1 + \kappa a_i} \right) f(\kappa a_i) \quad (1-79)$$

This equation predicts that the electrophoretic mobility will decrease as the ionic strength increases (Figure 1-13) because κ increases as the ionic strength increases (Equation 1-77).

The points in Figure 1-13 are the observed electrophoretic mobilities of the protein ovalbumin at various ionic strengths as measured by Tiselius and Svensson.¹⁶⁵ The top line is their calculation of the mobilities with Equation 1-70 by use of independent measurements of $\bar{Z}_{\text{ovalbumin}}$ and $f_{\text{ovalbumin}}$. The lower line is their calculation of the mobilities with Equation 1-79. The agreement between calculated values and observed values is surprisingly satisfactory. As the authors point out, the calculated value from Equation 1-70, in the absence of electrolyte, comes close to the extrapolated value of the actual mobilities.

According to Equation 1-78, at a constant ionic strength, the electrophoretic mobility of protein i should be directly proportional to \bar{Z}_i , and this proportionality is reflected in the direct proportionality that obtains between $\bar{Z}_{H,i}$ and u_i° (Figure 1-15)¹⁷⁰ as $\bar{Z}_{H,i}$ is varied by varying the pH at a constant ionic strength.¹⁷⁰ In fact, it is possible to display the titration curve of a protein visually by submitting a sample to electrophoresis on a two-dimensional electrophoretic field prepared so that there is a linear gradient of pH across the field perpendicular to the direction of electrophoresis.¹⁷¹ The absolute values of the electrophoretic mobilities of several proteins have been calculated from experimental values of their mean net proton charge numbers, $\bar{Z}_{H,i}$, by use of Equation 1-78 with the assumption that $\bar{Z}_{H,i} = \bar{Z}_i$ or a more complicated equation derived from a cylindrical model rather than a spherical one. The agreement between calculated values of u_i and experimental values of u_i was within a factor of 2 or less.¹⁶⁹

The lack of exact agreement between calculated and experimental values was assumed to be due to the difference between $\bar{Z}_{H,i}$ and \bar{Z}_i caused by the binding of inorganic ions to the proteins. In this case, the proportionality between $\bar{Z}_{H,i}$ and u_i observed in Figure 1-15 could still be explained, if the binding of counterions increases proportionately as $\bar{Z}_{H,i}$ increases in magnitude.¹⁵³ It has been demonstrated, however, by systematically varying the charge number on human carbonate dehydratase II that electrophoretic mobility is not directly proportional to charge number when charge number becomes large.¹⁷² This deviation from the behavior predicted by Equation 1-79 at high levels of charge number could be accounted for by using the nonlinear Poisson-Boltzmann equation rather than the linear form used in the derivation of Equation 1-79 and by using a correction for ion relaxation and polarization. The latter correction accounts for the local electric field arising

Figure 1-15: Comparison of the electrophoretic mobilities of trypsin ($\text{cm}^2 \text{ volt}^{-1} \text{ second}^{-1}$) at 0°C (u_{trypsin}^o ; points) with the acid-base titration curve of trypsin determined at 20°C ($Z_{\text{H, trypsin}}$, continuous curve).¹⁷⁰ The respective scales on the two vertical axes, those for electrophoretic mobility and mean net proton charge number, respectively, both with respect to pH, were adjusted to produce maximum coincidence. The value for $Z_{\text{H, trypsin}} = 0$ was arbitrarily set to coincide with the isoelectric point. The coincidence displayed is in shape rather than absolute value or excursion. The different symbols denote the different buffers used to maintain the pH during electrophoresis: (\times) Na^+ , H^+ , Cl^- ; (Δ) Na^+ , H^+ , acetate $^-$, Cl^- ; (\square) Ca^{2+} , H^+ , barbiturate $^-$, Cl^- ; (\circ) Mg^{2+} , H^+ , barbiturate $^-$, Cl^- ; (∇) Ca^{2+} , H^+ , glycinate $^-$, Cl^- ; (\diamond) Ca^{2+} , H^+ , NH_3 , Cl^- . The ionic strength was maintained at 0.13 M. Reprinted with permission from ref 170. Copyright 1952 Academic Press.

from the distortion of the outer layer of the double layer caused by its movement in a direction opposite to that of the protein and its inability to dissolve behind it and reform around it instantaneously.

At its isoelectric point, pI_i , the electrophoretic mobility of protein i becomes zero (Equation 1-78), and this fact permits the isoelectric point of a protein to be measured by electrophoresis.¹⁷³ Electrophoretic mobilities are measured at values of pH greater than and less than pI_i , and the pH of zero mobility is determined by interpolation (Figure 1-15).

The effect of ionic strength on the isoelectric point of a protein in the absence of actual binding of the ions in the electrolyte to the protein has been calculated to be smaller than the experimental error in measurement.¹⁵⁰ Nevertheless, significant variations in isoelectric point with ionic strength are generally observed (Figure 1-16),¹⁷⁴ and these depend on the particular neutral salt chosen to adjust the ionic strength. The explanation for this behavior can only be the **preferential binding** of particular ions—in Figure 1-16, always that of the anions—in the chosen electrolyte. The net binding of ions can be calculated from the observed changes in the isoelectric point because, from Equation 1-60, when $Z_i = 0$

$$Z_{\text{H},i} = -\sum_{j=1}^m \bar{v}_j z_j \quad (1-80)$$

Figure 1-16: Variations in the electrophoretic isoelectric points (pI) of a protein as a function of the square root of the ionic strength ($I_c^{1/2}$).¹⁷⁴ Line A, ovalbumin in acetate; line B, fructose-bisphosphate aldolase in phosphate; line C, fructose-bisphosphate aldolase in acetate; line D, carboxyhemoglobin in phosphate. and $Z_{\text{H},i}$ is available from titration data (Figure 1-11).

To this point, only the free electrophoretic mobility of a protein, u_i^o , has been discussed. The free electrophoretic mobility is the electrophoretic mobility displayed by a protein in free solution. This property of the protein is measured by moving boundary electrophoresis¹⁷⁵ in an apparatus developed by Tiselius.¹⁷⁶ This technique has been supplanted by electrophoresis in continuous **gels of cross-linked polyacrylamide**. A gel of cross-linked polyacrylamide is a hydrated plastic cast in a mold from a solution of acrylamide and the cross-linker N,N' -methylenebis(acrylamide) along with a buffer and other salts. The total concentration of acrylamide and N,N' -methylenebis(acrylamide) in the final gel can be varied from 3% to 20%.

It has been demonstrated experimentally by Morris¹⁷⁷ that the relative electrophoretic mobilities of proteins in polyacrylamide gels vary regularly with the concentration of acrylamide used to cast the gel (Figure 1-17)¹⁷⁷ and

$$u_i = u_i^o \exp(-K_{r,i} T_a) \quad (1-81)$$

where u_i is the electrophoretic mobility of protein i observed on a gel cast from a solution whose total concentration of acrylamide, in percent, was T_a and $K_{r,i}$ is a **retardation coefficient** unique to protein i . Such behavior was first noted by Ferguson¹⁷⁸ on gels cast from starch in which the same equation applies (Equation 1-81), but the concentration is T_s , the concentration of the starch.¹⁷⁸

According to Equation 1-81, u_i^o should be the free electrophoretic mobility of protein i , and this has been shown to be the case.¹⁷⁷ It follows that

Figure 1-17: Electrophoretic mobility, presented on a logarithmic scale, of various proteins on gels of various concentrations of polyacrylamide (T_a).¹⁷⁷ The gels were cast from solutions of pH 8.88 with total concentrations of acrylamide plus N,N' -methylenebis(acrylamide) (T_a) varying between 5% and 15%. The concentration of N,N' -methylenebis(acrylamide) was always 20-fold less than the concentration of acrylamide. The proteins were β -lactoglobulin (Lac), ovalbumin (Ova), ovomucoid (Ovm), pepsin (Pep), bovine serum albumin monomer (BSA_1) and dimer (BSA_2), myoglobin (Myo), and immunoglobulin G (IgG). Reprinted with permission from ref 177. Copyright 1966 Elsevier.

$$u_i \cong \frac{e_a \bar{Z}_i}{f_i} \left[\frac{f(\kappa a_i)}{1 + \kappa a_i} \right] \exp(-K_{r,i} T_a) \quad (1-82)$$

Examination of this relationship reveals that the electrophoretic mobilities of the proteins in a complex mixture upon a gel of polyacrylamide are directly proportional to their respective charges, which are determined by complex functions of pH (Figure 1-11); are complex functions of their respective frictional coefficients, which are determined by their sizes and shapes; and are exponentially proportional to the product of a constant, which is unique for each, and the concentration of acrylamide. At a given pH, ionic strength, and concentration of polyacrylamide, each of the proteins in this mixture will have a characteristic electrophoretic mobility (Figure 1-17) and they can be separated one from the other. In this way, electrophoresis can provide a catalogue of the number of proteins present in the mixture and the relative amounts of each.

Electrophoresis of native proteins* is the most reliable method available for assessing the homogeneity of a sample of purified protein. A sample of pure protein in its native state should display only one component upon gel electrophoresis. Because the electrophoretic mobilities of two proteins change disproportionately as either the pH (Figure 1-15) or the concentration of acrylamide (Figure 1-17) is changed, the possibility that the single component observed under one set of conditions results from the accidental coelectrophoresis of two or more proteins can be dismissed by running electrophoresis at several values of pH^{179,180} or several concentrations of acrylamide.¹⁷⁷

If they are to be used in the roles of cataloguing mixtures and establishing purity,¹⁸¹ electrophoretic separations of native proteins on polyacrylamide gels must have as high a resolution as possible. This high resolution is achieved by using a discontinuous buffer system and performing what has been referred to as **disc electrophoresis**,^{182,183} the pun apparently intended. This technique relies upon the creation of three **stable moving boundaries** (Figure 1-18).¹⁸² Each of the three is formed between two solutions of different ionic composition. It is the applied electric field that causes the boundaries to move.

Figure 1-18: Disc electrophoresis.¹⁸² At the start (left) the proteins in the original sample (black rectangle) are in a large volume and at a low pH (pH_{L1}). They are compressed to a small volume, or disc, as they move through the stacking gel by being trapped in the stable boundary between the upper solution (pH_U , buffer) and the solution of the original sample and the spacer (pH_{L1}). (Middle) Upon fusion of this descending boundary and the stable ascending boundary between the solution originally in the running gel (pH_{L2}) and the solution originally in the stacking gel (pH_{L1}), the pH at the boundary increases and the new more rapidly moving boundary outruns the proteins and deposits a newly created solution of higher pH (pH_{new}) behind it as it moves ahead of the separating proteins (right). The proteins also escape the first boundary because, at about the same time as the jump in pH at the fusion of the descending and ascending boundaries, they encounter the running gel, which has a higher percentage of acrylamide and which decreases their mobility. Reprinted with permission from ref 182. Copyright 1964 New York Academy of Sciences.

* The electrophoresis of proteins unfolded in solutions of dodecyl sulfate is quite different and will be discussed later.

The first of these boundaries is used to trap the proteins and sweep them into an extremely narrow band prior to the electrophoretic separation. This process has been called **stacking**. It significantly improves the resolution of the subsequent separation by shrinking the original sample to a hairline so that all of the molecules of protein begin the electrophoretic separation at nearly the same point. The stacking occurs because the proteins are initially placed as a sample that is sandwiched between an upper solution and a lower solution. The upper solution is simply poured on top of the sample, but the lower solution is in a polyacrylamide gel, so that convective turbulence does not disrupt the stable moving boundaries, but it is a gel of a low concentration of polyacrylamide, so that the mobilities of the proteins are as high as possible. This gel of high porosity is the **stacking gel**. The solution in which the protein is dissolved has the same composition as the lower solution.

The upper and lower solutions are prepared so their respective ionic compositions will form a stable moving boundary of a particular type. Although systems for cationic proteins are also available, to describe this boundary, it will be assumed that the direction of electrophoretic movement of both the proteins and this first stable moving boundary is downward and a pH has been chosen such that the proteins are all anionic. In this case, both the upper solution and the lower solution above and below the boundary, respectively, are prepared from salts of the same cationic weak acid [for example, tris(hydroxymethyl)methylammonium ion]. An anion (for example, glycinate ion) the mobility of which is less than the mobilities of all the proteins is used to make the upper solution, and an anion (for example, chloride ion) the mobility of which is greater than the mobilities of all the proteins is used to make the lower solution. The stable descending boundary formed is one between these two anions. If a molecule of one of the proteins finds itself in the lower solution, it is surrounded by anions that are moving faster than it is, and it is overtaken by the boundary. If a molecule of one of the proteins finds itself in the upper solution, it is surrounded by anions that are moving more slowly than it is, and it outstrips them and returns to the boundary. The result of these events is that the proteins all gather within the descending boundary itself, which remains extremely sharp and stable if the upper and lower solutions have the proper ionic compositions.¹⁸⁴

The stacking process is able to compress the proteins to thin lamella, but in order for electrophoretic separation to occur, they must be **released from the boundary** after they have been stacked. This can be done if the upper solution of this initial descending boundary has been made with an anion, α , that is slower than the protein only because it is the conjugate anionic base (for example, glycinate ion) of a weak neutral acid (glycine, $pK_a = 9.6$) and the pH of the upper solution has been chosen to be significantly lower than the pK_a of that weak

acid. Under these conditions, the anion α is slow because only a fraction of the weak acid is anionic at any instant. The acid-base equilibrium has the effect of decreasing the mobility of the anion α from its value in the absence of its conjugate acid to a lower value, and

$$u_{\alpha} = u_{\alpha}^{\circ} f_{\alpha} \quad (1-83)$$

where u_{α} is the mobility of the upper anion at the actual ratio of conjugate base to acid in the solution, u_{α}° is its mobility in the absence of its conjugate acid, and f_{α} is the fraction of the total weak acid that is ionized at the ratio chosen. In such a situation, the proteins can be released from the descending boundary by abruptly increasing the pH, and hence the value of f_{α} , so that u_{α} becomes greater than the mobilities of the proteins, and the new stable, but now rapidly descending, boundary that results drops the proteins behind at the origin of the electrophoretic separation.

The abrupt increase in the pH of the upper solution of the descending boundary can be accomplished by the arrival of a stable ascending boundary between two concentrations of the same cationic buffer. Behind this ascending boundary is a solution of the same cationic weak acid as used for the upper and lower solutions of the initial descending boundary [for example, tris(hydroxymethyl)methylammonium ion] but at a higher concentration and a higher pH than that of the solution behind the initial descending boundary. This ascending boundary between different concentrations of the same cationic buffer has been constructed so that the anion in both its upper and lower solutions (for example, chloride) is the same. Because its upper solution is by definition the lower solution of the initial descending boundary, this anion is already the fast anion of that boundary. The cationic weak acid of the upper solution of the ascending boundary is by definition the cationic weak acid in the two solutions used to make the initial descending boundary. The concentration and pH of the cationic buffer in the lower solution of the ascending boundary, however, is chosen to be high enough to adjust the final pH behind the new descending boundary to a value high enough to release the proteins from the initial descending boundary. If the release is unsuccessful, or only partially successful, the proteins, or some of the proteins, remain trapped in the new descending boundary and are never separated. These trapped unseparated proteins form an extremely sharp but uninformative and deceptive band at the bottom of the final electrophoretogram.¹⁸⁵

The release of the proteins from the initial descending boundary in which they were trapped and stacked can be accomplished even more effectively by using a stable ascending boundary behind which is a solution of a cationic weak acid of a higher pK_a than the cationic weak acid used as the counterion in the initial descending boundary.¹⁸⁶ This ascending boundary has been constructed so that the anion in both its upper and lower solu-

tions is the same. Because its upper solution is the lower solution of the initial descending boundary, this anion is the fast anion of the upper boundary (for example, chloride ion). The cationic weak acid of the upper solution of the ascending boundary must be the cationic weak acid of the two solutions used to make the initial descending boundary (for example, pyridinium ion; $pK_a = 5.14$). The cation of the lower solution of the ascending boundary is chosen to be the cationic conjugate acid [for example, tris(hydroxymethyl)methylammonium ion; $pK_a = 8.10$] of a neutral base strong enough to adjust the final pH behind the new descending boundary to a value higher than the pK_a of the neutral conjugate acid of the anion α (for example, 4-morpholineethanesulfonate ion; $pK_a = 6.15$) and release the proteins from the initial descending boundary. The difficulty with this strategy is that the pH of the upper solution of the initial descending boundary is often so low that the proteins are no longer anionic and move upward instead of downward. But it is effective with complexes of protein and dodecyl sulfate because they are anionic at all reasonable values of pH.

To ensure that as many proteins as possible are released from the initial descending boundary, shortly after the fusion of the ascending boundary and the initial descending boundary, the descending band of proteins in the stacking gel encounters a much higher concentration of polyacrylamide, **the running gel**, which decreases the mobilities of all of the proteins by virtue of the relationship in Equation 1–81. This frictional deceleration of the proteins increases the probability that all of their mobilities will be less than that of the now accelerated anion of the upper solution so that they can escape from the new descending boundary.

The polyacrylamide gel is poured in two stages (Figure 1–18): the running gel, the polyacrylamide concentration of which is high and upon which the separation will occur, and the stacking gel, the polyacrylamide concentration of which is as low as possible to keep the mobilities of the proteins as high as possible and in which the stacking will occur.

Three stable moving boundaries must be constructed (Figure 1–18). At the start of the electrophoresis, the initial descending boundary between the slow anion and the fast anion that will compress the proteins is the boundary between the upper electrode solution (pH_U) and the solution in the sample and the stacking gel (pH_{L1}). At the start of the electrophoresis, the ascending boundary between the two concentrations of the cationic conjugate acid of the weak base or between the cationic conjugate acids of the weaker base and the stronger base that will deliver the pH jump is the boundary between the solutions in the running gel (pH_{L2}) and the stacking gel (pH_{L1}). The third stable moving boundary is the new descending boundary that deposits behind it the solution in which the proteins are actually separated (pH_{new}). It forms upon the fusion of the other two.

As the initial descending boundary moves through

the stacking gel, it must maintain a constant pH and ionic strength behind it (pH_U) to maintain the low and constant mobility of the slow anion in the upper solution. As the new descending boundary moves, it must deposit behind itself a solution of constant pH and ionic composition (pH_{new}) to form a uniform electrophoretic field upon which the proteins can be separated. The pH and ionic composition of the solution that is deposited behind the new descending boundary is different from the pH and ionic composition of any of the solutions initially present, but the cation in this newly created solution is the weak cationic acid of the original lower phase of the ascending boundary and the anion in this solution is the now accelerated anion of the original upper phase of the initial descending boundary. The constant pH deposited behind this new descending boundary is established by the weak cationic acid found on both sides of the boundary and its conjugate base and the now accelerated slow anion found in the upper solution of the boundary, which is a weak anionic base, and its conjugate acid. All four of these species together buffer the deposited solution and determine both the ionic strength and the value of the deposited pH and hence the pH of the actual electrophoresis.

The equations that govern the creation of a stable moving boundary and the ability of that boundary to deposit a solution of uniform pH and ionic composition were derived by Ornstein¹⁸² from the regulating functions described by Kohlrausch.¹⁸⁴ On the basis of these equations, Jovin¹⁸⁷ has developed a more elaborate theoretical description of discontinuous electrophoresis, and he and his colleagues have provided the necessary recipes for a large number of discontinuous systems.¹⁸⁸

Problem 1–17: The uptake of protons by 1 mol of horse carboxyhemoglobin in the range of pH 6–8 is about 9 mol of protons for each drop of 1 unit in pH.¹⁸⁹ Use this value to estimate the moles of phosphate bound by a mole of horse carboxyhemoglobin at its isoelectric point at the phosphate concentration of the last point in curve D of Figure 1–16 ($[phosphate] = 0.12\text{ M}$). Assume that no cations other than protons are binding to the protein under these conditions.

Problem 1–18: Use interpolated values for the free electrophoretic mobility of ovalbumin (Figure 1–13) at ionic strengths of 0.0025, 0.01, and 0.16 M to calculate the charge number on the protein during the elec-

trophoresis. The pH for the measurements was 7.1, and the temperature was 294 K. The viscosity of water at 294 K is 1.0 mPa s. The diffusion coefficient of ovalbumin at 294 K is $4.2 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$.

Problem 1-19: The isoelectric point of normal hemoglobin, hemoglobin A, is 6.87, and that of sickle hemoglobin, hemoglobin S, is 7.09 when electrophoresis is carried out under the same conditions.¹⁷³ In the vicinity of the isoelectric point, the charge number on either of these hemoglobins changes by about 13 equiv for every mole of protein for every change of 1 unit in pH. At the same pH, anywhere between their two respective isoelectric points, what is the difference in charge number between hemoglobin A and hemoglobin S?

Problem 1-20: The frictional coefficient of trypsin at 10 °C is $5.5 \times 10^{-8} \text{ g s}^{-1}$. Assume the molecule to be a sphere and calculate its free electrophoretic mobility at 10 °C and at pH 6 and $I_c = 0.13 \text{ M}$ by using the results of the acid-base titration in Figure 1-15, which are for 20 °C, and Equation 1-79. Assume that $\bar{Z}_{\text{trypsin}} = \bar{Z}_{\text{H,trypsin}}$ and that $\bar{Z}_{\text{H,trypsin}}$ at pH 6 is the same at 10 °C as at 20 °C.

Problem 1-21: The frictional coefficient of ribonuclease at 25 °C is $2.6 \times 10^{-8} \text{ g s}^{-1}$. Assume the molecule to be a sphere and calculate its free electrophoretic mobility at pH 6 and $[\text{KCl}] = 0.15 \text{ M}$ by using the results presented in Figure 1-11 and Equation 1-79 with the assumption that $\bar{Z}_{\text{RNase}} = \bar{Z}_{\text{H,RNase}}$. In a field of 20 V cm^{-1} , how far would ribonuclease travel in 3 h if it had this mobility?

Problem 1-22: The mean net proton charge number on bovine serum albumin (BSA) at pH 8.0 and ionic strength 0.15 M is -17 .¹⁵⁹ The diffusion coefficient of bovine serum albumin at 20 °C is $6.0 \times 10^{-7} \text{ cm}^2 \text{ s}^{-1}$. Its retardation coefficient (K_r) on polyacrylamide gels is $0.16 (\%)^{-1}$. The viscosity of water at 20 °C is 1.0002 mPa s.

- Show that the ionic strength of a solution containing 0.10 M sodium phosphate at pH 8.0 is 0.27 M if the three values of the pK_a for phosphate are 2.12, 7.21, and 12.32.
- Estimate the mobility (u_{BSA}) of bovine serum albumin on a 7.5% gel of polyacrylamide run at 20 °C in 0.10 M sodium phosphate at pH 8.0. Assume for now that $\bar{Z}_{\text{H,BSA}}$ equals \bar{Z}_{BSA} at pH 8.0.
- How far would the bovine serum albumin move in 2 h if the field across the gel was 50 V cm^{-1} ?
- Refer to Figure 1-16. On the basis of the behavior displayed in this figure, would you expect the bovine serum albumin to have a larger or a smaller mobility than you estimated? Why?

Problem 1-23: The table below contains information about five imaginary proteins where a is the Stokes'

radius, \bar{Z} is the mean net charge number on the protein at pH 7, $(\partial \bar{Z}_{\text{H},i} / \partial \text{pH})_{I_c}$ is the change in mean net proton charge number with pH, K_r is the retardation coefficient for polyacrylamide, and u° is the free electrophoretic mobility for a temperature of 25 °C, an ionic strength of 0.1 M, and a pH of 7.0.

- Assume that, at constant ionic strength, $(\partial \bar{Z}_{\text{H},i} / \partial \text{pH})_{I_c}$ is equivalent to $(\partial \bar{Z}_i / \partial \text{pH})_{I_c}$ for each of the five proteins, and calculate the electrophoretic mobilities of these five proteins, at 25 °C and an ionic strength of 0.1 M, under each of the following conditions: (1) pH 7.0 on 5% polyacrylamide; (2) pH 7.0 on 10% polyacrylamide; (3) pH 5.0 on 5% polyacrylamide; (4) pH 5.0 on 10% polyacrylamide.
- What is the order of the migration of these five proteins under each of the four conditions?
- What will happen to protein E at pH 7.0 that would not happen at pH 5.0 if a mixture of the proteins is run on vertical polyacrylamide gels with the cathode at the bottom and the anode at the top?
- Assume that \bar{Z}_i does not change as ionic strength changes and calculate the mobilities of the five proteins at an ionic strength of 0.2 M at pH 5 and at 25 °C on 5% polyacrylamide. How does the increase in ionic strength affect the mobilities?

protein	a (nm)	\bar{Z} (pH 7)	$\left(\frac{\partial \bar{Z}_{\text{H}}}{\partial \text{pH}} \right)_{I_c}$	K_r ($\%^{-1}$)	u° $\left(\frac{\text{cm}^2}{\text{Vs}} \right)$

Criteria of Purity

When the purification of a particular protein is monitored analytically by disc electrophoresis (Figure 1-19),¹⁹⁰ the array of other proteins present at the early states of the purification is seen gradually to become less complex in the later stages as one component emerges from the background and becomes more prominent until it alone remains.^{190,191} To be certain that the single component observed at the last step of the purification is the only one present in the purified preparation, electrophoresis should be run at a variety of protein concentrations in addition to a few different acrylamide concentrations and values of pH.¹⁹² At high concentrations of protein, minor impurities are most easily recognized, while at low concentrations, two closely running

Figure 1-19: Disc electrophoresis on gels of polyacrylamide of native proteins from successive steps in the purification of [acyl-carrier-protein] S-malonyltransferase from *E. coli*.¹⁹⁰ Electrophoresis was performed on polyacrylamide gels cast from 15% solutions of acrylamide in a discontinuous system of tris(hydroxymethyl)methylamine and glycylglycine. The different gels represent samples from successive steps in a complete purification of the enzyme, seen in its final purified state on gel F. The gels were stained for protein with Coomassie brilliant blue. Reprinted with permission from ref 190. Copyright 1973 *Journal of Biological Chemistry*.

components can be resolved. Also, by running polyacrylamide gels loaded with a series of protein concentrations, the number and relative amounts of any minor impurities can be quantified.¹⁹³ The polyacrylamide gels should also be stained with two distinct dyes, for example Coomassie brilliant blue and silver oxide,^{194,195} because some proteins do not stain so strongly as others with a particular dye.

The single component observed upon electrophoresis of a sample from the final step of the purification must be shown to be the protein actually responsible for the biological function being purified. Either the polyacrylamide gel is sliced and the assay is performed on each slice (Figure 1-20),^{51,97,131,196} or the intact polyacrylamide gel is **stained for enzymatic activity** (Figure 1-21).¹⁹ The latter is accomplished by placing the gel in a solution that promotes the incorporation of radioactivity¹⁹⁷ or that gives a fluorescent product or a colored product from the enzymatic reaction. For example, by adding lead acetate, the SeH_2 produced in a polyacrylamide gel from the action of selenocysteine lyase can be made to form a yellow band where the enzyme is located.⁶⁰ The most widely used stain for enzymatic activity is based on the ability of NADH to reduce *p*-nitro tetrazolium blue to give a blue color.^{198,199} It is obvious that through coupled assays this reaction can be used to visualize a large array of different enzymatic activities. At times, the protein being purified is itself col-

Figure 1-20: Electrophoresis of purified porcine phosphomevalonate kinase (20 μg) on a gel cast from a 10% solution of acrylamide.⁵¹ Following the electrophoresis, the cylindrical gel was divided in half longitudinally. One half was cut into slices laterally, and the slices were assayed individually for enzymatic activity (A). The other half was stained for protein and then scanned for the resulting absorbance (B). The inset in panel B is a photograph of the stained gel. Reprinted with permission from ref 51. Copyright 1980 American Chemical Society.

Figure 1-21: Staining a polyacrylamide gel for enzymatic activity.¹⁹ Two samples of purified isocitrate dehydrogenase (NADP^+) from the final step on phenyl agarose (Table 1-2) were submitted to electrophoresis on separate lanes of a thin slab of polyacrylamide. After the electrophoresis, the lanes were cut from the slab. One of the lanes (lower) was stained for protein with Coomassie brilliant blue. The other lane (upper) was placed in a solution of isocitrate and NADP^+ . The intrinsic fluorescence of the NADPH produced by the enzyme was observed by illuminating the gel with ultraviolet light. ored, by virtue of a bound chromophore, such as the coenzyme B_{12} associated with D-lysine 5,6-aminomutase,²⁰⁰ and the coelectrophoresis of the purified protein and that color can be observed directly.

Several artifacts can produce misleading results on electrophoresis. For example, **aggregation** of individual molecules of the same protein can occur^{201,202} during

either the purification or the stacking process, and this produces an array of complexes, each with a different frictional coefficient and retardation coefficient. The neutral amides of glutamines and asparagines on the protein can hydrolyze randomly and in low yield during a harsh purification to produce anionic carboxylates, and this **modification** leads to variations in \bar{Z}_i that produce multiple components from the same protein. Because these or other similar modifications are integral processes, the components that result from them are usually evenly spaced upon the electrophoretogram,¹⁷² and the nature of the artifact can be recognized by this pattern.^{201,203,204} Each component, however, should be biologically active if the protein is pure.^{203,204}

Although the coelectrophoresis of the purified protein and the biological activity is the most convincing criterion of purity, occasionally the electrophoresis itself destroys the activity.²⁰⁵ For this reason, or simply for personal satisfaction, other criteria of purity are often used. Immunoglobulins raised against the purified enzyme should behave on **immunodiffusion** and **immuno-electrophoresis** as expected of immunoglobulins directed against a single antigen. It is also encouraging when these immunoglobulins are able to precipitate all of the protein and all of the biological activity^{19,206} but not essential, because some immunoglobulins are ineffective at immunoprecipitation. Activity and protein should **comigrate** on chromatography (Figures 1–6 and 1–10)²⁰⁷ or **cosediment** upon gradients of sucrose.²⁰⁸ Even more convincing is the observation that the single band of protein observed upon electrophoresis of samples from fractions collected from the final chromatographic step increases in intensity and then decreases in intensity in concert with the increase and decrease of enzymatic activity, respectively, across the peak.^{23,104}

The grams of protein for every mole of binding site is between 15,000 and 100,000 g mol⁻¹ for most proteins. The concentration of protein (milligrams milliliter⁻¹) and the concentration of **binding sites** (moles liter⁻¹) for a ligand, such as an agonist or antagonist, known to be specific for a desired protein, such as the respective receptor, can be determined on samples from the same solution. If the ratio of these two quantities lies within the expected range and if only one protein can be discerned on electrophoresis, these observations are taken to be convincing criteria of purity, especially if the value of grams mole⁻¹ agrees with the measured molar mass of the protomer of the protein that has been purified. For example, purified histidinol-phosphate transaminase binds 1 mol of pyridoxal phosphate for every 37,000 g of protein,¹⁹² purified methylmalonyl-CoA mutase contains 1 mol of adenosylcobalamine for every 73,000 g of protein,²⁰⁹ and purified α_1 -adrenergic receptor binds 1 mol of [³H]prazosin for every 69,000 g of protein.³⁴

Isoelectric focusing is a method for assessing purity that is based on electrophoresis. A gel of polyacrylamide is cast from a solution containing a mixture of

polyelectrolytes known as ampholytes. The isoelectric points of the ampholytes in the mixture vary over a continuous range of pH values. Upon application of an electric field, this mixture forms a stable gradient of pH in the gel. Each protein migrates through this gradient until it reaches a pH equal to its isoelectric point where it can no longer move, and the proteins in a mixture are spread upon the field in order of their respective isoelectric points. It is a technique that is less flexible than disc electrophoresis because it separates molecules on the basis of only one property rather than three. It also seems to be more sensitive to minor heterogeneities of charge than is electrophoresis. Because, however, isoelectric focusing detects heterogeneity of charge more successfully than electrophoresis, it is an even more stringent test of the homogeneity of a protein.²¹⁰ The coisoelectrofocusing of protein and biological activity,^{48,206,211–213} is an additional criterion of purity independent from the observation of coelectrophoresis. Isoelectric focusing has been combined with electrophoresis to resolve complex mixtures of proteins in two dimensions.²¹⁴ When the clarified homogenate produced from the cytoplasm of the bacterium *E. coli* was submitted to such a procedure, more than 1000 different proteins were represented upon the field (Figure 1–22).²¹⁴ This display indicates the complexity of the mixture of proteins in a cell. From such a mixture, a single protein with a single biological activity is purified.

Heterogeneity

Often heterogeneity in a preparation of a purified protein, observed as several different proteins capable of being separated, is detected by electrophoresis or isoelectric focusing even though all of the various components are biologically active; often heterogeneity is discovered in later experiments. This heterogeneity may have a biological origin, for example, because of varying levels of glycosylation or phosphorylation, and the various forms of the protein producing this heterogeneity may coexist in the tissue prior to homogenization, but usually the heterogeneity arises during the purification itself. Such heterogeneity is produced by processes that are minimized by avoiding extremes of pH through the use of well-buffered solutions, by working at low temperatures (0–5 °C), and by performing the purification in as short a period of time as possible.

That it is the purification itself producing the heterogeneity often becomes apparent when a new, more rapid, less debilitating method of purification is devised

Figure 1-22: Separation of proteins from the cytoplasm of the bacterium *E. coli* by electrophoresis in two dimensions.²¹⁴ A sample (10 μ g of protein) from a homogenate of the bacteria, grown in the presence of [14 C]amino acids, was submitted to isoelectric focusing (pH 3–10), under conditions where the proteins were unfolded (9 M urea), on a cylindrical (0.25 cm \times 13 cm) gel of polyacrylamide. After the unfolded proteins had reached their respective isoelectric points, the gel was removed from its tube, soaked in a solution of sodium dodecyl sulfate (SDS) to coat the unfolded polypeptides with this anionic detergent, and the cylinder was laid across the top of a flat slab (14 cm \times 16 cm \times 0.3 mm). The unfolded polypeptides separated by isoelectric focusing (IF) in the first dimension were then separated by electrophoresis (SDS) in the second dimension. [14 C]Polypeptides were located by placing the slab on photographic film and exposing the film for a long enough time that the radioactive disintegrations in each spot of protein produced the dark spots seen in the figure. Reprinted with permission from ref 214. Copyright 1975 *Journal of Biological Chemistry*.

for a certain protein, and the heterogeneity noted previously, the subject of many publications, simply disappears. When fructose-bisphosphatase was purified by a shorter method,²¹⁵ the previously studied requirement of the enzyme for alkaline conditions was no longer manifest. When aconitate hydratase was purified by a more rapid procedure,²¹⁶ it was isolated with its iron still attached. When glyceraldehyde-3-phosphate dehydrogenase from yeast was purified rapidly by affinity chromatography,²¹⁷ the heterogeneous behavior in its binding of ligands^{218–220} was no longer observed.

One of the most publicized causes of heterogeneity or artifactual alteration of a protein during its purification is **digestion by peptidases**.^{146,221} Proteins the biological role of which is to degrade other proteins are

known as peptidases. With the exception of a few peptidases that are located in the cytoplasm such as the calpains, which can be inactivated by chelating any free calcium, most of the peptidases capable of degrading the normal, native proteins in a cell are present in inactive forms or are segregated from the cytoplasm of the cell in which they are located or in which they were produced. This segregation is accomplished by enclosing the peptidases in tight, membrane-sealed packages, the lysosomes, or excreting them into the extracellular surroundings. Upon homogenization, the natural boundaries between the cytoplasm and the cellular compartments containing these peptidases are destroyed, and artifactual digestion of the proteins being purified can commence.

Peptidases are not always a problem. Most native proteins are remarkably resistant to digestion by peptidases, and in most instances, proteins can be purified without being digested. **Harsh treatments**, however, such as heat, the use of detergents, and extremes of pH encourage digestion by peptidases, and proteins purified by procedures employing these conditions often display evidence of deterioration. Because a protein can be nicked by a peptidase and remain almost unaltered in its functional and physical properties, the cumulative effects of digestion by peptidases become most obvious when proteins are unfolded and assessed by electrophoresis in solutions of sodium dodecyl sulfate,¹⁴⁶ a technique that is used to catalog the number and lengths of the polypeptides present in a given preparation.

There are four major classes of peptidases,^{222–224} and their properties determine the precautions that can be taken to inhibit them during a purification procedure. **Acid peptidases** are active only at acidic ranges of pH, and if the purification is carried out at neutral or slightly alkaline pH, their action can be avoided. **Sulphydryl peptidases** contain a thiol necessary for activity. If there is a suspicion that sulphydryl peptidases are responsible for the heterogeneity or loss of activity that is observed, they can be permanently inactivated by treating the solutions of protein with iodoacetate, iodoacetamide, or *N*-ethylmaleimide before the purification is initiated and at one or two intermediate stages during the purification. **Metallopeptidases** require transition metal cations or alkaline earth cations and can be inactivated by adding chelating agents such as *N,N,N',N'*-tetracarboxymethyl-1,2-diaminoethane or *o*-phenanthroline. **Serine peptidases** are invariably inactivated by diisopropyl fluorophosphate, but this compound is extremely toxic and dangerous to use. They are sometimes inactivated by phenylmethanesulfonyl fluoride or by chloromethyl ketones of various specificities. As with the inhibitors of sulphydryl peptidases, these reagents inactivate serine peptidases permanently so that solutions of protein need only be treated prior to initiating the sequence of steps in the purification and at one or two intermediate stages. Even when such precautions are taken, it is always wise to perform the purification in as short a time as possible.

There is a vast array of natural and synthetic **inhibitors of peptidases**^{222–224} that are more or less specific for one or several members of a particular class, and many of them are appropriate for preventing the action of unwanted peptidases during the purification of a protein.²²⁵ Some have been used successfully as additives during the purification of proteins. For example, acetyl-CoA carboxylase has been purified from chicken liver in the presence of parotid trypsin inhibitor,²²⁶ and phosphoglycerate dehydrogenase, from the same source in the presence of leupeptin.²²⁷ Often, however, inhibitors of the activity of peptidases are used prophylactically in the absence of any evidence that they are effective.

Crystallization

As in the isolation of a natural product in organic chemistry, the production of a crystalline preparation (Figure 1–23)²²⁸ was once considered to be the final step in any isolation of a protein. Although the time-consuming search for the proper conditions necessary to crystallize a given protein has gone out of fashion, the exhilarating gallery of photographs of crystalline enzymes compiled by Dixon and Webb²²⁹ testifies to the pleasure that such a conclusion to a long purification must inspire.

Crystallization as a method of purification is usually less effective than chromatography. Some examples of crystallization as the last step in a purification are the purification of 1.5-fold seen upon recrystallization of phosphoenolpyruvate carboxykinase (ATP),²³⁰ the purification of 1.4-fold with a 40% yield seen upon recrystallization of acylphosphatase,²³¹ and the 2-fold purification with a 90% yield seen upon recrystallization of nicotinate-nucleotide diphosphorylase (carboxylating).²³² Recrystallization has been observed to eliminate some of the heterogeneous behavior displayed by a purified protein,²³³ presumably due to an increase in its homogeneity.

Crystals of a protein, aside from their intrinsic beauty, are the specimens required to determine the molecular structure of the purified protein by **X-ray crystallography**, and there is considerable interest in crystallizing proteins.²³⁴ For crystallographic studies, single, untwinned crystals of 0.1–1 mm in size are required, and to produce suitable crystals is a process involving a good deal of trial and error. Because of the number of attempts required by this trial and error and because suitable crystals only form in concentrated solutions of the protein, about 10 mg of protein is required. Furthermore, crystals

Figure 1–23: Crystals of α -galactosidase isolated from *Mortierella vinacea*.²²⁸ Homogenates of cells of *M. vinacea* were submitted sequentially to ammonium sulfate fractionation, chromatography by anion exchange on (diethylaminoethyl)dextran, and chromatography by molecular exclusion. The final protein was crystallized from a solution of ammonium sulfate. The largest crystal in the field is about 10 μ m across. Reprinted with permission from ref 228. Copyright 1970 *Journal of Biological Chemistry*.

usually will grow most readily from homogeneous solutions of monodisperse protein, so the preparations used must be as pure as possible. Therefore, it is essential to examine the final protein from the purification by electrophoresis in its native state (not after it has been unfolded with dodecyl sulfate), by isoelectric focusing, and by dynamic light scattering before time is wasted trying to crystallize an inhomogeneous sample. The protein also must have suffered as little damage as possible during the procedures used to purify it. For all of these reasons, proteins purified rapidly in one or two steps from overproducing microorganisms, in which more than 10% of the cellular protein can be the protein of interest, are usually the ideal starting material for crystallizations. The construction of such a microorganism is now usually the first step in an attempt to crystallize a protein for crystallographic studies.

Crystals of proteins suitable for crystallography are produced by slowly and continuously increasing the concentration of both the protein and a solute that promotes crystallization. Any of the solutes, such as ammonium sulfate, poly(ethylene glycol), or trimethylamine oxide, that have negative preferential solvations and cause proteins to precipitate from solution can be used to promote crystallization. Choosing conditions of pH and ionic strength within ranges in which the second virial coefficient of the osmotic pressure of a solution of the protein is negative increases the odds of producing crystals.²³⁵ A solution is prepared of the protein and the solute promoting the crystallization, both at concentrations slightly below those at which precipitation would begin. A drop of this solution (1 μ L) is placed upon a glass cover slip. The cover slip is inverted over a well containing a concentrated solution of some salt or other solute in which the activity of water is less than that in the solution of the **hanging drop**. The system is sealed and left in the cold for several weeks. Slowly, water evaporates from the hanging drop and condenses in the well, and if one is lucky, crystals of protein form in the drop. As this is a rare event, hundreds of hanging drops are made, each with a different pH, ionic strength, or concentration of protein over wells with different solutions in them. Small molecules, for example, substrates or ligands, that are known to bind to the protein are also added to some of the drops in the hope that they might encourage crystallization.

Once the crystals are obtained, a sample of them should be dissolved and the protein that they contain submitted to electrophoresis to be certain that it is the one desired rather than a contaminant in that preparation that happened to crystallize while the desired protein did not.²³⁶

Chapter 2

Electronic Structure

When proteins are submitted to chemical analysis, they are found to be composed of 20 amino acids: aspartic acid, asparagine, threonine, serine, glutamine, glutamic acid, proline, glycine, alanine, cysteine, valine, methionine, isoleucine, leucine, tyrosine, phenylalanine, lysine, histidine, tryptophan, and arginine. Each protein has different relative amounts of each of these amino acids. The amino acids a protein contains are coupled together in a particular order to create polymers 50–5000 amino acids in length, referred to as polypeptides. To understand the structure of molecules of protein, one must understand the amino acids, the order in which they are connected, and the way that these long polymers are folded up to produce the native conformation of the molecule. The first level of understanding is grounded in a firm knowledge of the bonding and molecular structure of small molecules. The second level of understanding requires a description of the complete covalent structure of the polymers composing proteins. The third level of understanding proceeds from crystallographic molecular models of proteins that are the products of X-ray crystallography.

It is remarkable that each molecule of a particular protein, if it has not been heterogeneously posttranslationally modified, has the same covalent structure and that when it is in its natural environment, the polypeptides from which it is composed assume the same few conformations even though the complete molecule of the protein is large. These two properties are foreign to a synthetic chemist. Molecules produced synthetically are either precise but small or large but heterogeneous. Large heterogeneous polymers produced synthetically seldom have defined structures. Yet a molecule of protein is made from atoms held together by the same covalent chemical bonds holding together the smaller molecules to which one is already accustomed. All of the rules of bonding exerted with such inescapability in small molecules are as inescapable in a molecule of protein.

The covalent bonds holding the atoms together in any molecule are pairs of electrons confined to molecular orbitals. The molecular orbitals are either localized σ molecular orbitals or delocalized π molecular orbitals. A distinction between these two types of molecular orbitals is crucial to an understanding of bond lengths, bond angles, and rotational motions about bonds.

In addition to the covalent bonds, molecules of pro-

tein are filled with lone pairs of electrons. Because σ lone pairs of electrons are the only valence electrons that do not participate in covalent bonds and because there are also lone pairs of electrons participating in π molecular orbitals, to understand the details of molecular structure one must be able to distinguish localized σ lone pairs of electrons from delocalized π lone pairs of electrons. The distinction between these two types of electrons is reflected in their basicity, their ability to house a proton.

Each lone pair of electrons in a molecule is a potential base, and each hydrogen in a molecule is a potential acid. Which lone pair will act as a base is determined by the acid dissociation constant for its conjugate acid, and which hydrogen will act as an acid is determined by its own acid dissociation constant. Every lone pair is basic and every hydrogen is acidic, but most lone pairs are such weak bases and most hydrogens are such weak acids that their basicity or acidity can be ignored. To understand the atomic structure of a molecule of protein, the significant acids and bases within it must be identified and categorized. It is also necessary to distinguish an acid dissociation, in which a proton leaves the molecule, from a tautomerization, in which protons redistribute among lone pairs of electrons within the molecule.

The chemical capacities available to a protein are a reflection of the amino acids from which it is constructed. Each of the 20 amino acids has its own peculiar set of chemical capacities. These are mixed in a unique way by the amino acid sequence and the resulting native structure to produce those of the particular protein, but to understand the mixture, the properties of the ingredients must be understood. These properties include the bonding and acid–base behavior of each of the 20 side chains of the amino acids. With the exception of the regular polyamide backbone of the polymer, the covalent bonds, acidic hydrogens, and basic lone pairs of electrons that fill a molecule of protein are contributed by these side chains.

π and σ

Molecules, including proteins, are arrays of atomic nuclei required to maintain particular distances and angular dispositions relative to each other by electrons confined to particular regions of space known as

orbitals. Every electron in a molecule is confined to a specific orbital, and almost every orbital is occupied by two electrons. Each orbital is either confined exclusively to one nucleus or distributed between or among particular nuclei. The electrons, in their occupation of these orbitals, create the covalent structure of the molecule. The electrons present in a molecule can be divided into three categories, core electrons, π electrons, and σ electrons, that reflect the degree to which they are confined and that define their chemical reactivity.

Core electrons are the electrons that are immediately adjacent to a nucleus. Aside from hydrogen, almost all of the atoms present in molecules of protein are either carbon, oxygen, or nitrogen. Each of these atoms has two core electrons spherically confined about the nucleus. Occasionally, sulfur or phosphorus occurs in a protein, and these atoms each have 10 core electrons. Because they are confined close to the nucleus, the core electrons provide the greatest electron density and are the prominent features in a map of electron density. They are, however, chemically inert.

Valence electrons are the outermost electrons surrounding each atom. All of the chemistry of a molecule, which is the consequence of its chemical bonds and its sites of reactivity, results from these valence electrons. Unless one electron is missing, as in the case of a radical, or two electrons are momentarily missing, as in a carbocation, every carbon, nitrogen, oxygen, sulfur, or phosphorus in a molecule of protein can be formally associated with eight valence electrons. By convention, these octets are assigned by Lewis structures. This formalism divides valence electrons into **bonding electrons** and **lone pairs of electrons** and assigns **formal charge** to certain atoms. An example would be the Lewis structure of the model compound for glutamic acid in a polypeptide, *N*-acetylglutamate α -amide (Figure 2-1A). The intent of a Lewis structure is to count valence electrons.

A pair of bonding electrons occupies a **bonding molecular orbital** that is formed from the overlap of two or more atomic orbitals, each contributed by a different atom in the molecule. These bonding electrons must be clearly distinguished as occupants of either π molecular orbitals, forming π bonds, or σ molecular orbitals, forming σ bonds.

The overlap of two or more adjacent and parallel p atomic orbitals on two or more adjacent atoms in a molecule creates a **system of π molecular orbitals**. Two adjacent p atomic orbitals can overlap only above and below the line of centers between the two atoms from which they are contributed (Figure 2-2). This geometry has two consequences: it prevents rotation about axes connecting the nuclei of adjacent atoms and it permits a series of overlaps to occur simultaneously. Because rotation is prevented, structures containing a system of π molecular orbitals are rigid. The fact that a series of overlaps can occur permits the electrons occupying a system of π molecular orbitals to be delocalized.

Figure 2-1: Two ways of representing the electronic structure of *N*-acetylglutamate α -amide. (A) In the Lewis dot formula, each main atom is surrounded by an octet of electrons and the total number of electrons represented equals the sum of the number of valence electrons contributed by each neutral atom plus the elementary molecular charge. The negative sign surrounded by a circle locates formal charge. (B) In a σ - π stereochemical representation distinguishing types of electrons, a σ bond is designated by a line, a localized σ lone pair of electrons is designated by two dots surrounded by a circle, a π bond is indicated by a second or third line between two atoms, and a π lone pair of electrons is shown by two uncircled dots. The atoms are arranged in space to represent the tetrahedral or trigonal geometry dictated by their respective hybridizations.

Delocalization of a pair of electrons occupying one π molecular orbital in such a system results from the fact that each π molecular orbital is a linear combination of the p orbitals that overlap. Each π molecular orbital is spread over and shared by every atom that contributed a p orbital to the system unless a node is located at that atom. When a pair of electrons occupies a π molecular orbital, it cannot be assigned to a particular atom, notwithstanding the formal requirement of the Lewis dot structure that it be so localized for the purposes of book-keeping. Confusion between actuality and accounting sometimes leaves the impression that π electrons are localized.

An example of a combination of p atomic orbitals is the system of π molecular orbitals that forms when four parallel p orbitals mix (Figure 2-2). The number of π molecular orbitals that result from any combination of this type is always equal to the number of p orbitals that have mixed; in this case there are four π molecular orbitals in the system. Each p orbital can be mixed in one of two **phases**, and adjacent p orbitals can be either in phase, in which case they overlap—a favorable interaction—or out of phase, in which case a node—an unfavorable interaction—occurs between them. A **node** is a position at which the phase inverts. In a linear system such as the one shown in Figure 2-2, the number of nodes increases by one for each molecular orbital in the series.

Each of these four π molecular orbitals in Figure 2-2 has an **energy level** associated with it that is equal to the energy one electron would experience were it confined

Figure 2-2: A π molecular orbital system formed by the combination of four parallel p atomic orbitals on four adjacent atoms held together by three σ bonds. The four p orbitals overlap, and four linear combinations of these four atomic orbitals, the four π molecular orbitals, are permitted. In the combination of lowest electronic energy, all four p orbitals overlap in phase (indicated arbitrarily with + and -). In each of the higher π molecular orbitals, nodes are present, on either side of which the constituent p orbitals have opposite phase so overlap is antibonding. The four individual π molecular orbitals are arranged in order of increasing electronic energy from bottom to top. In all linear π molecular orbital systems, such as the one represented, the number of nodes increases by one upon moving to the next higher energy level. The nodes are evenly distributed from one end of the structure to the other. In this π molecular orbital system formed from four p atomic orbitals there are usually four electrons occupying the two π molecular orbitals of lowest energy. The sizes of the atomic orbitals approximately represent the magnitude of their contribution to each π molecular orbital.

within that orbital. In a π molecular orbital system formed entirely from p orbitals on atoms of the same element, such as that of the four carbon atoms of butadiene or that of the six carbon atoms in benzene, these energy levels are distributed symmetrically above and below the potential energy an electron would have in one of the isolated p orbitals from which the system has been created. The more nodes the molecular orbital has, the higher its energy and the less likely that an electron will occupy it. A π molecular orbital is designated as

bonding, nonbonding, or antibonding depending on whether its energy level is less than, equal to, or greater than the energy level of an isolated p orbital, respectively. If the π molecular orbital is bonding, the equivalent of a covalent bond is formed because a pair of electrons has a lower energy in the molecular orbital than it would have were it split between two isolated atoms. In π molecular orbital systems formed from three or more parallel p orbitals, that covalent bond is spread over the atoms contributing the p orbitals, notwithstanding the impression often left by the Lewis structure that it is the second localized bond in a double bond.

The general structure of each π molecular orbital is determined only by the number of p orbitals that have mixed together and their connectivity; however, the nature of the atom—carbon, nitrogen, or oxygen—that has contributed each of the p orbitals does affect the shape and energy of the molecular orbital through coulomb effects. These effects are most easily understood as perturbations of the symmetric π molecular orbital system that would be formed from the same number and arrangement of carbon atoms by the fact that some of the atoms are of other elements. A **coulomb effect** is the distortion of the system of symmetric π molecular orbitals that would exist if all of the atoms were carbons. It is caused by the electronegativity and electron deficiency of the atom other than carbon that the π molecular orbital system actually contains. A coulomb effect causes the region of a bonding or nonbonding π molecular orbital over a more electronegative atom, such as oxygen, or a more electron-deficient atom, usually nitrogen, to swell at the expense of the region or regions over the less electronegative atoms, usually carbons.

The number of π molecular orbitals in a given system is determined solely by the number of p orbitals that have been mixed together, but the number of those molecular orbitals that are occupied by pairs of electrons is determined by other properties of the molecule as well. The two decisions, how many p orbitals have combined and how many π electrons have occupied the system of π molecular orbitals, are made by examining all valid **resonance structures** for the molecule. Drawing resonance structures is nothing more than making this decision. Any electrons that are active participants in resonance have been explicitly designated as π electrons by the person who drew those resonance structures, and any atom the bonding of which changes among the resonance structures has been explicitly designated as an atom that has contributed a p orbital to the system of π molecular orbitals. All double and triple bonds in a molecule are necessarily participants in systems of π molecular orbitals.

The **amide**, which is of wide biochemical relevance, is a simple example of this process of designation (Figure 2-3). The chemical properties of an amide are usually explained by drawing two resonance structures.¹ These

two resonance structures state that each of the three atoms, the oxygen, the carbon, and the nitrogen, contributes a p orbital to the system of π molecular orbitals because their bonding changes between the two Lewis structures of the resonance pair. The resonance structures state that the system of π molecular orbitals contains four π electrons because two of the pairs of electrons shift between the two structures. When three adjacent p orbitals are mixed, three π molecular orbitals are created (Figure 2-3). That four electrons occupy these three molecular orbitals places one pair in each of the two molecular orbitals of lowest energy. If coulomb effects are disregarded for the moment, the two electrons

Figure 2-3: Electronic structure of an amide. In the upper left quadrant of the figure the two resonance structures for the amide are presented. The molecular orbital system in the center of the figure is formed from the linear combination of three p atomic orbitals: one from nitrogen, one from carbon, and one from oxygen. They are combined to produce three π molecular orbitals presented in order of increasing energy. To emphasize the symmetry of these π molecular orbitals, they have been drawn as if there were no coulomb effect. In the combination of lowest energy, all three of the constituent p orbitals overlap in phase. In linear π molecular orbital systems with an odd number, n , of atoms, the number of nodes in the central nonbonding molecular orbital is equal to $\frac{1}{2}(n - 1)$. To achieve a symmetric distribution of nodes in the central nonbonding molecular orbital, there are lobes on the two end atoms and nodes on every other atom in between, alternating lobe, node, lobe, node, and so forth. In the idealized three-atom system displayed here, there is a lobe at nitrogen, a node at carbon, and a lobe at oxygen in the central nonbonding π molecular orbital.

in the lowest bonding level would have half of their density distributed over carbon, one-quarter over oxygen, and one-quarter over nitrogen. The two electrons in the middle nonbonding level would have half of their density distributed over nitrogen and half over oxygen.

If the four π electrons were removed from the three atoms of the amide, the carbon and the oxygen would each have formal charges of +1 but the nitrogen would have a formal charge of +2, making it electron-deficient relative to the other two. If two pairs of π electrons occupy the two undistorted π molecular orbitals of lowest energy, oxygen would end up with a formal charge of $-\frac{1}{2}$; carbon, 0; and nitrogen, $+\frac{1}{2}$. This is the distribution of charge designated by the two resonance structures. Usually the resonance structures provide information about the distribution of electrons in the **highest occupied molecular orbital** or the distribution of electron deficiency in the **lowest unoccupied molecular orbital**. In the case of the amide, the resonance structures indicate that the pair of electrons in the highest occupied molecular orbital can occupy locations only over the nitrogen and the oxygen. This example illustrates the fact that resonance structures and molecular orbitals should agree in their assessment of electron distribution.

In Figure 2-3 and the description just presented, it was assumed that there was no coulomb effect; in other words, that all three atoms in the σ structure had the same electronegativity and formal charge. In a real amide, oxygen is the most electronegative atom and nitrogen is electron-deficient. The resulting coulomb effects cause the bonding molecular orbital of lowest energy to be skewed so that oxygen ends up with more electron density than carbon, rather than less, and the nonbonding molecular orbital of intermediate energy to be skewed so that nitrogen ends up with more electron density than oxygen. The node at carbon in the ideal nonbonding π molecular orbital shifts toward oxygen or toward nitrogen depending on whether or not the oxygen is hydrogen-bonded.²

Resonance theory has always incorporated the fact that the several structures drawn do not have independent existence, but occasionally, by mistake, it is implied that they do.³ In the extreme, the **double-headed arrow** of resonance becomes replaced with the two arrows of a chemical equilibrium, a mistake that engenders serious confusion.⁴ To avoid such confusion, a double-headed arrow should be used only to indicate resonance, never to indicate an equilibrium, and the two arrows of a chemical equilibrium should never be used to indicate resonance. That only one, undivided system of π molecular orbitals represents the resonance hybrid is a reaffirmation of the absence of independent existence. Unfortunately, while π molecular orbitals present a more accurate picture of the molecular structure and avoid the confusion with equilibrium, they do not have the accounting capability of formal resonance structures,

and each view, whether molecular orbitals or resonance structures, has its appropriate use.

The first decision that must be made about the electronic structure of any molecule is the location of all systems of π molecular orbitals. Any carbon, nitrogen, or oxygen that has contributed a $2p$ atomic orbital to a system of π molecular orbitals has only two other $2p$ atomic orbitals remaining to hybridize with its lone $2s$ atomic orbital, but any carbon, nitrogen, or oxygen that is not involved in a system of π molecular orbitals has three $2p$ atomic orbitals to hybridize with its $2s$ atomic orbital. It is these hybrids between s atomic orbitals and p atomic orbitals that overlap to form **σ bonds**. These σ bonds lie along the line of centers between the two respective atoms that they connect, and they are localized. Because they are localized, they are usually stronger covalent bonds than π bonds, and as a result every pair of atoms joined by one or more than one covalent bond must be joined by one σ bond. These σ bonds form the molecular skeleton defining the structure of the molecule, in particular its bond angles. This skeleton is the **σ structure** of the molecule. Each σ bond is also an occupied molecular orbital, but this realization is not informative in issues of molecular structure. In the particular instance of molecules in biological situations, when an atom has contributed one p orbital to a system of π molecular orbitals, it will almost always be hybridized [p , sp^2 , sp^2 , sp^2]. At that atom in the σ structure, the molecule will be planar, and the σ covalent bonds and σ lone pairs will radiate within that plane in three directions from the atom at approximately 120° angles. When an atom has not contributed a p orbital to a system of π molecular orbitals, it will almost always be hybridized [sp^3 , sp^3 , sp^3 , sp^3]. At that atom in the σ structure, σ covalent bonds or σ lone pairs will radiate in four directions tetrahedrally, at angles of approximately 109.5° .

Because the σ structure incorporates these bond orders and bond angles, it dictates the details of molecular structure. These details cannot be appreciated until decisions on hybridization can be made correctly. To pursue an earlier example, the oxygen, carbon, and nitrogen of an amide are each contributing a p orbital to the system of π molecular orbitals, and each is hybridized [p , sp^2 , sp^2 , sp^2]. In the σ structure each of these three atoms and all of the σ bonds and σ lone pairs of electrons radiating from them are in a plane, and each bond angle is approximately 120° (Figure 2-3).

Lone pairs of electrons are identified by writing a Lewis structure of the molecule. Thereafter, it is conventional to ignore them, on the assumption that everyone knows that they are there. This assumption is somewhat vain; it seems to say that if you do not always realize that they are there, you are not someone. Because lone pairs of electrons are of paramount importance in biochemistry and because an understanding of a biologically important molecule is incomplete if ever they are forgotten, it is safer to include them explicitly in any structure

drawn, especially if they contribute to what is being discussed.

Because of electron repulsion, a lone pair of electrons on any oxygen or nitrogen unconjugated to a system of π molecular orbitals will occupy one of the sp^3 orbitals of that atom. This σ lone pair of electrons resides at one of the tetrahedral vertices of the atom. A **σ lone pair of electrons** is a lone pair confined to a single atom because it resides within a hybridized or unhybridized atomic orbital that does not overlap with any other atomic orbital from another atom. A σ lone pair of electrons is designated in a σ - π stereochemical representation by enclosing it within a circle (Figures 2-1B and 2-3) to symbolize its confinement. A **σ - π stereochemical representation** (Figure 2-1B) is a drawing of the molecule that indicates the bond angles and angles of σ lone pairs and distinguishes σ lone pairs of electrons from π lone pairs of electrons.

If an oxygen or nitrogen containing a lone pair of electrons is sterically able to rotate until that lone pair is parallel to an immediately adjacent system of π molecular orbitals and sterically able to rehybridize to sp^2 at its three remaining bonded positions, the lone pair of electrons is capable of entering the system of π molecular orbitals. For the lone pair of electrons to do this, the atom carrying it must rehybridize. This rehybridization requires sufficient energy to overcome the electron repulsion that originally placed the lone pair in an sp^3 orbital. The favorable energy resulting from the delocalization of the lone pair into the system of π molecular orbitals must exceed this deficit. If it does, the lone pair of electrons becomes a delocalized **π lone pair of electrons**, occupying a π molecular orbital spread over two or more atoms. It is so designated in a drawing by not enclosing it within a circle (Figures 2-1B and 2-3) to indicate its unconfinement.

When either oxygen or nitrogen has contributed only one of its p orbitals to a system of π molecular orbitals and is left with three valence orbitals, one $2s$ orbital and two $2p$ orbitals, it is usually assumed that they mix to form three sp^2 orbitals that lie together within a plane normal to the system of π molecular orbitals and are arrayed at 120° angles. If there are two or three covalent σ bonds to the heteroatom, the hybridization is usually [p , sp^2 , sp^2 , sp^2] because sp^2 orbitals provide maximum overlap in a σ bond. Thus a single lone pair left on a nitrogen that has contributed only one p orbital and one of its valence electrons to a system of π molecular orbitals and also participates in two σ bonds is always a σ lone pair in an sp^2 orbital, and it is designated as such by surrounding it with a circle. An example of such a lone pair is the lone pair on a nitrogen in an imine:

2-1

The situation becomes ambiguous, however, in the case of an oxygen that has contributed a p orbital and one valence electron to a system of π molecular orbitals, participates in one σ bond, and remains with two lone pairs of electrons. An example of such an oxygen would be an **acyl oxygen** or the oxygen of a carbonyl (Figure 2–4). The possibility arises that such an oxygen is hybridized [p, p, sp, sp]. In this case, one lone pair would occupy an sp orbital in line but opposite to the σ bond between the carbon and the oxygen, and the other lone pair would occupy a p orbital normal to both the π bond and the axis of the two sp orbitals (Figure 2–4A). Indeed, there is evidence from ultraviolet spectra and mass spectra of isolated carbonyl compounds that this occurs. The alternative possibility is that oxygen is hybridized [p, sp^2, sp^2, sp^2] and that both lone pairs are in sp^2 orbitals (Figure 2–4B). The decision between these two alternatives is not an insignificant one, for oxygens that have contributed one p orbital and one valence electron to a system of π molecular orbitals and participate in only one σ bond are by far the majority of the oxygen atoms in a molecule of protein. In a hydrogen-bonding environment, such as the water in which all biochemistry occurs, it appears that these oxygens place their two lone pairs in two sp^2 orbitals. This follows from the fact that, in crystallographic molecular models of small molecules in which an N–H forms a hydrogen bond with such a carbonyl or acyl oxygen, the nitrogen–hydrogen σ bond of the N–H usually points to the location where an sp^2 lone pair of electrons would be located.⁵ On the basis of this observation, it will be assumed that acyl oxygens are hybridized [p, sp^2, sp^2, sp^2], and their two lone pairs will both be designated as sp^2 by enclosing them in circles at 120° angles to the carbon–oxygen bond (Figure 2–1B).⁶ These are σ lone pairs of electrons, they lie within a plane shared with the carbon–oxygen σ bond and normal to the plane of the carbon–oxygen π bond (Figure 2–4B).

The σ structure of a molecule is the basic skeleton producing the σ bonds, the bond angles, and the fixed positions of the localized σ lone pairs. The π electrons are spread over this skeleton above and below the atoms contributing the p orbitals. Therefore, neither the bond angles of the molecule, which are defined by hybridiza-

tion, nor the positions of σ lone pairs, which are localized, can be affected by resonance. It necessarily follows that when one draws two or more resonance structures, one must make certain that the same σ structure is present in each resonance structure and that only the disposition of π electrons differs among them. The best way to ensure this is to draw a σ structure for the second resonance structure identical to the σ structure of the first resonance structure before putting in the π electrons, and to draw an identical σ structure for each of the successive resonance structures before putting in the π electrons. Always include all σ lone pairs oriented as the hybridization of each atom requires. After the set of valid resonance structures has been exhausted, look closely at any lone pair that did not participate and decide if it might not be a σ lone pair. If it is not completing an aromatic complement or being withdrawn by an adjacent π bond, it is probably a σ lone pair in a σ orbital confined to only the one atom.

When the atoms contributing the p orbitals to a system of π molecular orbitals form an unbroken ring rather than being branched or linearly arrayed, the possibility of aromaticity arises. In a continuous **ring of p orbitals** of any size, the energy levels of the individual π molecular orbitals are arrayed in a peculiar pattern. The π molecular orbital with the lowest energy is always the completely overlapping ring of p atomic orbitals in phase with no nodes other than the one at the nuclear plane. This π molecular orbital is occupied by two electrons. If coulomb effects were disregarded, the other bonding π molecular orbitals in the ring would always come in pairs that have identical energies. Because of Hund's rule, no such pair of orbitals can be filled with electrons to form a stable closed shell until four electrons have been provided simultaneously. These two features, the one continuous ring occupied by a pair of π electrons and the pairs of orbitals of higher energy occupied by quartets of π electrons, define an aromatic system of π molecular orbitals. An **aromatic π molecular orbital system** is an unbroken ring of parallel p orbitals occupied by 2, 6, 10, 14, or 18 π electrons.

From these rules it is clear that a phenyl ring is aromatic, but it is the **aromatic nitrogen heterocycles** such as pyridine and pyrrole

Figure 2–4: Two alternative hybridizations for an oxygen in a carbonyl. (A) One lone pair is in an sp orbital collinear with the carbon–oxygen bond, and the other is in the p orbital orthogonal to the double bond. (B) Both lone pairs are in sp^2 orbitals in the σ plane.

that are more interesting examples. Pyridine is a neutral, six-membered ring with one nitrogen. Each carbon contributes one valence electron to the π system, so nitrogen can contribute only one to complete the sextet of the

aromatic system. This leaves a neutral nitrogen with two remaining valence electrons that end up as a lone pair in the σ structure confined to an sp^2 orbital. Pyrrole, however, is a five-membered ring. Each carbon again contributes one valence electron to the system of π molecular orbitals, and nitrogen provides the two required to complete the sextet required for the aromatic system. Nitrogen is left with one valence electron and forms a covalent N–H bond to finish the neutral molecule. Pyridinyl and pyrrolyl nitrogens appear throughout aromatic heterocycles. A nitrogen can be identified as one or the other by whether one or two of its valence electrons are used to complete the aromatic system of 6, 10, 14, or 18 π electrons.

An interesting heterocycle that serves as an example of the application of these considerations is porphine:

This is the simplest porphyrin; more elaborate porphyrins are components of the heme-containing coenzymes. Hidden within this molecule is an unbroken ring of 16 carbon atoms and two nitrogen atoms, each contributing a p orbital and creating a system of π molecular orbitals containing 18 π electrons. Therefore, porphine is aromatic. For this to be possible, two of the nitrogens must be pyridine nitrogens and each of them contributes a p orbital and one π electron. The other two nitrogens do not participate in the aromatic ring but nevertheless reside immediately adjacent to it and inside of it. They each retain a lone pair of electrons. Each of those lone pairs resembles the π lone pair on the nitrogen of aniline, but each is located endocyclically rather than exocyclically. This requires that each of them, as with the nitrogen in aniline, have three covalent σ bonds, hence the two central hydrogens.

Behind the distinctions among systems of π molecular orbitals, σ bonds, and σ lone pairs is the concept of **orthogonality**. Each system of π molecular orbitals, each σ bond, and each σ lone pair of electrons is orthogonal to every other system of π molecular orbitals, σ bond, and σ lone pair in the molecule. As such, to a first approximation, each is an independent moiety that does not share electrons with the others. It is this compartmental quality of bonding that permits each of these positions to be chemically distinct and have its own properties. It is this fact, rather than a desire to categorize, that renders these distinctions important. They must be clearly made in any drawing of the molecule.

The chemical properties of σ and π lone pairs of electrons are remarkably different. This difference is most clearly expressed in their behavior as bases, and it is the basicity of a lone pair of electrons that, in questionable cases, indicates whether it is a σ or π lone pair of electrons. When the basicity of the lone pair is relied upon as a criterion, a proton is being used to probe its availability. Lone pairs of electrons in π systems are far less basic than those in σ orbitals because σ lone pairs of electrons are localized and directionally oriented by the atomic orbital in which they are confined, whereas π lone pairs of electrons are delocalized and immersed within the system of π molecular orbitals.

Problem 2-1: Draw σ - π stereochemical structures as in Figure 2-1B for the *N*-acetyl α -amides of aspartate, asparagine, glutamine, proline, methionine, tyrosine, tryptophan, phenylalanine, histidine, and arginine.

Problem 2-2: The following skeleton structures are various heterocycles. None is intended to be a radical, all have pairwise filled molecular and atomic orbitals, and none has a total of more than one positive or negative elementary charge. No π electrons or lone pairs of electrons are shown, and all atoms are shown. All of the compounds are aromatic.

- Decide how many π electrons each heterocycle contains to make it aromatic.
- Draw resonance forms that indicate the distribution of these π electrons. There may be only one.
- Complete the octet for every nitrogen and oxygen by adding lone pairs.
- Assign formal charges in each resonance form.
- Draw the σ structure of each heterocycle, including all lone pairs, and assign hybridization to each atom.

Acids and Bases

The quantitative measure of the basicity of a lone pair of electrons is the microscopic acid dissociation constant of its conjugate acid. In this way all lone pairs of electrons are related to the lone pair on a molecule of water. The reaction that defines a **microscopic acid dissociation** for a particular proton in a molecule is

The **central atom** in a microscopic acid dissociation is the atom directly bonded to the proton that dissociates.* The lone pair on the resulting conjugate base is usually localized on the central atom (as represented in Reaction 2-1) when it is oxygen, nitrogen, or sulfur but usually delocalized when it is carbon. In a microscopic acid dissociation, the **acid** is a position within the molecule from which a proton can dissociate to produce a lone pair of electrons, and the **base** is a lone pair of electrons with which a proton can associate. Because the reaction occurs in aqueous solution, a bare proton is transferred between the lone pair of the base and a lone pair on a molecule of water and back again. Every acid is always present in solution with a finite concentration of its conjugate base, and every base is always present in solution with a finite concentration of its conjugate acid.

The equilibrium constant for Reaction 2-1 is

$$K_{\text{eq}} = \frac{[\text{H}_3\text{O}^+][\text{X}]}{[\text{H}_2\text{O}][\text{HX}]} \quad (2-2)$$

Because $[\text{H}_2\text{O}] = 55 \text{ M}$ at all times, this term is passed to the left, and for convenience $[\text{H}_3\text{O}^+]$ is written as $[\text{H}^+]$.** These substitutions produce the definition of the microscopic acid dissociation constant:

$$K_a \equiv \frac{[\text{H}^+][\text{X}]}{[\text{HX}]} \quad (2-3)$$

A **microscopic acid dissociation constant** is the acid dissociation constant of a particular proton in a polyprotic acid. An acid dissociation constant is usually presented as a $\text{p}K_a$, where $\text{p}K_a \equiv -\log K_a$, solely for convenience. A theoretical justification of this practice is that the $\text{p}K_a$ is directly proportional to the change in free energy for Reaction 2-1. The larger the $\text{p}K_a$, the less likely is

Reaction 2-1 in the direction written and the more likely is it in the opposite direction. Because water is the same in all acid dissociations, the difference in $\text{p}K_a$ between two acids is proportional to the free energy for transferring a proton from the one acid to the conjugate base of the other. The smaller the $\text{p}K_a$, the more acidic is the acid and the less basic, or less available, is the lone pair of electrons on its conjugate base, and vice versa. There are several properties of the position from which the proton dissociates that affect the value of its microscopic $\text{p}K_a$.

The atomic number of the central atom from which the proton dissociates and on which the lone pair remains has a profound effect (Table 2-1). Within the same period of the periodic table, as **electronegativity** increases to the right, for example, carbon, nitrogen, oxygen, the atom is more capable of supporting the lone pair, and the acidity increases. Atoms in lower periods hold a lone pair of electrons in a larger atomic orbital, making it easier to support. For example, a proton on sulfur is more acidic than one on oxygen. Because a localized σ lone pair of electrons on carbon is such a strong base, the only time that there is a lone pair associated with carbon in biochemical situations is when it is a delocalized π lone pair of electrons. Because nitrogen and oxygen are more electronegative elements than carbon, delocalized π lone pairs of electrons associated with these elements are rarely bases in biochemical situations, and bases on these atoms are almost always localized σ lone pairs of electrons.

The **successive creation of negative elementary charge** on the same polyprotic acid causes each dissoci-

$\text{p}K_a = 7.7$		$\text{p}K_a = 9.1$	$\text{p}K_a = 9.7$

* The central atom is not in the center of the molecule; it is just the atom that is central to the acid dissociation.

** In fact, the designation H_3O^+ is as misleading as H^+ because the dissociated proton in water is shared by four molecules of water^{7,8} as the cation H_9O_4^+ to 21 molecules of water^{9,10} as the cation $\text{H}_{43}\text{O}_{21}^+$.

ation of a proton to be more difficult than the previous one, and the successive creation of positive charge on the same polybasic molecule causes each association of a proton to be more difficult than the previous one (Table 2-1). The farther apart the charges that are created, however, the narrower are the increments in pK_a . For example, the difference in the two values of pK_a for 1,3-diaminopropane (1.98) is smaller than the difference in the two values of pK_a for 1,2-diaminopropane (2.87).

The **hybridization** of the central atom affects its pK_a considerably (Table 2-1). All localized σ lone pairs of electrons are in hybrid orbitals formed by mixing one s orbital with one, two, or three p orbitals, as indicated by the designations sp , sp^2 , and sp^3 , respectively. The fewer the number of p orbitals in the mixture, the greater the fraction of the s orbital distributed into each hybrid and the more s character the hybrid will have. The more s character there is to the orbital, the closer the lone pair of electrons is held next to the nucleus, the less extension of electron density along any particular axis will be displayed, and the less basic will be the orbital.

Electronegative or electropositive atoms adjacent to the central atom also have a significant but less remarkable effect on acidity (Table 2-1). These withdraw or donate electrons by **induction** through σ bonds and decrease or increase the basicity of the lone pair of electrons accordingly.

Because the conjugate acid has a single, σ covalent bond between the central atom and the hydrogen, the pair of electrons that has been protonated in its creation must already be or must become σ electrons. If they were a σ lone pair of electrons before the proton was added, **rehybridization** of the central atom is not usually involved in the protonation. If, however, they were a π lone pair of electrons prior to the protonation, the favorable delocalization energy that they gained within the π system is eliminated as the σ bond is formed. The greater this delocalization energy, the more free energy will be required to protonate the lone pair of electrons and, because this free energy is supplied by the concentration of protons, the smaller will be the pK_a of the conjugate acid. It is this fact that causes the pK_a of the conjugate acid to register the **degree of delocalization** of a pair of π electrons or in other words the strength of their π character. This ability is most clearly exemplified in the protonation of aromatic compounds where the lone pair of electrons is delocalized over the aromatic ring. For example, cyclopentadiene is a strong carbon acid¹¹

compared to propane ($pK_a = 50$)¹¹ because protonation of the lone pair of electrons on the conjugate base of the former destroys the aromaticity of the anion. Likewise, *N*-methylpyrrole is a weak base¹²

compared to *N*-methylazacyclopentane¹²

because protonation of the former destroys its aromaticity. In this case, the comparison is a minimum estimate of the difference in pK_a resulting from aromatic delocalization because pyrrole protonates on carbon rather than on nitrogen. The pK_a for the conjugate acid protonated on nitrogen must be much lower than -2.9 .

There are lone pairs of electrons in nonaromatic configurations, the acid-base behavior of which reveals the degree of their π character. The pK_a associated with the lone pair of electrons on aniline ($pK_a = 4.6$)¹² can be compared with the pK_a associated with the lone pair of electrons on cyclohexylamine ($pK_a = 10.6$).¹² The significant difference in basicity demonstrates that the lone pair in aniline is a π lone pair of electrons conjugated to the neighboring π system of the phenyl ring. The pK_a ($pK_a = -6$)¹⁴ associated with the lone pair of electrons on the nitrogen in an amide (Figure 2-3) is even lower than that of the lone pair on aniline and indicates that it is even more delocalized. This is not surprising since the phenyl ring of aniline is otherwise involved in its own aromaticity and the oxygen of the amide has a strong coulomb effect in the lowest occupied molecular orbital.²

Other examples of the use of a proton to evaluate the π character of a lone pair of electrons occur in carbon acids. The pK_a of a methyl group in propene ($pK_a = 43$)¹¹ is much lower than that in propane ($pK_a = 50$)¹¹ because the lone pair produced upon the dissociation of a proton from propene conjugates with the neighboring π system of the alkene. The analogous lone pair on carbon in the conjugate base of acetaldehyde ($pK_a = 17.6$)¹⁵ is even less basic because, as occurs with an amide, an oxygen is located two atoms away and exerts a strong coulomb effect. When the π system of the conjugate base is extended from three to five atoms in length, as in the conjugate base of 2,4-dioxopentane ($pK_a = 9$), the lone pair of electrons in the conjugate base becomes even more delocalized and less accessible to protonation.

In making such comparisons, care must be taken to avoid confounding the reasons for the changes in pK_a . A common confusion is that between the effects of hybridization and conjugation. One reason that the acetate anion, the conjugate base of acetic acid ($pK_a = 4.75$),¹² is a weak base compared to the ethoxide

anion, the conjugate base of ethanol ($pK_a = 16$),¹² is that the basic lone pairs of electrons in the acetate anion are hybridized sp^2 (Figure 2-5) rather than sp^3 . The system of π molecular orbitals of the acetate anion, composed of four π electrons in a three-atom system (Figure 2-3), does not provide a pair of electrons to be protonated, notwithstanding any drawing suggesting this to be the case. It is a σ lone pair of electrons orthogonal to the system of π molecular orbitals that is protonated, and acetate anion cannot be used as an example of the decrease in basicity that results when the lone pair of electrons created upon the departure of the proton is conjugated to a π system.

There is an indirect effect of conjugation on the acidity of a carboxylic acid such as acetic acid. When one of the σ lone pairs on the acetate anion is protonated or alkylated, the functional group is no longer symmetric, and the oxygen that has been so modified becomes more electronegative. This change withdraws more electron density onto the protonated or alkylated oxygen, as indicated by the resonance structures:

Figure 2-5: Resonance structures (top) and atomic orbital overlap (bottom) in a carboxylate anion. The resonance structures indicate that one pair of electrons from each oxygen is delocalized and that the π molecular orbital system results from the overlap of three p atomic orbitals, one from the central carbon and one from each of the two oxygens. Each of these three atoms is hybridized [p , sp^2 , sp^2 , sp^2]. As indicated schematically, the two σ lone pairs of electrons in the molecular plane are the bases that can associate with a proton, not the delocalized lone pairs of the π molecular orbital system. The *syn* and *anti* lone pairs are labeled.

The separation of charge in the structure on the right is the reason that the lone pair of electrons on the alkylated oxygen or protonated oxygen is less delocalized than the π lone pair of electrons on an unalkylated or unprotonated oxygen in the carboxylate anion. Nevertheless, the bond between the protonated or alkylated oxygen and the acyl carbon retains some of the double-bond character indicated by the less advantageous form on the right. This is manifested in the almost 120° angle (116.5°) between an alkyl carbon and an acyl carbon at the oxygen of an ester and a shortening of the bond between the oxygen of an ester and the acyl carbon by 0.09 nm relative to carbon–oxygen bonds between sp^2 carbons and oxygens in aryl and vinyl compounds.¹⁶ Therefore, an ester or the conjugate acid of a carboxylic acid retains the overlap of the system of π molecular orbitals, but the overlap is considerably weakened relative to the unalkylated or unprotonated anion. During protonation of a carboxylate anion, the delocalization in the orthogonal π system is considerably diminished, and this effect destabilizes the conjugate acid and lowers the pK_a . A similar but less pronounced effect of a decrease in delocalization upon protonation occurs with phenol. In the case of phenol, the conjugation in the anionic conjugate base is weaker than that in the anionic conjugate base of a carboxylic acid because the elementary negative charge is distributed over the oxygen and three carbons. Consequently, the effect of diminishing this conjugation upon protonation is less, and phenol is a weaker acid than acetic acid.

The acetate anion illustrates another property of a system of π molecular orbitals—its ability to **redistribute charge**. The elementary negative charge in the acetate anion is shared between the two oxygens because the system of π molecular orbitals is spread over all three atoms. The two electrons in the highest occupied molecular orbital, which account for the negative charge of the functional group, can reside only over the two oxygens, as there is a node over carbon (Figure 2-3). When one of the oxygens becomes protonated, the π system redistributes and more π electron density is shifted over the oxygen that has become protonated because its coulomb effect has increased. This shift in distribution of charge is reflected in the resonance structure chosen for portraying the conjugate acid:

A similar ability of a π system to redistribute charge is reflected in the lower acidity of *p*-methoxypyridinium ($pK_a = 6.67$) compared to pyridinium ($pK_a = 5.17$). This difference results from the ability of the electron density

of the methoxy substituent to push into the π system through the conjugation represented by the resonance structure

so that the elementary positive charge on the nitrogen is delocalized. In the opposite sense, an example of a shift of electron density away from the central atom occurs in the *p*-nitrophenolate anion, whose associated pK_a is 7.2, compared to the phenolate anion, whose associated pK_a is 10.0. This can be explained by the resonance structure

In each of these examples, the redistribution of charge among electronegative atoms is accomplished by the highest occupied molecular orbital of the π system, which is spread over the whole molecule.

The microscopic pK_a of an acid–base is determined by a combination of all of these properties: the electronegativity and hybridization of the central atom, any creation of charge, the inductive effect, any delocalization of the lone pair of electrons, and any redistribution of charge.

The biological molecules that illustrate most extensively the various aspects of bonding and acid–bases discussed so far are the **bases of the nucleosides**.

Pyrimidines

Purines

Each of these nucleosides, **uridine**, **cytidine**, **guanosine**, and **adenosine**, is composed of the base itself, **uracil**, **cytosine**, **guanine**, and **adenine**, respectively, and a ribosyl group attached to N1 or N9 of that base. The nucleoside bases are hybrid structures of aromatic heterocycles and amides. The most aromatic base is adenine. It is susceptible to electrophilic aromatic substitution at carbons 2 and 8 but is also susceptible to nucleophilic substitution at carbon 6 in reactions that resemble acyl exchange. The most amidic base is uracil. It is unambiguously an *N*-acyl-*N'*-alkenyl-*N'*-ribosylurea. The carbon–carbon double bond in uracil has almost olefinic character. It is susceptible to addition reactions, unlike the system of π molecular orbitals in an aromatic compound, which would be susceptible only to substitution.

The nucleoside bases in adenosine, guanosine, and cytidine have exocyclic nitrogens resembling the nitrogen in aniline. The lone pairs of electrons on these nitrogens are even more delocalized than the one on the nitrogen in aniline ($pK_a = 4.6$) because the pK_a for the conjugate acid of each of these nitrogens in the nucleoside bases¹⁷ is less than or equal to -2 , similar to that for *N*-protonated urea ($pK_a \leq -4$). Therefore, each of these exocyclic nitrogens is planar and trigonal, as is always depicted in drawings of the base pairs.

The nucleoside bases in uridine, cytidine, and guanosine have exocyclic oxygens resembling the oxygen in an amide. The values of pK_a for the conjugate acids of these exocyclic oxygens are 0.5, <4.2 , and <1.6 , the upper limits being the values of pK_a for the *N*-protonated tautomers. These values can be compared to -0.7 , the pK_a for the oxygen of acetamide.¹⁸ The values of pK_a for these oxygens in the iminolic tautomers of these three bases, estimated from the measured¹⁹ or theoretical^{20,21} values for the equilibrium constants between the amidic and iminolic tautomers, are 5, 4, and -3 for uridine, cytidine, and guanosine, well below the value of 10 for the pK_a of phenol. These values of pK_a as well as the fact that the iminol tautomers are far less stable than the amidic tautomers are the justification for depicting these oxygens as acyl oxygens.

There are two types of calculations performed with acid–bases. The pH of a solution to which a weak acid or

weak base has been added can in theory be calculated, and the ratio of the molar concentrations of conjugate acid and conjugate base in a solution of a given pH can in practice be calculated.

The calculation of the **pH of a solution** upon the addition of an acid–base is an exercise in simultaneous equations. The problem takes the form “Calculate the pH of a solution to which 0.1 mol of sodium acetate has been added for every liter.” The equations always used are the **conservation of mass**

$$[\text{HOAc}] + [\text{OAc}^-] = 0.1 \text{ M} \quad (2-7)$$

where HOAc is acetic acid and OAc^- is acetate anion; the **conservation of charge**

$$[\text{OAc}^-] + [\text{OH}^-] = [\text{Na}^+] + [\text{H}^+] \quad (2-8)$$

where $[\text{Na}^+] = 0.1 \text{ M}$; the **acid dissociation constant** or constants

$$K_a = \frac{[\text{OAc}^-][\text{H}^+]}{[\text{HOAc}]} \text{ M} \quad (2-9)$$

where $\text{p}K_a = 4.75$ and $K_a = 1.78 \times 10^{-5} \text{ M}$; and the **water constant**

$$[\text{H}^+][\text{OH}^-] = 10^{-14} \text{ M}^2 \quad (2-10)$$

These comprise four—or if necessary more, depending on the number of dissociation constants the acid has— independent simultaneous equations with four, or if necessary more, unknowns. In the case of acetate, the four unknowns are $[\text{H}^+]$, $[\text{OH}^-]$, $[\text{OAc}^-]$, and $[\text{HOAc}]$. These four equations with four unknowns can be readily solved for $[\text{H}^+]$ ($1.33 \times 10^{-9} \text{ M}$) if the assumption is made that $[\text{H}^+]$ in Equation 2–10 is negligible relative to the other terms.

The value of this exercise is that the creation of the simultaneous equations and the cancellation of certain terms to avoid a cubic or quadratic equation requires an understanding of the acid–base chemistry that is occurring in the solution. For example, one is required to know that the only ions that can be present are H^+ , Na^+ , OAc^- , and OH^- and that sodium acetate is a base so the concentration of protons in the final solution will be small.

The calculation of the concentrations of a conjugate acid and its conjugate base at a given pH fulfills one of two purposes. First, if the solution contains an acid–base of experimental interest, such as an acid–base in a molecule of protein, this calculation will provide the molar concentrations of the conjugate acid and the conjugate base of that acid–base. Second, if a particular buffer is used to stabilize the pH at a particular value, this calculation can be used to determine the concentrations of conjugate acid

and conjugate base required for the buffer. A **buffer** is a solution of an acid and its conjugate base, both present at high enough concentrations so that the acid can neutralize bases added to the solution and the base can neutralize acids added to the solutions, and between them they can keep the pH of the solution constant.

A problem concerning a buffer can be stated “Calculate the number of moles of acetic acid and sodium acetate that are present in 2.00 L of an 0.1 M solution of acetate plus acetic acid at pH 5.5.” This problem requires only two simultaneous equations, Equations 2–7 and 2–9. Because $[\text{H}^+]$ is given as $3.16 \times 10^{-6} \text{ M}$, there are only two unknowns, $[\text{HOAc}]$ and $[\text{OAc}^-]$, which are 0.015 and 0.085 M, respectively. The answer is 0.03 mol of acetic acid and 0.17 mol of sodium acetate.

The quantitative behavior of the concentrations of the conjugate acid and conjugate base of each acid–base is described by a **titration curve** (Figure 2–6) that relates the fraction of the acid–base in the form of the conjugate acid or in the form of the conjugate base to the pH of the solution. This can be presented as the fraction itself (Figure 2–6A), as is usually done, but this presentation leaves the erroneous impression that the fraction of acid goes to zero about 2 pH units above the $\text{p}K_a$ and the fraction of base goes to zero about 2 pH units below the $\text{p}K_a$. This misimpression is corrected by examining the logarithms of the fractions as a function of pH (Figure 2–6B). It can be seen that finite fractions of both acid and base are still present at high and low pH, respectively. At a distance of 2 pH units above the $\text{p}K_a$, 1% of the acid–base is in the form of the acid, and this percentage drops off by a factor of 10 for every rise of unit of pH but never reaches zero. The importance of this point is that often only one species of the acid–base participates in a chemical reaction, yet the reaction will occur quite well at a pH where the reactive species is present at only 1% or 0.1% or 0.01% or less of the total acid–base. Protonation and deprotonation are extremely rapid, and as the minor but reactive species is consumed in the reaction, it is continuously replaced.

Problem 2–3: Complete the following acid–base equilibria. Draw the structures of the conjugate base and the acid in σ – π stereochemical representation (Figure 2–1B).

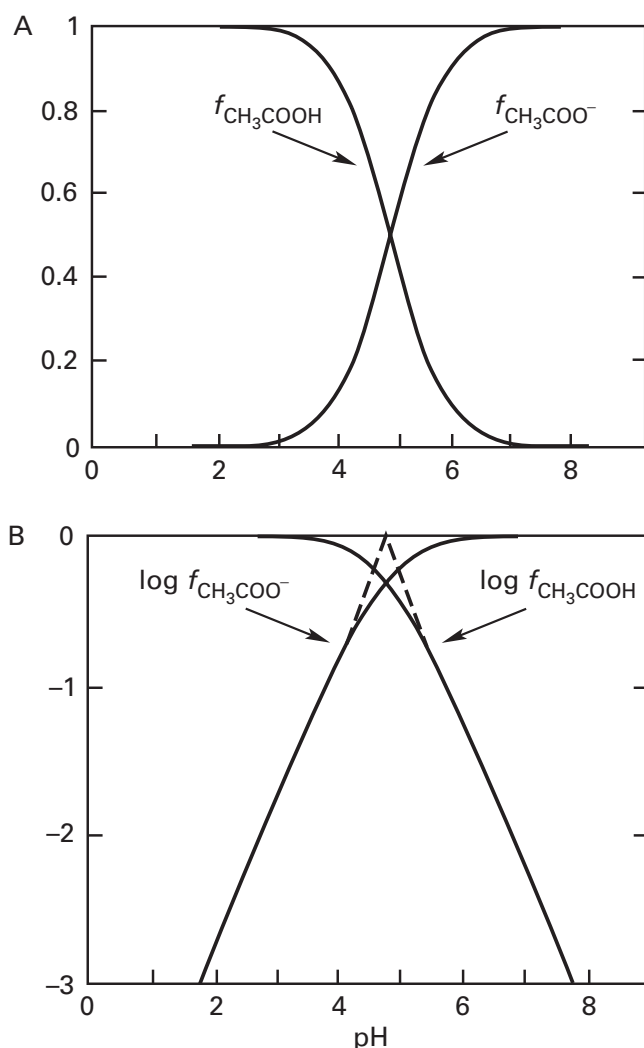

Figure 2-6: Titration curves for acetic acid. From the acid dissociation constant for acetic acid ($pK_a = 4.75$), the fraction of the acid–base present in solution as the conjugate acid ($f_{\text{CH}_3\text{COOH}}$) or as the conjugate base ($f_{\text{CH}_3\text{COO}^-}$) as a function of pH, or the logarithms of these values (B) can be plotted as a function of pH. When the pH is greater than the pK_a by 2 units, the concentration of acetic acid decreases by a factor of 10 for each increase in pH of 1 unit. When the pH is less than the pK_a by 2 units, the concentration of acetate ion decreases by a factor of 10 for each decrease in pH of 1 unit.

Problem 2-4: Write the acid–base equilibrium to which each of the following values of pK_a refer. Write each as a chemical reaction, and draw out the structures of the conjugate acid and the base in σ – π stereochemical representation. In tables¹² of values of pK_a , the name of the compound and the value of the pK_a are all that one is given, so it will be necessary for you to compare each of these values of the pK_a with those for acids and bases about which you are certain to judge whether the pK_a is for the molecule as named or for one of its conjugate bases or one of its conjugate acids.

compound	pK_a
1-amino-2-bromoethane	8.49
1-aminoethane	10.56
2,2,2-trifluoroethanol	12.43
ethanethiol	10.50
3-hydroxypropyne	13.55
diethylamine	10.98
ethanol	–2, 16

trichloroacetic acid	0.65
fumaric acid	3.03, 4.52
thiazole	2.44
methoxyacetic acid	3.53
thiourea	–0.96

Problem 2-5: The following zwitterionic acid–bases are used widely for buffering solutions of protein.²² Write the full structures of both the acid and the conjugate base for the acid–base equilibrium to which the pK_a refers. In what range of pH would each of these acid–bases buffer?

buffer	p <i>K</i> _a
<i>N</i> -(2-sulfoethyl)morpholine (MES)	6.1
1,4-bis(2-sulfoethyl)piperazine (PIPES)	6.8
<i>N,N</i> -bis(2-hydroxyethyl)-2-aminoethanesulfonic acid (BES)	7.1
<i>N</i> -(3-sulfopropyl)morpholine (MOPS)	7.2
<i>N</i> -(2-sulfoethyl)-2-amino-1,3-dihydroxy-2-hydroxymethylpropane (TES)	7.4
1-(2-hydroxyethyl)-4-(3-sulfoethyl)piperazine (HEPES)	7.5
1-(2-hydroxyethyl)-4-(3-sulfopropyl)piperazine (EPPS)	8.0
<i>N</i> -[2-hydroxy-1,1-bis(hydroxymethyl)ethyl]glycine (Tricine)	8.1
<i>N,N</i> -bis(2-hydroxyethyl)glycine (Bicine)	8.3
<i>N</i> -(3-sulfopropyl)-2-amino-1,3-dihydroxy-2-hydroxymethylpropane (TAPS)	8.4
<i>N</i> -(2-sulfoethyl)cyclohexylamine (CHES)	9.3

Why is HEPES more acidic than EPPS?

Problem 2-6: From the following list, select the reason for the difference in p*K*_a between the two molecules in each pair presented below.

- (A) hybridization
- (B) electronegativity
- (C) π donation
- (D) σ donation
- (E) π withdrawal
- (F) σ withdrawal-induction
- (G) aromaticity

Problem 2-7: What two effects in combination cause the p*K*_a of the methyl ester of 2-methoxypropenoic acid (−3.37) to be 0.9 unit less than that of dimethylether (−2.5)?^{13,23}

Problem 2-8: What are the exact pHs of the following solutions?

- 10^{−2} M acetic acid
- 10^{−2} M imidazolium acetate
- 5 × 10^{−2} M sodium dihydrogen phosphate
- 5 × 10^{−2} M aniline
- 10^{−3} M pyridinium chloride
- 10^{−2} M *p*-nitroanilinium chloride
- 10^{−2} M morpholine
- 5 × 10^{−2} M sodium 2,2-difluoroethoxide

Problem 2-9: Calculate the concentration of imidazolate anion in a 0.1 M solution of imidazole at pH 9.52.

Problem 2-10: Determine the molar concentrations of each species of the weak acids and weak bases in the following solutions.

solute and concentration	pH
0.4 M 1-aminobutane	6.5
0.2 M 1-aminobutane	11.0
0.05 M <i>p</i> -chlorophenol	12.0
0.01 M <i>p</i> -chlorophenol	7.3
0.01 M <i>p</i> -methylaniline	5.0
0.001 M <i>p</i> -methylaniline	2.0
0.03 M 2-aminoethanethiol	9.2
0.08 M 2-aminoethanethiol	5.0
0.05 M morpholine	3.5
0.002 M piperazine	7.5
0.03 M ethanol	6.4
0.03 M diethyl ether	8.0
0.03 M 3-hydroxypropyne	4.0

Problem 2-11: From the following information calculate the pH of the final solutions.

buffer species	concentration of buffer (M)	initial pH	amount of NaOH added (mol L ⁻¹)
imidazole	0.1	6.70	0.02
imidazole	0.03	6.50	0.02
phosphate	0.01	6.80	0.005
phosphate	1.0	6.35	0.1
borate	0.2	9.50	0.002
borate	0.15	8.40	0.05
imidazole	0.1	6.50	0.01
imidazole	0.05	7.00	0.02
phosphate	0.2	7.20	0.05
phosphate	0.3	6.20	0.15
borate	0.05	9.40	0.001
borate	0.02	8.60	0.01

Tautomers

One isomer is a **tautomer** of another isomer if the only difference between them is the position of a proton. There are several tautomers of uridine (2-9):

Each of these three tautomers of uridine is a distinct molecule with distinct chemical properties. It can be converted to another tautomer in the set by the removal of its acidic hydrogen by a base in solution, almost always a molecule of water (Reaction 2-1), and the readdition of another proton in the solution to another lone pair of electrons in the conjugate base. None of the interconversions between two of these tautomers can result from the intramolecular transfer of a proton because none of the lone pairs of electrons in the molecules is disposed properly for such an intramolecular transfer. Because they are acid-base reactions and because the conjugate base common to all of them

is a stable, anionic molecule, these interconversions are rapid. In water, the tautomer of uridine that is normally written, the one in which the proton occupies the nitrogen, is the dominant one, exceeding in concentration the other two combined by a factor of more than 4000.¹⁹

By formal definition, two otherwise identical isomers are tautomers of each other only when the tautomeric proton sits on two different atoms in the two isomers, as in the case of the three tautomers of uridine in Equation 2-11. If the proton sits on two different lone pairs on the same atom, the two isomers are, by formal definition, **conformational isomers** of each other. An example of two such conformational isomers would be the *syn* and *anti* conformations of acetic acid:

Because the barrier to rotation around the carbon-oxygen bond is large²⁴ due to the conjugation in the acid (2-5) and because protons shuttle on and off the oxygens rapidly due to the aqueous solution, neither of these two conformational isomers probably exists long enough to convert to the other by rotation about the carbon-oxygen bond. If this is the case, each of these isomers over its lifetime is a distinct molecule, each has distinct chemical properties, each is almost always converted to the other isomer only by the removal of its acidic hydrogen by a base in solution and the readdition of a proton to one of the two lone pairs of electrons that have the opposite orientation in the acetate anion (Figure 2-5), and the two isomers are in fact, if not by definition, tautomers of each other.

In the gas phase, the *syn* isomer of acetic acid is about 20 kJ mol⁻¹ more stable than the *anti* isomer.²⁵⁻²⁸ This difference in stability results from steric repulsion between the methyl group and the proton,^{25,27} from the repulsion between the dipole of the carbon-oxygen double bond and the dipole of the oxygen-hydrogen bond in the *anti* conformation, and from the fact that the unfavorable electron repulsion between the two *syn* lone pairs of electrons (Figure 2-5) is relieved when one of them is protonated but not when an *anti* lone pair is protonated.²⁹ Although the high relative permittivity of

water should damp both the dipolar repulsion and the electron repulsion,³⁰ it has been proposed that the difference in stability between these two tautomers is the same in water as in the gas phase.³¹ If this were the case, the microscopic acid dissociation constant for the *anti* isomer should be about 3000 times larger than that for the *syn* isomer; or in other words, the *syn* lone pairs of electrons should be 3000 times more basic than the *anti*. There is, however, experimental evidence suggesting that in water the difference in basicity between the *syn* and *anti* lone pairs is much less significant.³²

If the rotation about the carbon-oxygen bond in each of the two tautomers of uridine in which the oxygens are protonated (Equation 2-11) is also sufficiently hindered that neither interconverts significantly by rotation around the carbon-oxygen bond during its lifetime, then there would be *syn* and *anti* conformations of each of them that would be in fact two tautomers of each of them. In this case, the five actual tautomers of uridine would be the five molecules resulting from the protonation in turn of the five respective σ lone pairs on anion 2-13. As the protons shuffle, the σ structure of the uridine remains constant, and a proton is simply found on a different σ lone pair of electrons.

In some sets of tautomers, however, **rehybridization** of the atoms in the acid-base occurs during tautomerization. Such rehybridization is required to take place when one of the lone pairs that is protonated is a π lone pair in the intermediate base. The usually cited example of this is that of the keto and enol tautomers of a carbonyl compound such as ethyl acetoacetate:

The most stable form of the acid, the ketoester (KE), is in equilibrium with two tautomers, the enol at carbon 3 (E3) and the enol at carbon 1 (E1). The common conjugate base of all three of these tautomers is the enolate anion (enolate). The enolate anion has a five-atom system of π molecular orbitals, and each of the five atoms of the system is hybridized [p , sp^2 , sp^2 , sp^2]. Two of the six π electrons of the anion, however, must be protonated at carbon to form the ketoester, an event requiring rehybridization at that central carbon.

In the case of the two enols of ethyl acetoacetate, in contrast to the tautomers of acetic acid or the tautomers of uridine, the proton can be readily transferred intramolecularly between the two oxygens. In fact, in either enol the proton forms a hydrogen bond to the adjacent carbonyl oxygen. These comparisons illustrate the specific geometric requirements for **intramolecular proton transfer**. Not counting the proton transferred, efficient intramolecular proton transfer requires that a ring of five or six atoms can be formed.

There are three aspects of the situation that must be clearly distinguished from each other. One is the set of tautomers itself (Equations 2-11 and 2-13). The second is the resonance structures that can be written for each member of the set of tautomers. The third is the microscopic acid dissociations of the individual tautomers.

Each of the tautomers in the set can often be drawn as a subset of **resonance structures**. For example, just one of the tautomers of uridine can be examined in this way:

The resonance structures, as distinct from the tautomers themselves, are not independent molecules and do not have independent existences. In such a subset of resonance structures, as is always required, no σ bond or σ lone pair has engaged in the exercise because they are all orthogonal to the π electrons that are being shifted. The resonance structures designate which electrons are

the π electrons and which atoms—in the case of uridine, all of them—are contributing p orbitals to the system of π molecular orbitals. Each of the three tautomers of uridine can be submitted to this treatment to generate three subsets of resonance structures. It becomes clear that if the hierarchy of tautomers and resonance structures is not always clearly recognized, significant confusion ensues.

Because it is a tautomer, any one of the tautomers in a set can simply lose a proton in a microscopic acid dissociation that produces its conjugate base. Although the conjugate base may itself be a member of a set of tautomers existing at its level of protonation, in the examples discussed so far, none of the conjugate bases have had acidic protons. For example, the enolate is the common conjugate base produced upon the dissociation of a proton from any one of the three tautomers of ethyl acetoacetate (Equation 2-13). The ratios between the concentrations of each of the pairs of the members of a set of tautomers is independent of the pH of the solution because a proton appears on neither side of any chemical equation interconverting the two. For example, as the pH increases, the molar concentration of the enolate increases according to a function of the same form as that displayed for the conjugate base in Figure 2-6, and the sum of the molar concentrations of the three tautomers decreases accordingly, but the ratio between their concentrations remains unaltered at all values of pH, even when the conjugate base accounts for almost all of the molecules in the solution. In the case of ethyl acetoacetate, these ratios are defined by the three **equilibrium constants among the tautomers**:

$$K_{1K} = \frac{[KE]}{[E1]} \quad K_{3K} = \frac{[KE]}{[E3]} \quad K_{31} = \frac{[E1]}{[E3]} = \frac{K_{3K}}{K_{1K}} \quad (2-14)$$

To treat this situation quantitatively, a distinction must be made between the microscopic dissociation constants and the macroscopic dissociation constant. The microscopic dissociation constants involved are those for the dissociation of each tautomer:

$$K_{aE1} = \frac{[H^+][\text{enolate}]}{[E1]} \quad K_{aE3} = \frac{[H^+][\text{enolate}]}{[E3]} \quad K_{aKE} = \frac{[H^+][\text{enolate}]}{[KE]} \quad (2-15)$$

In contrast to such relationships, a **macroscopic acid dissociation constant** is an acid dissociation constant in which all tautomers with the same number of protons

are considered to be indistinguishable. As a result, the molar concentrations of all tautomers with the same number of protons must be summed, and only those undivided sums can appear in the expression defining a macroscopic acid dissociation constant. The expression for the macroscopic dissociation constant of ethyl acetoacetate is

$$K_{aEAA} = \frac{[H^+][\text{enolate}]}{[KE] + [E3] + [E1]} = 2.1 \times 10^{-11} \text{ M} \quad (2-16)$$

Were there more than one tautomer of the enolate, the molar concentrations of all these tautomers would be summed and that sum would be multiplied by $[H^+]$ in the numerator.

It is the macroscopic pK_a that is measured during the titration of an acid–base because such a measurement makes no distinction among all of the tautomers yielding a proton at a particular pH or among all of the tautomers produced upon the surrender of the proton. All that is measured is the consumption of hydroxide ions or protons by the solution. A tautomeric acid behaves as if it were a simple acid with an acid dissociation constant equal to its macroscopic acid dissociation constant. The total concentrations of conjugate bases and conjugate acids behave as if they were the concentrations of one simple base and one simple acid. Because only the macroscopic pK_a is the result of an acid–base titration and because measurements of the ratios of tautomers or their microscopic acid dissociation constants are more difficult, it is always the macroscopic pK_a that appears in a table. The tabulated value¹² for the macroscopic pK_a of ethyl acetoacetate (pK_{aEAA}) is 10.68.

By simple manipulation it can be shown that

$$\frac{1}{K_{aEAA}} = \frac{1}{K_{aKE}} + \frac{1}{K_{aE1}} + \frac{1}{K_{aE3}} \quad (2-17)$$

This relationship demonstrates that the macroscopic acid dissociation constant is a function of all of the microscopic acid dissociation constants, in particular if the magnitudes of the microscopic acid dissociation constants are all similar to each other. In the case of ethyl acetoacetate, however, the ketoester is much less acidic than the enols ($K_{aKE} < K_{aE3} < K_{aE1}$). As a result, $K_{aEAA} \cong K_{a2}$.

It is possible to calculate a microscopic acid dissociation constant from the macroscopic dissociation constant and the equilibrium constants among the tautomers (Equations 2-14). For example, Equation 2-17 can be rearranged and Equations 2-14 and 2-15 can be used to obtain

$$K_{aE3} = K_{aEAA} (1 + K_{3K} + K_{31}) \quad (2-18)$$

If it is assumed that the enol at carbon 3 is the more stable ($K_{31} < 1$) and that the measured equilibrium constant between the enols and the ketoester (250)¹¹ is approximately K_{3K} , then the pK_a for the microscopic acid dissociation of the enol at carbon 3 is approximately 8.3.

As Equation 2-18 suggests, the ratios among the tautomers can also be calculated from their microscopic acid dissociation constants. In fact, all of the equilibrium constants governing the tautomers and the conjugate base of ethyl acetoacetate are dependent upon each other, or linked. The linkage is reflected in the relationships

$$K_{1K} = \frac{K_{aE1}}{K_{aKE}} \quad K_{3K} = \frac{K_{aE3}}{K_{aKE}} \quad K_{31} = \frac{K_{aE3}}{K_{aE1}} \quad (2-19)$$

The equalities of Equations 2-19 simply state that the ratio between the concentrations of any two tautomers is equal to the inverse of the ratio of their respective microscopic acid dissociation constants, which makes chemical sense. The stronger the bond between the heteroatom and the proton, the smaller will be its intrinsic acid dissociation constant but the greater its relative concentration.

A molecule of protein has a large number (>100) of acidic protons and basic lone pairs distributed over the side chains of its amino acids. As a result it is a waste of time even to imagine all the tautomers of that protein that are present in solution, but usually these acid-bases on the side chains are separated widely enough from each other that each behaves as an independent acid-base and can be treated as such. Occasionally, however, two or three amino acids are not only of functional significance, so attention is paid to them, but also close enough to each other that tautomers and the distinction between macroscopic acid dissociation constants and microscopic acid dissociation constants become important.³³ In thioredoxin from *Escherichia coli*, there is an aspartate (Aspartate 26) close enough in the structure to a cysteine (Cysteine 32) that their acid dissociations become linked.³³ When both are protonated or both are unprotonated, there are no tautomers; but when one is protonated and the other is not, there are two tautomers, one in which the proton is on the aspartic acid and the cysteinate is in the form of the anionic base, and the other in which the proton is on the cysteine and the aspartate is the anionic base:

The equilibrium constant for the tautomerization (K_{SO}) is defined with the thiol-carboxylate as product and the thiolate-carboxylic acid as reactant. The linkage relationships are

$$K_{SO} = \frac{[\text{HSO}^-]}{[\text{⁻SOH}]} = \frac{K_{a\text{HSOH}}}{K_{a\text{HOSH}}} = \frac{K_{a\text{⁻SOH}}}{K_{a\text{⁻OSH}}} \quad (2-21)$$

and the relationships between the macroscopic dissociation constants and the microscopic dissociation constants are³⁴

$$K_{a1} = \frac{([\text{HSO}^-] + [\text{⁻SOH}])[\text{H}^+]}{[\text{HSOH}]} = K_{a\text{HOSH}} + K_{a\text{HSOH}} \quad (2-22)$$

and

$$\frac{1}{K_{a2}} = \frac{[\text{HSO}^-] + [\text{⁻SOH}]}{[\text{⁻SO}^-][\text{H}^+]} = \frac{1}{K_{a\text{⁻OSH}}} + \frac{1}{K_{a\text{⁻SOH}}} \quad (2-23)$$

The equation describing the titration curve for the cysteine is

$$f_{\text{cysteinate}} = \frac{K_{a\text{HOSH}}([\text{H}^+] + K_{a\text{⁻SOH}})}{K_{a\text{HOSH}}([\text{H}^+] + K_{a\text{⁻SOH}}) + [\text{H}^+](\text{[H}^+] + K_{a\text{HSOH}})} \quad (2-24)$$

where $f_{\text{cysteinate}}$ is the fraction of the cysteine that is the anionic base. It is possible to **walk through the titration**

curve. Assume that the first and second macroscopic acid dissociation constants are well separated, that the respective pairs of microscopic acid dissociation constants are close together ($K_{aHOSH} \cong K_{aHSOH} > K_{a-OSH} \cong K_{a-SOH}$), that the initial pH is low, and that the titration is performed by adding hydroxide ion. As the concentration of protons decreases into the range of the first macroscopic acid dissociation constant, the inequality $[H^+] \geq K_{aHOSH} \cong K_{aHSOH} > K_{a-OSH} \cong K_{a-SOH}$ holds and

$$f_{\text{cysteinate}} \cong \frac{K_{aHOSH}}{(K_{aHOSH} + K_{aHSOH}) + [H^+]} \quad (2-25)$$

This equation describes a normal titration curve for a conjugate base (Figure 2-6A) with a macroscopic acid dissociation constant equal to $K_{aHOSH} + K_{aHSOH}$, the sum of the two lower microscopic dissociation constants, which is the macroscopic dissociation constant K_{a1} , and that reaches a plateau at

$$f_{\text{cysteinate}} = \frac{K_{aHOSH}}{K_{aHOSH} + K_{aHSOH}} = \frac{K_{a-OSH}}{K_{a-OSH} + K_{a-SOH}} = \frac{1}{1 + K_{SO}} \quad (2-26)$$

which is the fraction of cysteinate in the tautomeric mixture. The plateau is reached when $K_{aHOSH} \cong K_{aHSOH} > [H^+] > K_{a-OSH} \cong K_{a-SOH}$.

As $[H^+]$ is decreased further during the titration into the range of the second macroscopic dissociation constant and on above it, the inequality $K_{aHOSH} \cong K_{aHSOH} > K_{a-OSH} \cong K_{a-SOH} \cong [H^+]$ holds and

$$f_{\text{cysteinate}} \cong \frac{\frac{K_{a-OSH}}{K_{a-OSH} + K_{a-SOH}} (K_{a-SOH} + [H^+])}{[H^+] + \frac{K_{a-OSH} K_{a-SOH}}{K_{a-OSH} + K_{a-SOH}}} \quad (2-27)$$

which is the equation for a normal titration curve beginning at the tautomeric fraction (Equation 2-26), having a macroscopic acid dissociation constant equal to the term $K_{a-SOH} K_{a-OSH} (K_{a-OSH} + K_{a-SOH})^{-1}$, which is the macroscopic dissociation constant K_{a2} , and reaching a final level at which all of the cysteine is unprotonated (the fully ionized form on the right of Equation 2-20).

The titration curve for the cysteine of thioredoxin conforms to these expectations.^{33,35-37} The values observed for the macroscopic acid dissociation constants are $pK_{a1} = 7.2$ and $pK_{a2} = 9.5$ and the tautomeric ratio, as determined by the level of the plateau observed

in the titration curves (Equation 2-26), is 1.3. These values, when inserted into the equations, give microscopic acid dissociation constants for the cysteine and the aspartic acid of $pK_{aHOSH} = 7.6$, $pK_{aHSOH} = 7.5$, $pK_{a-OSH} = 9.2$, and $pK_{a-SOH} = 9.1$. The titration curve for the aspartic acid has tautomeric ratios and macroscopic acid dissociation constants of about 1.3, 7.2, and 9.5, as expected.^{33,35,36}

From the microscopic acid dissociation constants, it can be seen that when the aspartic acid is protonated, the thiol is a much better acid ($pK_{aHOSH} = 7.6$) than when the aspartate is unprotonated and anionic ($pK_{a-OSH} = 9.2$). Because of the linkage, the same difference in microscopic acid dissociations is necessarily seen for the aspartic acid ($\Delta pK_a = 1.6$) when the cysteine is the neutral thiol or the anionic thiolate. These differences make electrostatic sense because it should be significantly more difficult to produce two adjacent negative charges than a single negative charge. For example, the pK_a of the first macroscopic acid dissociation of succinic acid is 1.29 units less than that of the second. Before the ionization of these two acid-bases in thioredoxin was analyzed in terms of tautomeric equilibria and microscopic acid dissociation constants,³³ there was considerable confusion as to what was happening.^{35,37,38}

Glutamate 172 and Glutamate 78 in the *endo*-1,4- β -xylanase from *Bacillus circulans* are close enough to each other in the native protein to be linked by a tautomeric equilibrium.³⁹ The microscopic pK_a of Glutamate 172 when Glutamate 78 is the neutral acid is 5.5, but when Glutamate 78 is the anionic carboxylate, it is 6.7.

Problem 2-12:

- (A) Draw complete σ structures for the above heterocycles in the above tautomeric forms including all σ lone pairs. Draw them with proper bond angles. Abbreviate the ribose as R.
- (B) Indicate which protons are involved in tautomeric shifts between which lone pairs of electrons. Draw some of the tautomeric forms of these neutral molecules.
- (C) How many π electrons are there in each compound?
- (D) The macroscopic values of pK_a for guanosine are 1.6, 9.2, and 12.5; those for xanthosine are 0.0, 5.5,

and 13.0; and those for cytidine are 4.2 and 12.5. Draw vertically chemical equations for the two or three acid dissociations that have these values of pK_a and horizontally next to the molecule in each level of protonation draw two of its tautomers.

- (E) How many of the tautomers at each level of protonation are insignificant because they require separation of charge?
- (F) Draw the σ structure of a tautomer of xanthine that could substitute for adenine in the A–T base pair.

Problem 2–13: Derive Equation 2–17.

Problem 2–14: If

$$f_{\text{cysteinate}} = \frac{[\text{SOH}^-] + [\text{SO}^{2-}]}{[\text{HSOH}] + [\text{HSO}^-] + [\text{SOH}^-] + [\text{SO}^{2-}]}$$

where the four species are as labeled in Equation 2–20, derive Equations 2–22, 2–23, 2–24, 2–25, 2–26, and 2–27. The values observed for the macroscopic acid dissociation constants for the tautomeric equilibrium of Equation 2–20 are $pK_{a1} = 7.2$ and $pK_{a2} = 9.5$ and the tautomeric ratio is 1.3. Calculate the values of the four microscopic dissociation constants.

Problem 2–15: Write a set of linked equilibria resembling the one in Equation 2–20 for the tautomeric equilibrium and four microscopic acid dissociations of 1,5-dimethyl-4-mercaptoimidazole. The two macroscopic acid dissociations of 1,5-dimethyl-4-mercaptoimidazole have values of pK_a equal to 2.3 and 10.3.⁴⁰ Assume that the microscopic acid dissociation constant between 1,5-dimethyl-4-mercaptoimidazolium cation and its neutral conjugate base has the same value as the macroscopic acid dissociation constant for *S*-methyl-1,5-dimethyl-4-mercaptoimidazole ($pK_a = 6.0$), and calculate values for the other three microscopic acid dissociation constants and the tautomeric equilibrium constant for 1,5-dimethyl-4-mercaptoimidazole. At pH 7, what is the major form of the molecule present in the solution?

Problem 2–16: The macroscopic acid dissociation constants for succinic acid are $10^{-4.19}$ and $10^{-5.48}$. What are its four microscopic acid dissociation constants as values of pK_a ?

Amino Acids

The fundamental, covalent scaffold of a molecule of protein is the polypeptide (see 2–15 below).

A **polypeptide** is a long (50–5000 amino acids) linear polymer, the monomers of which are L- α -amino acids. Because a protein constructed entirely of D- α -amino acids is functionally indistinguishable from its biological enantiomer,⁴¹ the original choice of L- α -amino acids was arbitrary. The covalent bonds that link the amino acids together to form a polypeptide, which are referred to as **peptide bonds**, are those of amides. Because a molecule of water is lost between two amino acids when a peptide bond is formed, the amino acids, when they are incorporated into a polypeptide, should be referred to as **amino acid residues**. Every polypeptide has the same backbone of peptide bonds and α carbons with an end at which an unbonded primary amine is usually located, the **amino terminus**, and an end at which an unbonded carboxylic acid usually is located, the **carboxy terminus**. At the values of pH usually encountered in living organisms (pH 7–8), the amino terminus ($pK_a = 8.0$)¹² should be partially protonated and cationic, and the carboxy terminus ($pK_a = 3.3$)¹² should be unprotonated and anionic. The rhythm of a polypeptide is N, C α , CO, N, C α , CO, N, C α , CO.

In a polypeptide, the amino acid residues each contribute a **side chain** (R_i in 2–15) to the covalent structure. It is the order in which these side chains appear along the polymer that defines the protein. Conceptually, the contribution of an amino acid residue to the structure of the protein can be divided into its α -imido nitrogen, its α carbon, and its α -acyl carbon and oxygen on the one hand and its side chain on the other. The former always provide the same six atoms (with the minor exception of a carbon for an α hydrogen in the case of proline) to the backbone of the polypeptide. The structure of this backbone can be treated as if it were an independent molecule, albeit a long tortuous polymer, and the six atoms contributed to it by each amino acid as if they were separate from each side chain. The side chains themselves can be treated as separate entities by detaching them, in the imagination, from their respective α carbons and replacing what was the bond to the α carbon with a hydrogen. In this way, a model compound for the amino acid side chain is created.⁴²

A **model compound** for a particular amino acid residue in a polypeptide would be a small molecule that

2–15

incorporates the structure of the side chain and any additional structural elements necessary to duplicate the properties of the amino acid residue that are of interest. The model compounds in which the α carbon is replaced only by a hydrogen are simple, readily available chemicals. For example, in this set, the model compound for glutamic acid would be propionic acid; that for histidine, 4-methylimidazole. Another set of model compounds that has been used is the *N*-acetyl α -amides of the amino acids.⁴³ *N*-Acetylaspartic acid α -amide and *N*-acetylglutamic acid α -amide (Figure 2-1) are members of this set.

Unfortunately, the free amino acids themselves are poor model compounds for the amino acid residues in a polypeptide. This arises from the fact that, at all values of pH, they are either zwitterionic or bear net charge. Their solubilities, acid-base behavior, and ability to participate in noncovalent interactions are dominated by the carboxylate anion and ammonium cation they contain. Contrary to original expectations, an understanding of the properties of proteins depends little on an understanding of the properties of the amino acids themselves, while an examination of the structures of the amino acid side chains and the behavior of uncharged model compounds for them does provide essential information.

One of the more important properties of an amino acid residue incorporated in a polypeptide is the value of the **pK_a of its side chain**. The amino acid side chains that contain acid-bases are those of aspartate, asparagine, serine, threonine, glutamate, glutamine, cysteine, tyrosine, histidine, lysine, tryptophan, and arginine (Table 2-2). The *N*-acetyl α -amides of glutamate and aspartate have been useful in examining the electronic effects of the peptide bonds that surround the α carbon on the acid dissociation constants of the amino acid side chains in a polypeptide.⁴³ The α carbon in an *N*-acetyl α -amide, which is transmitting inductively the significant electron-withdrawing capacity of both the carboxamido and the acylimido groups that are attached to it, seems to have about the same electron-withdrawing capacity as a hydroxyl, a cyanomethyl, a chloromethyl, or a bromomethyl group. This conclusion follows from the fact that replacing the α carbon of *N*-acetylaspartic acid α -amide or *N*-acetylglutamic acid α -amide with any of these functional groups produces little change in the pK_a of the respective carboxylic acid, but the completely aliphatic model compounds, acetic acid and propionic acid, respectively, are significantly less acidic than the respective *N*-acetyl α -amides (Table 2-2). These four more common electron-withdrawing substituents can be used to estimate the inductive effect of the polypeptide on the acid dissociations of the various acid-bases on other amino acids (Table 2-2).

These values of pK_a for the side chains have been shown to be accurate when the amino acid is in a polypeptide if the polypeptide is in the form of a struc-

Table 2-2: Acid Dissociation Constants for Model Compounds for the Amino Acid Residues^a

amino acid residues	model compound	pK _a
aspartic acid	in polypeptide (estimate) ^b	4.0
	<i>N</i> -acetylaspartic acid α -amide ⁴³	4.0
	Gly-Gly-Asp-Gly-Gly ⁴⁴	3.9
	3-chloropropionic acid ¹²	4.1
	hydroxyacetic acid ¹²	3.8
	3-bromopropionic acid ¹²	4.0
	3-cyanopropionic acid ¹²	4.0
	acetic acid ¹²	4.75
glutamic acid	in polypeptide (estimate)	4.3
	<i>N</i> -acetylglutamic acid α -amide ⁴³	4.3
	Gly-Gly-Glu-Gly-Gly ⁴⁴	4.1
	glutamic acid (microscopic pK _a neutral) ⁴³	4.5
	4-chlorobutyric acid ¹²	4.5
	3-hydroxypropionic acid ¹²	4.5
	4-bromobutyric acid ¹²	4.6
	4-cyanobutyric acid ¹²	4.4
	propionic acid ¹²	4.9
serine	in polypeptide (estimate)	-3, 14.2
	2-chloroethanol ¹²	14.3
	2-bromoethanol ¹²	14.4
	2-cyanoethanol ¹²	14.0
	ethanol ^{11,12,45}	2, 15.9
	methanol ¹²	15.5
threonine	in polypeptide (estimate)	-3, 15
cysteine	in polypeptide (estimate)	8.7
	glutathione ⁴⁶	8.7
	cysteine (microscopic pK _a neutral) ⁴⁷	9.1
	ethanethiol ¹²	10.5
	2-mercaptoethanol ¹²	9.5
	ethyl mercaptoacetate ¹²	8.0
tyrosine	in polypeptide (estimate)	9.8
	polytyrosine ⁴⁸	9.5
	tyrosine (microscopic pK _a neutral) ⁴⁹	9.8
	4-(hydroxymethyl)phenol ¹²	9.8
	phenol ¹²	10.0
histidine	4-methylphenol ¹²	10.2
	in polypeptide (estimate) ⁵⁰	6.6, 14
	Pro-His-glycinamide ⁴⁷	6.4
	histidine hydantoin ⁵¹	6.4
	histidine (microscopic pK _a neutral) ⁵²	6.0
	<i>N</i> -acetyl-L-histidine methylamide ⁵⁰	6.5
	Gly-Gly-His-Gly-Gly ⁵⁰	6.7
	Gly-His-Gly ⁵⁰	6.6
	imidazole ¹²	7.1, 14.5
lysine	4-methylimidazole ⁵²	7.5
	in polypeptide (estimate)	10.5
	Gly-Gly-Lys-Gly-Gly ⁵³	10.5

arginine	in polypeptide (estimate)	-1.4, 16
	in polypeptide (estimate)	13
tryptophan	<i>N</i> -methylguanidine ¹²	13.4
	in polypeptide (estimate)	17
	indole ¹²	16.9

^aThe values for the pK_a of the model compounds are from the noted sources for 25°C. ^bThe estimate for each amino acid is based entirely on the values tabulated for the model compounds.

tureless random coil⁴⁷ and if that amino acid does not have an immediate neighbor in the polypeptide with an ionized side chain. When the polypeptide folds to form a globular protein, however, significant shifts in the values of pK_a for its side chains occur.^{36,38,54,55} Neighboring charged functional groups in the compact folded structure can affect the pK_a of a particular acid–base. An adjacent anion makes it harder to remove a proton from an acid and raises its pK_a (Equation 2–20). An adjacent elementary positive charge makes it easier to remove a proton from an acid and lowers its pK_a . If, upon the folding of the protein, the acid–base finds itself in an aprotic environment, secluded from water, the more charged form of the acid–base will be less stable relative to the less charged form than it would be in water. This shifts the pK_a in the direction favoring the less charged form of the acid–base. A simple paradigm for such an effect would be the shift in the pK_a of acetic acid in dimethyl sulfoxide, a relatively polar but aprotic solvent, to 12.9 from its value of 4.75 in water, which occurs because the anionic conjugate base is poorly solvated by the dimethyl sulfoxide relative to the solvation provided by water. For all of these reasons, when the polypeptide folds to form the native structure, the values for the pK_a of the various amino acids shift away from their ideal values.

Alanine (A, Ala), valine (V, Val), leucine (L, Leu), and isoleucine (I, Ile) have unsaturated alkyl groups as side chains:*

All of their carbons are hybridized sp^3 . Because alkyl groups are sterically more bulky than functional groups containing atoms hybridized [p , sp^2 , sp^2 , sp^2], steric considerations are more important in examining the

* The drawings of all of the side chains in this section, except for proline, are for the entire functional group that is attached through a carbon–carbon bond to the respective α -carbon in the backbone of the polypeptide. The open bond in each drawing indicates the point of this attachment.

structures of these four amino acids than with most of the others. The view down every carbon–carbon bond should be staggered, and methyl or other alkyl groups should be *anti* to each other in the most stable conformers.

Proline (P, Pro) and **glycine (G, Gly)** are amino acid residues the effect of which on the polypeptide is almost entirely steric. Glycine has no side chain at all, merely a hydrogen, and as such can occupy positions in the native structure of a protein that are cramped. A proline, because it is a ring

forces the polypeptide to assume particular orientations.

Phenylalanine (F, Phe) is aromatic by virtue of its phenyl ring:

The six π electrons are delocalized above and below the plane of the ring in three bonding molecular orbitals over the six carbons that contribute the six p orbitals. This causes the σ structure of the ring to be planar, and it is sandwiched between two circular clouds of π electrons. A phenylalanine side chain absorbs ultraviolet light ($\lambda_{\max} = 253 \text{ nm}$, $\epsilon = 1550 \text{ M}^{-1} \text{ cm}^{-1}$), and its absorption spectrum displays the usual fine structure seen in unadorned alkylbenzenes.

The side chain of **tryptophan (W, Trp)** is an indole, which is a benzopyrrole. The indole is entirely aromatic, consisting of an unbroken ring of nine atoms each contributing a p orbital, and the aromatic system of π molecular orbitals contains 10 π electrons:

The hydrogen on the pyrrole nitrogen of indole ($pK_a = 17.0$)¹² is even less acidic than the hydrogen on a molecule of water ($pK_a = 15.7$):

When it departs as a proton, the lone pair left behind is an sp^2 lone pair, and the negative formal charge can be distributed by the system of π molecular orbitals over all nine atoms in the ring. This delocalization is greater in extent than the delocalization available to pyrrole, which is somewhat less acidic ($pK_a = 17.5$) than indole ($pK_a = 16.9$).¹² The indolyl group of tryptophan is planar with hydrogens directed outward along its edge and clouds of π electrons above and below the σ plane. It has the strongest ultraviolet absorption of any functional group in an amino acid ($\lambda_{\max} = 281 \text{ nm}$, $\epsilon = 5690 \text{ M}^{-1} \text{ cm}^{-1}$)^{56,57} and is the principal contributor to the absorbance of protein at 280 nm (Figures 1-6 and 1-10).

The side chains of **serine (S, Ser)** and **threonine (T, Thr)** are primary and secondary aliphatic alcohols resembling ethanol and 2-propanol, respectively, except that they are more acidic because of the electron withdrawal of the immediately adjacent polypeptide. Their oxygens are hybridized sp^3 and have two σ lone pairs that can act as bases as well as an acidic hydrogen:

The values of pK_a for these acid-base reactions can be estimated (Table 2-2) from a series of alcohols containing appropriate electron-withdrawing substituents.

Tyrosine (Y, Tyr) resembles phenylalanine because it is aromatic and serine because it has a hydroxyl group. As a phenol, however, its properties are distinct from either. Tyrosine ($pK_a = 9.7$) is more acidic than serine ($pK_a = 14.2$) because of the ability of the neighboring π system to delocalize the excess electron density of the anion:

The six p orbitals from the ring and the one p orbital from the exocyclic oxygen that overlap in the anion are distributed above and below the plane of the ring. As indicated schematically in 2-23, the two σ lone pairs on the oxygen of the anion are in the plane of the ring at angles of 120° to the carbon-oxygen bond and are the only bases on the anion that associate with a proton. To the extent that one of the lone pairs of electrons on the conjugate acid is delocalized,

the lowered pK_a of the hydroxyl reflects the lowered pK_a of an sp^2 oxygen-hydrogen bond. To the extent that the lone pair is not so delocalized in the conjugate acid as it is in the anion, the lowered pK_a reflects the stability of the anion relative to the neutral acid resulting from the ability of the system of π molecular orbitals to spread its excess electron density over one oxygen and three carbons. Because of this increase of delocalization in the anion, a significant change in the ultraviolet spectrum of a tyrosine side chain occurs when the acid ($\lambda_{\max} = 275 \text{ nm}$, $\epsilon = 1410 \text{ M}^{-1} \text{ cm}^{-1}$) becomes the conjugate base ($\lambda_{\max} = 293 \text{ nm}$, $\epsilon = 2380 \text{ M}^{-1} \text{ cm}^{-1}$) upon acid dissociation.⁵⁶ It is for this reason that proteins absorb more light at 280 nm when the pH of the solution is raised.

The side chain of **histidine (H, His)** is also an aromatic acid-base by virtue of its imidazolyl group (Equation 2-31):

The neutral imidazolyl group is an aromatic heterocycle containing one pyrrole nitrogen and one pyridine nitrogen, which together contribute three valence electrons to an aromatic ring formed from five p orbitals. Six π electrons are located in the three bonding molecular orbitals of the aromatic system. The six π electrons remain in this aromatic system of π molecular orbitals at all times in all three protonation states but fluidly redistribute in response to changes in coulomb effects as the nitrogens gain or lose protons at their σ lone pairs.

The anion of the parent compound, **imidazole**

2-24

is the best place to begin. All atoms are hybridized [p , sp^2 , sp^2 , sp^2], the two nitrogens each have a σ lone pair of electrons located in the plane of the ring, and both are electronically equivalent. The excess electron density associated with the formal negative charge is distributed by the π system over both nitrogens, and resonance structures can be drawn to show this (Equation 2-31). The first proton adds to one of the two σ lone pairs in the imidazolate anion to form an sp^2 covalent bond in an acid-base reaction with a macroscopic $pK_{a2} = 14.5$. Thus, the imidazolate anion is less basic than the pyrrolate anion ($pK_a = 17.5$)¹² because its system of π molecular orbitals can spread the excess electron density over two nitrogens, but the adenosinate anion ($pK_a = 12.5$) is less basic than the imidazolate anion because its system of π molecular orbitals can spread the excess electron density over three nitrogens.

In neutral imidazole, the two nitrogens are necessarily nonequivalent because one has a proton attached to it. The proton causes its nitrogen to be more electronegative, and the lobes of the π molecular orbitals at this location swell accordingly. This is represented in the resonance structures by placing a π lone pair of electrons over this nitrogen, but such formalism is not meant to imply that this becomes a basic position or that this nitrogen rehybridizes or that the ring is no longer aromatic. The only base on a neutral imidazole is the σ lone pair on the other nitrogen, and it gains a proton in an acid-base reaction with a macroscopic $pK_{a1} = 6.6$ when the base is a histidine side chain in a polypeptide (Table 2-2) or $pK_{a1} = 7.1$ when the base is imidazole itself. The imidazolium cation ($pK_{a1} = 7.1$) is less acidic than the pyridinium cation ($pK_a = 5.2$) because its system of π molecular orbitals can spread its electron deficiency over two nitrogens.

The two ring nitrogens in a histidine side chain, unlike the two in imidazole, are not stereochemically equivalent to each other because of the substitution at carbon 4. The behavior, as a function of pH, of the chemical shifts of the nuclear magnetic resonances of the various carbon-13 nuclei of the imidazole ring in histidine has been compared to their behavior in 1-methylhistidine and 3-methylhistidine. It was concluded from these observations⁵⁸ that in aqueous solution the ratio between the two neutral tautomers (Equation 2-31), 1-protiohistidine and 3-protiohistidine, is 4:1. Assume that the same ratio obtains for histidine in a polypeptide,⁵⁹ and let H_2^+ be the cation of a histidine side chain in an unfolded polypeptide and 1-H and 3-H be the two tautomers (Equation 2-31). If

$$K_{13} = \frac{[3-H]}{[1-H]} = 0.25 \quad (2-32)$$

and

$$K_{aH3H1} = \frac{[1-H][H^+]}{[H_2^+]} \quad (2-33)$$

and

$$K_{aH1H3} = \frac{[3-H][H^+]}{[H_2^+]} \quad (2-34)$$

then the ratio of the two microscopic dissociation constants is 4 as it should be.⁵⁹ If the macroscopic dissociation constant⁵⁰

$$K_{a1} = \frac{([1-H] + [3-H])[H^+]}{[H_2^+]} = K_{aH3H1} + K_{aH1H3} = 10^{-6.6} \quad (2-35)$$

then

$$K_{aH3H1} = 0.8K_{a1} = 10^{-6.7} \quad (2-36)$$

and

$$K_{aH1H3} = 0.2K_{a1} = 10^{-7.3} \quad (2-37)$$

If a histidine in a protein is fully accessible to the aqueous phase, either one of its two protons can dissociate, and the imidazolium cation of that histidine side chain has two microscopic acid dissociation constants, $pK_{aH3H1} = 6.7$ and $pK_{aH1H3} = 7.3$. All of these relationships can be presented graphically (Figure 2-7).

It is important to distinguish carefully between the use of the macroscopic and microscopic acid dissociation constants. If the imidazolium of a histidine side chain is on the surface of a molecule of protein and free to rotate around the carbon-carbon σ bonds connecting it to the polypeptide so that both nitrogen-hydrogens can participate freely in acid dissociations, the macroscopic pK_a will dictate its acid-base behavior as it did in the model compounds. If the imidazolium is held in place by the neighboring amino acids in such a way that the surroundings have the same polarity as water and such that one of its acidic hydrogens is always engaged in a hydrogen bond with an acceptor that resembles water closely, the single remaining site available for acid dissociation would display its respective microscopic acid dissociation constant.⁵⁹ A decision to use the macroscopic pK_a or the microscopic pK_a implies that the respective situation has been assumed to occur.

The side chains of **aspartic acid (D, Asp)** and **glutamic acid (G, Glu)** are simple carboxylic acids (Figure 2-5 and Table 2-2). The side chains of **asparagine (N,**

Figure 2-7: Titration curves for the three conjugate acids of histidine (Equation 2-31): H_2^+ , 1-H, and 3-H. The titration curves for histidine graphically illustrate the equations (Equations 2-32 to 2-37) governing the tautomerization. The ratio of the two tautomers remains constant over the entire range. The value of each microscopic pK_a is defined by the intersection between the curve representing the concentration of the respective tautomer and the curve representing the concentration of its nontautomeric conjugate base or conjugate acid. As a result, the microscopic acid dissociation constant for a reaction producing a tautomer from a nontautomer is always less than the corresponding macroscopic acid dissociation constant, and the microscopic acid dissociation constant for the reaction in which a tautomer dissociates to form a nontautomer is always greater than the corresponding macroscopic acid dissociation constant. The pK_a for each of the two macroscopic dissociations coincides with the pH at which half of the histidine is in the form of the nontautomer, the H_2^+ cation or the H^- anion, respectively.

Asn) and **glutamine (Q, Gln)** are the primary amides of these two carboxylic acids. Primary amides participate in two acid-base reactions:

As is the case with imidazole, two protons are removed successively from two heteroatoms separated by one carbon and connected to each other by a system of π molecular orbitals. The acid dissociations also proceed from a cation through a neutral form to an anion. The values for the two acid dissociation constants, however,

are more widely separated from each other ($pK_{a1} = -0.7$ and $pK_{a2} = 17$) than the two for imidazole ($pK_{a1} = 7.1$ and $pK_{a2} = 14.5$).

The side chain of **arginine (R, Arg)** contains a cation

that slightly resembles the protonated amides of glutamine and asparagine but has a system of π molecular orbitals larger by one atom, a nitrogen:

The functional group in arginine is a guanidinium cation, and it is composed from four atoms, three nitrogens and a central carbon, in the shape of a Y. Each of the four atoms contributes one p orbital, and the four mix to produce the four π molecular orbitals, one bonding (ψ_1) and two nonbonding (ψ_2 and ψ_3) molecular orbitals shown, as well as a fourth antibonding orbital (ψ_4) not shown.

The **guanidinium cation** has six π electrons distributed in pairs among the bonding molecular orbital and the two nonbonding molecular orbitals above and below the plane of the ring. The two highest occupied nonbonding molecular orbitals are responsible for distributing two pairs of electrons evenly over the three nitrogen atoms as is described by the resonance structures of 2-25. This causes the one elementary positive charge to be divided evenly among the three nitrogens. An arginine side chain ($pK_a = 13$) is less acidic than a histidinium side chain ($pK_a = 6.4$) because the elementary positive charge is distributed by the system of π molecular orbitals over three nitrogens rather than over two.

The guanidinium of an arginine side chain (2-25)

defines a plane in which its central carbon, three nitrogens, five hydrogens, and the δ carbon all reside. The hydrogens bristle from the three nitrogens at 120° angles around the periphery, and the flat clouds of π electrons sandwich the σ structure from above and below. The entire structure bears a net elementary positive charge that is neutralized by removing a proton from any one of the three nitrogens.

The side chain of **lysine (K, Lys)**, the other strongly basic amino acid side chain ($pK_a = 10.5$), is a simple primary ammonium cation at neutral pH:

With four carbons, it has the longest linear alkane chain among the amino acids. The conformation of lowest free energy is all *anti* as shown. The introduction of a *gauche* conformation at any of the carbon-carbon bonds requires about 4 kJ mol^{-1} standard free energy.

The side chain of **cysteine (C, Cys)** is fairly acidic ($pK_a = 8.7$). The thiolate anion that results from the acid dissociation (Figure 2-8), although it is not a strong base, is a strong nucleophile because sulfur is an element of the third row. The side chain of **methionine (M, Met)**, although it contains a thioether, resembles in its properties the side chains of the amino acids that are purely alkanes, but it is linear rather than branched. The sulfur of methionine is large and electron-rich but not very basic; the pK_a for its conjugate acid¹¹ is about -9.

Methionine is, however, nucleophilic. At low pH, only methionine and cysteine react with alkylating electrophiles.⁶⁰

A drawback of methionine and cysteine, both to a protein in its normal environment and when the protein is studied in the laboratory, is the susceptibility of the sulfur they contain to oxidation by reaction with molecular oxygen, peroxides, or other oxidants. These reactions produce, in addition to disulfides, various oxides of sulfur (Figure 2-8). These are sulfoxides and sulfenic acids, sulfones and sulfinic acids, and sulfonic acids. To understand the bonding in these various products, the best way to begin is to examine **sulfate**:

Figure 2-8: Products of the oxidation of cysteine and methionine side chains and their conjugate acids and bases. When a cysteine side chain is oxidized by the removal of two electrons, the sulfenic acid is formed, and when a methionine side chain is oxidized by the removal of two electrons, the sulfoxide is formed. One of the tautomers of a sulfenic acid is the lower homolog of a sulfoxide. Cystine is the disulfide of two cysteines formed either by their direct oxidation or by the reaction of the sulfenic acid of one cysteine with the thiol of another cysteine. When a cysteine side chain is further oxidized by the removal of two more electrons, the sulfinic acid is formed, and when a methionine side chain is further oxidized by the removal of two more electrons, the sulfone is formed. One of the tautomers of a sulfinic acid is the lower homolog of a sulfone. Cysteine can be further oxidized by the removal of two more electrons to produce the sulfonic acid.

2-28

The sulfate dianion is perfectly tetrahedral so sulfur is hybridized [sp^3 , sp^3 , sp^3 , sp^3] to provide the atomic orbitals that overlap to produce the four σ bonds. Every sulfur–oxygen bond is the same length so each oxygen must be electronically identical. The sulfur–oxygen bonds are quite short so they must possess double-bond character. Sulfur has expended its s and p orbitals on the four σ bonds, but as an element of the third period, it has vacant, accessible $3d$ orbitals that can be involved in overlap with adjacent $2p$ orbitals on the oxygens to form dp π bonds. The lobes on a $3d$ orbital are of the proper size to accomplish such an overlap:

2-29

All of these features are indicated by the six resonance structures of sulfate, one of which is 2-28. The double bonds in these resonance structures indicate the dp π overlaps, not pp π overlaps as are indicated by the double bonds in resonance structures for molecules containing only elements of the second period. Because they are dp π overlaps, the octet rule can be violated in resonance structures involving sulfur. In all of the oxides of sulfur (Figure 2-8), between the tetrahedral sulfur and the various oxygens, there are the σ bonds and dp π bonds.

A **sulfenic acid**, the first oxidation level of a thiol, would be the monothio analog of a peroxide just as a **disulfide** is the dithio analog of a peroxide. One of the tautomers of a sulfenic acid would be the hydrogen analog of a sulfoxide. A **sulfoxide** is the first oxidation level of a thioether. Sulfoxides are stable oxides of sulfur, but sulfenic acids have not been isolated because they are so unstable. They have been postulated to exist as intermediates in the cleavage of disulfides produced by hydroxide in the presence of catalytic amounts of metal ions:

It has been proposed⁴⁶ that the sulfenic acids that are intermediates in this reaction would disappear as the result of their immediate disproportionation,

in a reaction homologous to but much more rapid than the disproportionation of peroxides. This reaction, however, requires the collision of two sulfenic acids. A sulfenic acid at a cysteine in a molecule of a native protein can be sterically prevented from such a collision. A cysteine that is buried in the structure of amidophosphoribosyltransferase from *E. coli* is a mixture of its sulfenic acid and its sulfinic acid, each protected and stabilized in turn by the protein that surrounds it.⁶¹ In the absence of such protection, however, a cysteine in the form of a sulfenic acid would be both a strong reductant and a strong oxidant and rapidly susceptible to further oxidation and reduction.

Sulfinic acids, the next level in the oxidation of thiols, are stable compounds that can be isolated. One of the tautomers of a sulfinic acid is the hydrogen analog of a sulfone. **Sulfones**, the next level in the oxidation of thioethers, are also stable oxides of sulfur.

The **sulfonate** is the last oxidation state available to an alkylthiol. The sulfonate of cysteine is **cysteic acid**. Sulfonates are also quite stable. Methionine and cysteine are often purposely converted to methionine sulfone and cysteic acid to make them stable to further oxidation.⁶²

Oxidations such as those outlined in Figure 2-8 often occur adventitiously and can introduce charge heterogeneity into a protein or peptide owing to the formation of cysteic acid. Such oxidations can also cause functional damage to a protein. It is the adventitious oxidation of a methionine in α_1 -antitrypsin caused by cigarette smoke that destroys the function of this protein and produces emphysema.⁶³

Phosphoserine, phosphothreonine, and phosphotyrosine*

phosphoserine
2-30

are formed by posttranslational modification. The phosphate is attached to the side chain of the amino acid as a monoester of phosphoric acid.

The model for the bonding in these phosphorylated amino acids is the trianion of **phosphate**, PO_4^{3-} . The bonding in the phosphate trianion is similar to that in

* Unfortunately, the prefix for the $-\text{PO}_3^{2-}$ functional group officially sanctioned by IUPAC for use by organic chemists is “phosphono”, but the prefix for the same functional group officially sanctioned by IUPAC for use by biochemists is “phospho”. Consequently, some confusion can arise.

sulfate dianion with $dp \pi$ bonds, formed by the overlap of d orbitals on phosphorus and p orbitals on oxygen. These bonds are indicated by the four resonance structures for the phosphate trianion, indicating the equivalence of all of the bonds between phosphorus and oxygen. The σ lone pairs of electrons in the unperturbed trianion must be distributed around each oxygen in such a way that the tetrahedral symmetry of the entire anion is retained. This symmetry is, however, readily perturbed because the $dp \pi$ bonds are polarized owing to the difference in electronegativity between phosphorus and oxygen. For example, the donors of hydrogen bonds are oriented at randomly assumed angles around each of the three equivalent oxygens in the hydrogen phosphate dianion bound to phosphate-binding protein from *E. coli* as if there were no incontrovertible geometry for the lone pairs on each of them.⁶⁴

The acid–base properties of inorganic phosphate (Table 2–1) and monoesters and diesters of phosphoric acid reflect this ability of the system of the $dp \pi$ molecular orbitals to spread negative charge over two or more oxygens because the acid dissociation constants (Table 2–1) are much closer together than one might expect for a series of steps that each increase the negative charge number of a small acid–base by 1 unit. The acid dissociation constants for an alkyl monoester of phosphoric acid ($pK_{a1} = 1.7$ and $pK_{a2} = 6.7$)¹² and for a dialkyl diester of phosphoric acid ($pK_a = 1.5$)¹² are close to those of phosphoric acid itself, but sugar phosphates, and presumably also serine phosphate and threonine phosphate, are more acidic ($pK_{a1} = 0.9$ and $pK_{a2} = 6.1$)¹² because of inductive electron withdrawal.

Problem 2–17:

- At pH 7.0, what fraction of the lysine in the peptide Gly-Pro-Lys-Ala-Thr would be in the neutral nucleophilic form? What fraction at pH 12?
- The ϵ -amino group of lysine in a polypeptide reacts readily with acetic anhydride. Write a mechanism for this reaction.
- At pH 12, 10 °C, and 0.1 M KCl, the lysine in the above pentapeptide would react with acetic anhydride at a rate of $1.3 \times 10^5 \text{ M}^{-1} \text{ min}^{-1}$ (k_N). Write a kinetic mechanism for this reaction at any pH that involves only this rate constant and the acid dissociation constant K_{aK} of the lysine, and solve it for the initial velocity (v_i) of the reaction between lysine and acetic anhydride. Assume that the acid dissociation equilibrium is rapid compared to k_N .

Problem 2–18: In the peptide $\text{CH}_3\text{CO-Gly-Glu-Gly-His-NH}_2$, which acid–bases would be titrating in the region between pH 2 and 11? What are the approximate values of each pK_a ? Plot as a function of pH the fraction of each of the three major ionic forms of the peptide present in solution.

Problem 2–19: Two compounds (A and B) have been isolated from a protein by enzymatic hydrolysis. Both have the composition $\text{C}_5\text{H}_{10}\text{N}_2\text{O}_3$. The titration behavior of the compounds is the following:

compound A		compound B	
pK_{a1}	3.85	pK_{a1}	2.15
pK_{a2}	8.25	pK_{a2}	9.19

After acid hydrolysis for 20 h in 6 M HCl, both compounds have the composition $\text{C}_5\text{H}_9\text{NO}_4$ and the following titration behavior:

compound A'		compound B'	
pK_{a1}	2.16	pK_{a1}	2.16
pK_{a2}	4.32	pK_{a2}	4.32
pK_{a3}	9.95	pK_{a3}	9.95

- What are compounds A and B?
- Explain their behavior on titration.

Problem 2–20: Draw a linkage relationship between the microscopic acid dissociation constants of glycine and its two tautomers in the form of Equation 2–20. The values of pK_a for the two macroscopic acid dissociation constants of glycine are $pK_{a1} = 2.34$ and $pK_{a2} = 9.6$. The macroscopic pK_a for glycolic acid is 3.82 and that for acetic acid is 4.75. Estimate the equilibrium constant between the two tautomers of glycine and its four microscopic equilibrium constants.

Chapter 3

Sequences of Polymers

By direct chemical analysis of purified proteins, it has been shown that they are composed of linear polymers of amino acids, referred to as polypeptides. These polymers are formed by a ribosome that reads the messenger RNA and converts the sequence of codons into a sequence of amino acids coupled covalently together in the dictated order. Every polypeptide begins its existence as a single polymer of amino acids of a precise length coupled in a precise order. By and large, this polymer of amino acids is conserved in the mature protein. On its way to maturity, however, various alterations can occur. One class of such alterations is the one that includes changes to the sequence of the amino acids. Short segments of amino acids are often removed from the amino-terminal or carboxy-terminal ends of the protein or cut out of the middle, leaving a broken chain. If such an alteration occurs, it causes the actual amino acid sequence of the polypeptide in a mature protein to differ from the sequence encoded in the messenger RNA.

The sequence of the amino acids in a mature polypeptide can be determined directly, but this is rarely done anymore. It is far easier to sequence the messenger RNA for the protein and translate the sequence of nucleotides into a sequence of amino acids. Because an amino acid sequence determined today is almost always the one encoded by the messenger RNA, alterations in the amino acid sequence of a protein that occur naturally during its maturation often escape detection initially. Eventually, however, most are detected, for example, as unexpected behavior of the protein upon electrophoresis or an incorrect mass on mass spectrometry, and then the sequence of the mature protein must be defined by direct analysis. This direct analysis always relies heavily on the knowledge of the amino acid sequence encoded by the messenger RNA because the lion's share of the original amino acid sequence usually remains in the polypeptides forming the mature protein.

As part of the process that produces a mature protein, other changes are often made to the constituent polypeptides. These changes are either chemical modifications of the amino acids themselves or the attachment of other compounds to the amino acids. For the most part, these posttranslational modifications are unpredictable, and each presents a challenge in analytical chemistry. There is a series of such modifications, however, that consists of the addition of oligosaccharides to particular amino acids, and these modifications are

defined by the sequences in which the sugars are linked together in these oligomers.

With the exception of the unexpected posttranslational modifications, which are relatively infrequent, defining the covalent structure of a mature polypeptide is an exercise in the sequencing of polypeptides, nucleic acids, and oligosaccharides.

Sequencing of Polypeptides

Each naturally occurring polypeptide (2–15) has its own length and its own amino acid sequence. The **amino acid sequence** is the order in which the side chains of the amino acids (R_i in 2–15) are arranged along the polymer. The continuous lengths of the polypeptides found in molecules of protein, and hence the lengths of their unique sequences, can be quite long. For example, human apolipoprotein B100 is 4560 amino acids (aa) long,¹ human mucin MUC2 is 5159 aa long,² and human cardiac titin is 26,926 aa long.³ The amino acid sequence of a given polypeptide is written as a word, each of whose letters stands for an amino acid. The word begins at the amino terminus, ends at the carboxy terminus, and is usually spelled correctly.

The amino acid sequence of a polypeptide determines which protein it will become. Bovine pancreatic ribonuclease can be defined as the protein produced in the pancreas of a steer that can cleave ribonucleic acid at random along its length in a reaction that leaves the phosphate on the 2'- and 3'-positions of the products, or it can be defined as the folded polypeptide, 124 amino acids long, with the amino acid sequence KETAAAKFER-QHMDSSTSAASSSNYCNQMMKSRNLTKDRCKPVNTFV-HESLADVQAVCSQKNVACKNGQTNCYQSYSTMSITDC-RETGSSKYPNCAYKTTQANKHIIIVACEGNPYVPVHFDASV. That the sequence is sufficient to define ribonuclease has been demonstrated by total synthesis.⁴ A similar demonstration was made for the peptidase from human immunodeficiency virus.⁵

The complete amino acid sequences of polypeptides were, in the past, determined directly. The amino acids in a polypeptide can be removed in single steps from the amino-terminal end by the **Edman degradation**⁶ (Figure 3–1).^{*} The strategy of the Edman degradation relies upon

^{*} From here on only those lone pairs involved in each step of a chemical mechanism will be drawn.

Figure 3-1: Steps in the mechanism of the Edman degradation.⁶ Phenyl isothiocyanate is used under basic conditions to produce an *N*-phenyl-*N'*-peptidylthiourea at the amino terminus. The nucleophilic sulfur of the thiourea then can attack intramolecularly the acyl carbon of the first peptide bond, but only under conditions of strong general acid catalysis, which promote protonation of the acyl oxygen. Anhydrous trifluoroacetic acid (TFA) is used to prevent any unwanted hydrolytic side reactions at this step. The shortened polypeptide that leaves during this second step is unreactive at its amino terminus under these conditions owing to protonation. The anilinothiazolinone and the shortened polypeptide are then separated from each other. The shortened polypeptide is recycled through coupling and cleavage. The anilinothiazolinone is opened and recycled in aqueous acid to produce the phenylthiohydantoin of the first amino acid.

the separation of the chemistry into two discrete, controlled steps (labeled ① and ② in Figure 3-1) that permit the removal of one amino acid at a time from the polypeptide as the **phenylthiohydantoin**. The phenylthiohydantoin from each step can be positively identified on chromatography by adsorption.⁷

Only in fortuitous circumstances, however, can the Edman degradation be run for more than 20 or 30 cycles. The necessity for two steps in each cycle as well as the step separating the shortened polypeptide from the thiazolinone, none of which can be performed in 100% yield, causes the cumulative yield of phenylthiohydantoin to decrease inexorably and noise to increase apace. Side reactions such as random hydrolysis of the polypeptide and cyclization of amino-terminal glutamines to

pyrrolidones⁸ also increase noise and lower yield, respectively. Methods for sequencing a polypeptide from its carboxy terminus⁹ and alternative methods for sequencing one from its amino terminus¹⁰ have been described. So far, the former have been far less reliable than the Edman degradation and the latter have been supplanted by automated machines the chemistry of which relies on the Edman degradation.⁷ These machines are able to provide a sequence from tens of picomoles of a peptide, but they have not overcome the inherent shortcomings of the chemistry.

In its present applications, the **automated Edman degradation** is performed on peptides or polypeptides noncovalently¹¹ attached to thin membranes of glass fiber⁷ or poly(vinylidene difluoride).¹² Because the pep-

tide remains bound to a solid phase, the reagents, in solution or as gases, can be sequentially applied to and removed from the peptide efficiently. It is also possible to transfer polypeptides that have been separated by electrophoresis onto these supports and then submit them to sequencing.¹²⁻¹⁴

Because polypeptides cannot be sequenced in their entirety by the Edman degradation, they are cleaved into pieces, or **peptides**, that can be. This cleavage can be performed with **endopeptidases** that hydrolyze the peptide bonds at the locations of specific amino acid residues in the sequence (Figure 3-2).¹⁵⁻²⁵ All of these enzymes, except the papain from *Zingiber officinale*, have been used to digest long polypeptides specifically during elucidations of their complete amino acid sequences. Because these enzymes cleave only peptide bonds adjacent to specific amino acids, high yields of a reasonable number of peptides, each with a specific sequence, can be obtained from a long polypeptide.

If polypeptides are to be cleaved by endopeptidases, they must be unfolded or **denatured**. A folded, compact molecule of protein is usually resistant to digestion by endopeptidases for steric reasons. Although the most common way to denature a protein to prepare it for digestion is to precipitate it irreversibly at high temperature, this approach can fail. If it does, denaturing the protein that is to be cleaved without simultaneously denaturing the endopeptidase, which is itself a protein, requires some strategy. Usually the chemical modification of one type of amino acid in the polypeptide while it is unfolded in a solution of a salting-in solute such as urea is sufficient to prevent it from refolding after the denaturant is removed. The carboxymethylation of cysteines with 2-iodoacetate, after the cystine side chains in the protein have been reduced,²⁶ and the maleylation of lysines^{17,27} are examples of this strategy. When proteins that are normally embedded in biological membranes are removed from the membrane, their polypeptides often remain soluble and unfolded and can be cleaved with endopeptidases.²⁸ Some endopeptidases are themselves quite stable and will function in solutions of denaturants sufficient to unfold the protein to be cleaved.

At times it is useful to cleave a polypeptide at only one or two specific locations in its sequence so that long fragments can be isolated from it. The most common way that this is done is to take advantage of the resistance of the native, properly folded protein to digestion by endopeptidases. The consequence of this resistance is that when a properly folded protein is treated with an endopeptidase such as trypsin or chymotrypsin, often only one or two of its peptide bonds are exclusively hydrolyzed, and this hydrolysis produces the long fragments desired. Because this is completely the result of steric effects, no control over the location of the sites of cleavage, other than that exerted by the intrinsic specificity of the endopeptidase, can be exercised.

Polypeptides can also be cleaved chemically. The

paradigm of **chemical cleavages** is that produced to carboxy-terminal sides of methionines by **cyanogen bromide** (Figure 3-3).²⁹ Several other chemical cleavages of more limited usefulness have been developed. 2-Nitro-5-thiocyanatobenzoate induces cleavage on the amino-terminal side of cysteine residues (Figure 3-4), but the yield is less than quantitative and the amino terminus of the carboxy-terminal product is blocked.³⁰ Cleavage at tryptophan residues can be performed chemically with brominating agents under heterolytic conditions.³¹

This reaction proceeds through a bromonium cation that results from insertion of Br^+ into the olefin between carbons 2 and 3 of the indole to create an electrophilic center. A nucleophilic attack of the acyl oxygen five atoms away then occurs as in the cleavage with cyanogen bromide. The resulting iminolactone hydrolyzes as it does in the cleavage with cyanogen bromide to release a fragment with a free amino terminus from the carboxy-terminal side of the tryptophan. The olefin between carbons 2 and 3 in indole is an easily brominated position, and the mildest brominating agent capable of reacting at this location should be used under the mildest conditions to avoid widespread bromination of the polypeptide elsewhere.³²

A chemical cleavage that can produce large fragments from a polypeptide is the cleavage that occurs preferentially at the peptide bond between an aspartate and a proline under mildly acidic conditions (Figure 3-5).³³ This **cleavage with acid** results from intramolecular attack of the carboxylate anion of the 3-carboxy group of the aspartate on its own acyl carbon, the acyl oxygen of which has been protonated, to produce, upon departure of the amide nitrogen of the proline, an anhydride, which is subsequently hydrolyzed.³⁴ The cleavage occurs preferentially at proline because the amine in the initial tetravalent intermediate is by far the poorer leaving group, but proline, because it is a hindered secondary amine, is the best leaving group of all the amino acids.

Figure 3-2: Specific cleavage of a polypeptide with endopeptidases. Pancreatic **trypsin** hydrolyzes the peptide bonds on the carboxy-terminal sides of lysine and arginine residues with high specificity to produce a series of peptides. Each of these peptides has the respective lysine or arginine at its carboxy terminus.¹⁵ The lysine side chains can be rendered incapable of being recognized by trypsin by modification with succinic anhydride, maleic anhydride,¹⁷ or citraconic anhydride.¹⁶ The latter two modifications are reversible, and the lysines can be regenerated, after cleavage with trypsin, to yield a series of unmodified peptides the carboxy-terminal residues of which are the respective arginines. **Glutamyl endopeptidase** (Glu-C) from the bacterium *Staphylococcus aureus*, strain V8, hydrolyzes polypeptides with high specificity at the peptide bonds on the carboxy-terminal sides of glutamate residues.¹⁸ Under the proper conditions, the same enzyme also can be made to hydrolyze the bonds on the carboxy-terminal side of aspartate residues. **Thermolysin**, an endopeptidase from the bacterium *Bacillus thermoproteolyticus*, hydrolyzes polypeptides at peptide bonds on the amino-terminal sides of leucine, isoleucine, valine, phenylalanine, methionine, and occasionally alanine and tyrosine.¹⁹ Pancreatic **chymotrypsin** usually catalyzes the hydrolysis of the amide bonds on the carboxy-terminal sides of phenylalanine, tyrosine, and tryptophan.²⁰ **Lysyl endopeptidase** (Lys-C) from either of the bacteria *Achromobacter lyticus*²¹ or *Lysobacter enzymogenes*²² hydrolyzes polypeptides with high specificity at the peptide bonds on the carboxy-terminal sides of lysines. **Arginyl endopeptidase** (Arg-C) from murine submaxillary gland hydrolyzes polypeptides at the peptide bonds on the carboxy-terminal sides of arginines.²³ **Peptidyl-Asp metalloendopeptidase** (Asp-N) from the bacterium *Pseudomonas fragi* hydrolyzes polypeptides at the peptide bonds on amino-terminal sides of aspartate residues²⁴ and, occasionally, glutamate residues. Papain from *Zingiber officinale* hydrolyzes peptides at the next peptide bond beyond the one to the carboxy-terminal side of proline residues with little preference for the amino acids immediately adjacent to the peptide bond that is cleaved.²⁵

Figure 3-3: Mechanism of cyanogen bromide cleavage of a polypeptide on the carboxy-terminal side of a methionine. At acidic pH, a methionine side chain, because it is not protonated, remains nucleophilic enough to react in an acyl exchange reaction with cyanogen bromide to produce a cyanosulfonium cation. This cationic center causes the carbon of the adjacent methylene to be electrophilic. This electrophile is five atoms away from the weakly nucleophilic acyl oxygen of the same amino acid, and an intramolecular, nucleophilic substitution ensues. The conjugate acid of the iminolactone formed in this nucleophilic substitution is susceptible to hydrolysis under the acidic conditions. This hydrolysis produces a mixture of the lactone and the open γ -hydroxycarboxylic acid of homoserine at the carboxy terminus of the resulting peptide.

Figure 3-4: Cleavage of a polypeptide to the carboxy-terminal side of cysteine by cyanylation with 2-nitro-5-thiocyanatobenzoate.

Figure 3-5: Cleavage of a polypeptide at the peptide bond between an aspartate and a proline under acidic conditions.

The treatment with acid can be prolonged intentionally to produce cleavage to the carboxy-terminal side of many more of the aspartates in the polypeptide.^{35,36} Preferential chemical **cleavage between an asparagine and a glycine** can be produced with hydroxylamine at alkaline pH and elevated temperature.^{37,38} Both the cleavage between aspartate and proline and the cleavage between asparagine and glycine produce large fragments of the polypeptide because the frequency at which aspartylprolyl and asparaginylglycyl positions occur within the amino acid sequence of a protein is low.

Each of these enzymatic or chemical cleavages produces a particular set of peptides from a given polypeptide, and the complex mixtures that result must be separated by **chromatography**. Chromatography by molecular exclusion can be used to separate the mixture into groups of peptides of different lengths (Figure 3-6).³⁹ The larger peptides from this first step can be further separated on chromatography by ion exchange with matrices of cellulose or dextran.⁴⁰ Because these larger peptides often aggregate or precipitate, these columns are generally run in solutions of trifluoroacetic acid⁴¹ or formic acid⁴² or denaturants such as urea. At high or low pH, the net charges on all of the peptides are negative or positive, respectively, and aggregation is discouraged by mutual electrostatic repulsion. Large peptides can also be made more soluble by modification of all the lysine side chains with citraconic anhydride to increase their net negative charge at neutral and basic pH.⁴²

The smaller peptides, either those isolated first on chromatography by molecular exclusion or those in the whole digest, can be separated on chromatography by cation exchange with sulfonated polystyrene^{15,43} or **high-pressure liquid chromatography** by reverse-phase adsorption under acidic conditions on alkylated silica gel (Figure 3-7).^{36,41} The latter method can also be used to sep-

Figure 3-6: Separation of peptides produced by cleavage of S-carboxymethylated human phosphoglycerate kinase with cyanogen bromide.³⁹ The protein (50 mg) was dissolved in 70% formic acid and solid cyanogen bromide was added to a final concentration of 20 mg mL⁻¹. After 24 h, the solution was frozen and the water and cyanogen bromide were removed by sublimation. The cyanogen bromide fragments (50 mg) were applied to a column (1.9 cm × 150 cm) of Sephadex G-75 run in 0.2 M ammonium bicarbonate. The fractions of the effluent were monitored by absorbance at 230 nm (●) and 280 nm (○). Pools (I-X) were made as indicated. The numbers indicate which fragments, identified later in other separations, were in each pool. Reprinted with permission from ref 39. Copyright 1980 *Journal of Biological Chemistry*.

arate large peptides such as cyanogen bromide fragments.⁴¹ The resolution obtained with either chromatography by cation exchange or high-pressure chromatography by adsorption are similar, but the latter has become the method of choice because of its rapidity, the continuous spectrophotometric monitoring it permits, and its adaptability to samples containing small quanti-

Figure 3-7: Separation of peptides from cytochrome *c* peroxidase on chromatography by adsorption.³⁶ The hemoprotein cytochrome *c* peroxidase from *Paracoccus denitrificans* was dissolved in 8 M urea containing HgCl_2 , and after 20 h, the heme was separated from the protein by molecular exclusion chromatography performed in 5% formic acid. The solvent was evaporated and the resulting solid protein (30 nmol) was suspended in 0.1 M ammonium hydrogen carbonate. Lysyl endopeptidase from *L. enzymogenes* (30 μg) was added to the suspension, and after 4 h at 37°C, the solution had clarified. The sample was evaporated to dryness and redissolved in a dilute solution of trifluoroacetic acid. The peptides were injected onto a column (0.46 \times 25 cm) of a reverse-phase chromatographic medium of octadecylated silica equilibrated with 0.1% trifluoroacetic acid. The peptides were eluted with a linear gradient between 0.1% trifluoroacetic acid and 70% acetonitrile, 0.1% trifluoroacetic acid (solvent B).⁴¹ Peptides were detected by their absorbance at 220 nm. Peaks were pooled as indicated. Reprinted with permission from ref 36. Copyright 1997 American Chemical Society.

ties of peptide. In all cases, the art of the chromatography lies in choosing solvents and buffers that will dissolve the peptides, meet the demands of the chromatographic process chosen for the separation, and be easily removed from the peptides after they have been separated.

Once the peptides have been purified, their **amino acid composition** can be determined by hydrolysis,³⁶ performed under vacuum in 6 M HCl, followed by quantitative cation-exchange chromatography with sulfonated polystyrene (Figure 1-3). In this way, if the peptide is pure and not too long, the amount of each amino acid it contains can be determined. Usually, however, the peptides are sequenced directly because procedures for sequencing by automated Edman degradation⁷ have become more sensitive than procedures for amino acid analysis.

Exopeptidases, such as carboxypeptidase A,⁴⁴ carboxypeptidase B,⁴⁵ serine-type carboxypeptidase,⁴⁶ or leucyl aminopeptidase,⁴⁷ can be used to assist in determining or confirming the sequence of a peptide. These

enzymes remove amino acids one at a time from one or the other of the ends of the peptide. Because the shortened peptide released as a product by one of these enzymes immediately becomes a reactant for the next cleavage, these digestions do not release the amino acids from the respective end in a stepwise fashion as does the Edman degradation but by a progressive process,⁴⁸ and absolute information about sequence beyond three or four residues from the end is rarely obtained with one of these enzymes alone.

A strategy similar to those just described has been developed for the mass spectrometric analysis of mixtures of peptides produced by digesting a protein.⁴⁹

A **mass spectrometer** is an instrument that separates a population of ionic molecules in the gas phase in the order of their mass to charge number ratio (m/z). The ionic molecules, after they have been separated by the mass spectrometer, can be registered individually by a detector to produce a mass spectrum (Figure 3-8),⁴⁹ which records the amount of each ion in the sample as a function of its mass to charge number ratio. A mass spectrometer can also be used to select only ions of a particular mass to charge number ratio, which can then be directed into another instrument. **Quadrupole mass spectrometers** and **ion-trap mass spectrometers** separate the ionic molecules by passing them through specifically designed, oscillating electric fields. **Time-of-flight (TOF) mass spectrometers** accelerate the entire population of ionic molecules in a uniform electric field and then pass them through a vacuum chamber. Because $e_a E_x x = \frac{1}{2} m z^{-1} v^2$ and the electric field (E_x) accelerates all of the ionic molecules over the same distance (x), the time it takes each of them to arrive at the end of the chamber is proportional to the square root of its mass to charge ratio.

There are currently three ways to transfer a biological molecule such as a peptide, an oligosaccharide, a nucleic acid, or a molecule of protein from the aqueous solution in which it is normally found to the gas phase in the form of a **monodisperse vapor** of individual, ionized molecules.

The first method is to pass a dilute aqueous solution containing the macromolecule through an electrospray atomizer,⁵⁰ which produces a mist or **electrospray** so fine that each macromolecule finds itself in its own droplet. The solvent in the droplet evaporates and leaves the intact macromolecule in the gas phase bearing one or more of the elementary positive charges or negative charges that were generated on the surface of the droplet by the atomizer. For proteins and oligosaccharides, the atomizer is usually polarized to produce positive ions, while for nucleic acids, which are already negatively charged in solution, it is polarized to produce negative ions. The elementary charges generated by the atomizer are the result of an excess or a deficit of protons, just as charge is produced on a macromolecule in solution (Figure 1-11). Electrospray produces a family of ions from each macromolecule, each one of the ions differing

Figure 3–8: Mass spectrometry of a tryptic peptide from thioredoxin.⁴⁹ Thioredoxin from *Chromatium vinosum* was dissolved in 6 M guanidinium chloride and 0.1 M tris(hydroxymethyl)aminomethane, pH 8.5. The cysteines in the protein were reduced with dithiothreitol, and the resulting cysteines were alkylated with iodoacetamide. The product was separated from the small molecules by molecular exclusion chromatography and evaporated to dryness, and a portion (50 nmol) of the dry powder was suspended in 0.1 M ammonium hydrogen carbonate and 0.1 mM CaCl₂. Bovine pancreatic trypsin (12 μ g) was added to the suspension and the digestion proceeded for 2 h at 37°C. The peptides produced by the digestion were collected by evaporating the solvent, and they were redissolved in a dilute solution of trifluoroacetic acid and injected into a column of octadecylated silica equilibrated with 0.05% trifluoroacetic acid. They were eluted with a linear gradient from 0% to 50% acetonitrile in 0.05% trifluoroacetic acid. The peptides in one of the 10 pools of peaks from this chromatographic step were vaporized by fast-atom bombardment from a matrix of glycerol and passed into a tandem mass spectrometer. The beam of monocationic ($M + H^+$) peptide ions of mass 1208.2 Da was selected, fragmented by a beam of helium atoms of high kinetic energy, and passed into the second mass spectrometer. The abundances of the various fragments produced are displayed as a function of their mass. The fragment patterns are labeled as in Equation 3–2, and the amino acids, identified by the distances in mass units between each of the steps, are indicated above the respective steps. Fragments are produced by cleavage at successive points from each end of the peptide. Reprinted with permission from ref 49. Copyright 1987 American Chemical Society.

from the others in the number of elementary charges that it bears. For example, ions of cytochrome *c* ($n_{aa} = 104$) carrying between 11 and 21 elementary positive charges were generated by such an atomizer.⁵⁰

The other two methods rely on the initial monodispersion of the individual macromolecule into a solid glass or liquid of low volatility referred to as a **matrix**. The matrix is formed from a small molecule such as nicotinic acid, a solid, or glycerol, a liquid. An aqueous solution of the macromolecule, at a low molar concentration, and the molecule that will form the matrix itself, at a high molar concentration, is applied to a solid surface, and the water is evaporated to produce the dilutely occupied matrix.

There are two ways to shatter the matrix and in the process eject the macromolecules within it into the gas phase. A beam of neutral argon atoms of high kinetic energy can be directed onto the matrix (**fast-atom bombardment**, FAB), and the explosive collisions of these atoms with the matrix vaporize the macromolecules as a mixture of mainly neutral intact molecules, monoprotonated neutral molecules (monocations), and singly unprotonated neutral molecules (monoanions) dispersed in the gas phase^{51,52} Alternatively, a neodymium-Yag laser emitting light of wavelength 266 nm, which is absorbed by the molecules of the matrix, for example, nicotinic acid, can be directed onto the sample (**matrix-**

assisted-laser-desorption ionization, MALDI).⁵³ The heat evolved from the absorption of the light by the matrix produces an explosive vaporization of its top layer, ejecting the macromolecules into the gas phase mostly as monoactions⁵³ and presumably neutral molecules and monoanions as well.

Electrospray and fast-atom bombardment are both continuous processes that produce a continuous flux of ionic molecules. This continuous flux can be directed into a quadrupole mass spectrometer to produce continuous streams of separated ionic molecules. Matrix-assisted-laser-desorption ionization, however, is accomplished with short pulses of the laser (<10 ns) to avoid overheating the sample. As a result, the source emits short pulses of ionic molecules, and each pulse contains only a few of each of the individual ionized molecules. In such a situation, a time-of-flight mass spectrometer, which requires a pulsed source, is usually used to separate the gaseous ionic molecules.

Each of these three procedures has its advantages and, unfortunately, its disadvantages. To its detriment, electrospray produces a mass spectrum in which each macromolecule is represented by an envelope of many individual peaks. For example, the envelope for α -amylase contained more than 30 peaks, each representing a molecule of α -amylase with a particular number

(30–60) of elementary positive charges.⁵⁰ These large numbers of peaks generated from each molecule complicate the analysis of mixtures of molecules such as the mixtures of peptides obtained from endopeptidolytic digestion of a protein. Electrospray, however, is the mildest method for producing a high yield of a vapor of ionized molecules, and large molecules of protein can be vaporized. Matrix-assisted-laser-desorption ionization and fast atom bombardment both produce mainly mono-cations or monoanions of a molecule, thereby providing only one unambiguous molecular ion for each molecule. The former technique is able to vaporize significantly larger molecules (up to 200,000 Da) than the latter (up to 20,000 Da),⁵⁰ but the former has the disadvantage that the yield of ions for each pulse is low. Nevertheless, mass spectrometry has become a routine procedure, and in the sequencing of peptides it is rapidly supplanting chemical sequencing based on the Edman degradation.

When mass spectrometry is applied to dissecting proteins and sequencing the resulting peptides,⁴⁹ the polypeptide of the protein is first digested with an endopeptidase. Usually the digest is then separated with one chromatographic step (Figure 3–7). Each pool of a peak from the chromatogram is subjected to vaporization, and the flux of cations produced is directed into a **tandem mass spectrometer**. In addition to being able to register the mass of each peptide in the pool, the first mass spectrometer of the tandem can choose the stream of only one of the ionic molecules and hence only one of the monocationic peptides. This beam of purified peptide cations is passed through an orthogonal beam of helium atoms of high kinetic energy that cleave the molecules of peptide by collision-induced dissociation (CID) into characteristic fragments:

These **fragment ions** are then passed into the second mass spectrometer of the tandem, which can be either a quadrupole mass spectrometer or a time-of-flight mass spectrometer. The resulting pattern of masses that is observed (Figure 3–8) is a set of four separate arrays (a_1 – a_n , b_1 – b_n , y_1 – y_n , and x_1 – x_n), one from each type of fragmentation (Equation 3–2). The number of mass units between each step in each of these arrays provides the sequence of the peptide. In this procedure, the first mass spectrometer performs the separation of the peptides in each chromatographic pool that would normally be performed by subsequent steps of chromatography, and the second mass spectrometer performs the sequencing that would normally be performed by automated Edman degradation.

If only the identity of the polypeptide is desired, not its complete sequence, it is possible to slice a band containing that polypeptide from a polyacrylamide gel, digest it with trypsin, and introduce the entire digest into a tandem mass spectrometer without performing the initial chromatography. Peptide ions that are well resolved by the first mass spectrometer can be selected for fragmentation, and the pattern of the fragments obtained provides the amino acid sequence of those peptides.⁵⁴ In this way, a protein appearing on an electrophoretogram can be positively identified from the amino acid sequences of many of its constituent peptides.

The grand strategy for determining the complete sequence of a polypeptide directly is to separate and sequence all of the peptides from one particular cleavage, to cleave the protein at a set of different locations, to identify all of the peptides in this second set that contain the points of cleavage for the first set, and to sequence these overlapping peptides to learn the order in which the first peptides are arranged in the intact polypeptide. The dramatic epics,^{55–62} in each of which this strategy was applied to another protein and its sequence was revealed, are now seldom produced.³⁶ The expectation and excitement surrounding each of them is only dimly remembered. In their place are myriads of short essays that present the sequences of often long polypeptides. This flood of information has been possible because the sequences of polypeptides are now determined by sequencing DNA complementary to the messenger RNA that encodes them.

Cloning, Sequencing, Expressing, and Mutating of Deoxyribonucleic Acids

Nucleic acids are linear polymers (see 3-1 below) the monomers of which are **nucleoside 5'-monophosphates**. The covalent bonds that link the monomers together to form the polymer are the oxygen-phosphorus bonds that connect the 3'-hydroxyl group of one nucleoside and the 5'-phosphoryl group of the next. Each of these bonds produces a diester of the respective phosphoryl group (a phosphodiester linkage). Nucleic acids are divided structurally and biologically into ribonucleic acids (RNA), which have a 2'-hydroxyl group on each of their furanosyl rings as in 2-9 to 2-12, and deoxyribonucleic acids (DNA), which are unsubstituted at the 2'-position of their furanosyl rings as in 3-1. Aside from this distinction, every nucleic acid has the same polymer backbone. One end of a molecule of single-stranded nucleic acid is a phosphorylated 5'-hydroxyl group (5'-phosphate); the other end is a 3'-hydroxyl group. The 5'-phosphate and 3'-hydroxyl group are the **5'-end** and **3'-end**, respectively, of the polymer. At the pH usually encountered in living organisms (pH 7-8), the oxygens on each of the phosphoryl diesters in the backbone of a nucleic acid are unprotonated and each monomer bears a full elementary negative charge except for the monomer at the 5'-end, the phosphate of which bears an average of between 1.5 and 2 elementary negative charges, depending on the exact pH.

There are four nucleoside 5'-monophosphates incorporated into a particular nucleic acid as it is synthesized biologically. These four nucleoside 5'-monophosphates are distinguished by the heterocyclic bases they contain (R_i in 3-1). Cytosine (C) is the base in the nucleosides cytidine (2-10) and 2'-deoxycytidine,

guanine (G) is the base in the nucleosides guanosine (2-11) and 2'-deoxyguanosine, and adenine (A) is the base in the nucleosides adenosine (2-12) and 2'-deoxyadenosine. The ribonucleoside 5'-monophosphates are incorporated into RNA, and the 2'-deoxyribonucleoside 5'-monophosphates are incorporated into DNA. Uracil (U) is incorporated into RNA on the 5'-monophosphate of the nucleoside uridine (2-9). Uridine, however, is converted by dehydroxylation and methylation into **thymidine**, the 2'-deoxyribonucleoside of 5-methyluracil, before its 5'-monophosphate is incorporated into DNA. The base 5-methyluracil is called **thymine** (T).

Within each nucleoside, the base is attached to its respective ribose or 2'-deoxyribose in an azacetal (*N*-glycosidic) linkage (see 2-9 to 2-12) between a pyridine nitrogen or an imidazole nitrogen of the pyrimidine or purine, respectively, and the aldehydic carbon at position 1 in the furanose ring. In the unpolymerized nucleoside phosphates, a monophosphate, diphosphate, or triphosphate group is found on the 5'-carbon. A nucleoside 5'-monophosphate, 5'-diphosphate, or 5'-triphosphate is referred to as a **nucleotide**.

Each nucleic acid has its own length and its own **sequence** in which the nucleotide bases, R_i in 3-1, are arranged. The sequence of a nucleic acid is written as a word, each of whose letters stands for the base of the respective nucleotide. Unless otherwise noted, the word begins at the 5'-end and ends at the 3'-end.

Deoxyribonucleic acid usually and ribonucleic acid often occur as double helices. In a **double helix**, two molecules of nucleic acid, running in opposite directions, are wrapped around each other (Figure 3-9). The bases in the core of the double helix are paired, adenine next to thymine and guanine next to cytosine. Because the positions in the sequence of the one strand of DNA occupied by deoxyadenosine, deoxyguanosine, thymidine, and deoxycytidine are paired with positions in the sequence of the other strand of DNA occupied by thymidine, deoxycytidine, deoxyadenosine, and deoxyguanosine, respectively, the sequence of one strand read 5' → 3' **complements** the sequence of the other strand read 3' → 5' (Figure 3-10). For example, the sequence -AGCAGA- complements the sequence -TCTGCT-.

A polypeptide can be cleaved at specific sites with a particular endopeptidase (Figure 3-2), and DNA can be cleaved at specific sites with **site-specific deoxyribonucleases** (restriction enzymes). Just as trypsin or ther-

3-1

molysin catalyzes hydrolysis of amide bonds in a protein only next to particular amino acids to produce specific peptides, site-specific deoxyribonucleases catalyze the hydrolysis of double-helical DNA only at phosphate diesters within particular sequences of nucleotides (Figure 3–10). The particular sequences of nucleotides and the associated points of cleavage are known as **restriction**

Figure 3-9: Double-helical DNA in the standard B conformation.⁵⁴⁵ A segment of single-stranded DNA with the self-complementary sequence CGCGAATTCGCG was chemically synthesized. When dissolved in solution, the individual molecules paired up and formed double-helical segments of DNA containing two identical strands running antiparallel to each other. The double-helical dimers were crystallized and a crystallographic molecular model was generated. A stereo view of the model is presented in the figure. Atoms of oxygen are white; atoms of nitrogen, light gray; atoms of phosphorus, dark gray; and atoms of carbon, black. The unattached white circles are the oxygens of molecules of water that assume fixed positions in the crystal. The dashed lines represent hydrogen bonds.

sites, and the fragments of DNA produced by these cleavages are known as **restriction fragments**. Unlike the situation in dissecting proteins, a much larger number of site-specific deoxyribonucleases⁶³ are available, the specificities of which vary in their complexity. The particular sequence recognized by a given site-specific deoxyribonuclease can be anywhere from four to 12 nucleotides long. The longer the sequence recognized, the less frequently will it occur in the DNA, and the longer will be the restriction fragments produced. By using the appropriate site-specific deoxyribonuclease and carrying the digestion to the appropriate degree of completion, restriction fragments can be obtained of a desired size range containing within their population the complete sequence of the original DNA, just as a digest of a protein contains within its population of peptides the complete sequence of the protein.

Site-specific deoxyribonucleases produce restriction fragments with **blunt ends** or **sticky ends**. If the particular enzyme used cleaves phosphodiester linkages in the two strands that are directly opposite each other, the two new ends it produces will both be completely double-stranded and blunt. If the particular enzyme used cleaves phosphodiester linkages on the two strands that are offset relative to each other (Figure 3–10), a short segment of single-stranded DNA will protrude from each of the new ends. Because they were before the cleavage, these two segments will necessarily be complementary to each other in sequence, will adhere to each other when they come in contact, and, consequently, are sticky.

In addition to site-specific deoxyribonucleases, there are several other enzymes that are used to manipulate DNA (Figure 3–10). The phosphate on the 5'-end of a nucleic acid can be removed with polynucleotide 5'-phosphatase

and the phosphate can be added back to the 5'-hydroxyl group of DNA, usually as a radioactive [³²P]phosphate, with polynucleotide 5'-hydroxyl-kinase:

Both DNA ligase (ATP)

and DNA ligase (NAD⁺)

Figure 3–10: Enzymes that are used to manipulate DNA. A double-stranded segment of DNA is represented diagrammatically. In the core of the double helix, the bases are paired adenine next to thymine and cytosine next to guanine. The two antiparallel strands each have a 3'-end, at which there is usually a free 3'-hydroxyl, and a 5'-end, at which there is usually a phosphorylated 5'-hydroxyl group. **Polynucleotide 5'-phosphatase** (phosphatase) is used to remove the phosphoryl group from the 5'-hydroxyl group. **Polynucleotide 3'-hydroxyl-kinase** (kinase) is used to phosphorylate a dephosphorylated 5'-hydroxyl group, usually with radioactive [γ - 32 P]ATP. Either **DNA ligase (ATP)** or **DNA ligase (NAD $^{+}$)** (ligase) can be used to join the 3'-hydroxyl group and the 5'-phosphate at a single-strand break in the DNA between two nucleotides. The two nucleotides to be joined are usually held immediately adjacent to each other by their pairing with partners on the adjacent unbroken strand. **Site-specific deoxyribonucleases** are used to cleave double-stranded DNA on both strands. The cleavages occur within a sequence specific to the particular site-specific deoxyribonuclease chosen. The site-specific deoxyribonuclease *Pst*I, used as an illustration, cleaves each strand between the A and the G in the sequence –CTGCAG– to produce the two complementary, sticky 3'-ends –TGCA. **DNA-directed DNA polymerase** (polymerase) elongates a strand of DNA, the primer, at its 3'-end by successively adding the nucleotides that pair with the consecutive bases on the opposite strand of the DNA, the template. The reactant for each step of the elongation is the deoxyribonucleoside triphosphate of the appropriate base.

specific deoxyribonuclease. The junctions that are effected by this procedure are at random, but the desired product in which the restriction fragment of DNA has been inserted into the middle of the other molecule of DNA are selected from the overall population. The site-specific deoxyribonuclease is often chosen because it produces blunt ends, which can be ligated at random with other blunt ends. If the restriction fragment to be inserted has been produced with one site-specific deoxyribonuclease and the molecule of DNA into which it is to be inserted has been cleaved with another, the sticky ends are usually removed and the pieces ligated at their blunt ends.

Polymerases are enzymes that synthesize a new strand of nucleic acid in consecutive steps:

repair single-stranded breaks in a double helix. The complementarity of the bases around the break usually juxtapose the two ends to be ligated.

Site-specific deoxyribonucleases and DNA ligases are used to **insert** one molecule of DNA into another molecule of DNA. The molecule to be inserted has been prepared by cleaving a longer molecule of DNA with a particular site-specific deoxyribonuclease, usually one that produces sticky ends. The molecule of DNA into which the restriction fragment is to be inserted is then cleaved with the same site-specific deoxyribonuclease to produce a break with the same sticky ends as those on the restriction fragment to be inserted. The two preparations of DNA are then mixed, and the various sticky ends, for example, the two 3' sticky ends, –TGCA, produced by *Pst*I (Figure 3–10), spontaneously pair up. The pairs of resulting offset breaks in the two strands of the double helices are then repaired with DNA ligase (Figure 3–10) to produce a new unbroken molecule of DNA in which the restriction fragment has been inserted into the other molecule of DNA at the restriction site specific to the site-

Polymerases usually require a particular arrangement of double-helical nucleic acid. There must be a shorter strand of nucleic acid, the **primer**, associated in a double helix through complementary base pairing with a longer strand of nucleic acid. The longer strand of nucleic acid, the **template**, must extend beyond the 3'-end of the primer. The polymerase elongates the primer from its 3'-end by adding a nucleotide at each step that is complementary to the adjacent base on the template. **DNA-directed DNA polymerase** synthesizes a single strand of DNA that is complementary to a template of DNA and that remains associated with the template of DNA in a double helix. **RNA-directed DNA polymerase** synthesizes a single strand of DNA that is complementary to a template of RNA and that remains associated with the template of RNA in a double helix. The enzyme pairs A with U and T with A. **DNA-directed RNA polymerase** synthesizes a single strand of RNA that is complementary to a template of DNA but that does not remain associated with the template. It pairs A with T and U with A. The DNA polymerases use the 2'-deoxyribonucleoside

triphosphates as reactants; the RNA polymerases use, the ribonucleoside triphosphates.

Polypeptides are synthesized biologically by ribosomes that translate the sequence of nucleotides in a single-stranded **messenger RNA** (mRNA) into a sequence of amino acids in a polypeptide. The two corresponding words written in the respective sequences are in the same language, the language of the structure of the protein, and they have the same spelling, but the alphabets are different. The alphabet of the polypeptide sequence consists of the 20 amino acids; the alphabet of the messenger RNA consists of triplets of nucleotides. The correspondence between the letters in the two alphabets is known as the **genetic code**. Each triplet specifies a particular amino acid, and the triplets are sequentially arranged in the same order as the amino acids of the protein encoded by the message (Figure 3–11). Because the sequence of the nucleotides, however, is continuous and does not indicate how they are grouped as triplets, there are three ways to divide any sequence of nucleotides into triplets, or three distinct **reading frames**, only one of which encodes the sequence of the protein. If the sequence and the correct reading frame of a messenger RNA have been determined, it can be immediately translated on paper into the sequence of the polypeptide which it encodes.

Messenger RNA is synthesized by DNA-directed RNA polymerase from a gene in the double-helical DNA of the genome of the organism. Its sequence matches that of one of the strands of DNA in the double helix, the **sense strand**, except that uridine monophosphate replaces thymidine monophosphate. During the synthesis of messenger RNA, the other strand of the DNA, the **antisense strand**, serves as the template (Figure 3–11). The sequence of the sense strand of a prokaryotic gene is identical to that of the messenger RNA transcribed from it, and the sequence of the protein encoded by that sense strand can be read directly from the sequence of the genomic DNA. The genomic DNA of eukaryotes, however, contains introns. An **intron** is a segment of unrelated DNA that has been inserted during evolution into the genomic DNA of the eukaryote and that interrupts the sequence on the sense strand that encodes the protein. These introns are **spliced out** of the messenger RNA

before it is read by the ribosome. Although they cause no problems for the organism, introns make it difficult if not impossible to read the sequence of a eukaryotic protein from the sequence of the gene that encodes the sequence of that protein. Consequently, it is the messenger RNA for a eukaryotic protein that must be sequenced.

Almost every protein molecule present at a particular time in a living cell is being continuously produced by ribosomes from messenger RNA molecules, and it follows that if a protein is found in a eukaryotic cell or tissue, the messenger RNA encoding it should be there as well. Messenger RNA can be isolated as a complex mixture of all of the messages normally being expressed in a particular tissue. This isolation is assisted by the fact that all eukaryotic messenger RNAs have a segment of poly(adenosine monophosphate) about 200 bases in length at their 3'-ends. Affinity adsorption with a stationary phase to which poly(thymidine monophosphate) has been attached covalently is used to separate the messenger RNA from all of the other RNA in the homogenate.

The stratagem devised to obtain the nucleic acid sequence of a particular single-stranded messenger RNA in this purified mixture is to transcribe all of the single-stranded messenger RNAs in the mixture into a mixture of double-helical DNAs of the same respective sequences, separate these molecules of DNA biologically, select the DNA derived from the messenger RNA of interest, and sequence that DNA. Deoxyribonucleic acid that has the same sequence in one of its two complementary strands as the sequence of a messenger RNA is referred to as **complementary DNA** (cDNA). Messenger RNA is transcribed into complementary DNA in the laboratory by first using RNA-directed DNA polymerase to synthesize single-stranded DNA complementary in sequence to the messenger RNA. The single strands of DNA end up in hybrid double helices with the messenger RNAs. The RNA is then removed by digesting it with RNase, and then DNA-directed DNA polymerase is used to synthesize the complements to the single strands of DNA. Each strand of this newly synthesized DNA remains associated with its template in a double helix. In its sense strands, this double-helical DNA contains the original sequences of the messenger RNAs. One advantage of the complementary

Figure 3–11: Relationships between the sense strand and the antisense strands of a segment of double-helical DNA and the messenger RNA and between the messenger RNA and the amino acid sequence encoded by that messenger RNA. In the messenger RNA, the amino acid sequence of the protein is encoded by triplets of bases. Each triplet of bases is a letter in the alphabet of the messenger RNA. The genetic code is the correspondence between each of these triplets and the amino acid it encodes. The amino acid is the letter in the alphabet of the protein. The messenger RNA is synthesized by DNA-directed RNA polymerase using the antisense strand of the DNA as a template and has the same sequence of nucleotides as the sense strand, except that uridine monophosphate is in place of each thymidine monophosphate. When RNA-directed DNA polymerase synthesizes a single strand of complementary DNA using messenger RNA as a template, that single strand of DNA has the same sequence as the antisense strand from which the messenger RNA was synthesized.

DNA derived from a particular tissue is that it catalogs all of the genes that are being expressed in that tissue.

To **clone** a particular segment of DNA is to insert that DNA, usually present in a complex mixture of other DNAs, into the DNA of a bacteriophage or a bacterium and then isolate a population of identical bacteria or identical bacteriophage, all of which carry just that one segment of DNA. A bacteriophage is a virus that infects and replicates within a bacterium. For the purposes of this discussion, the segment of DNA to be cloned is a segment encoding a protein of interest. In the **cloning** of eukaryotic DNA encoding a protein, complementary DNA is usually the starting point because of the problem of the introns in the genomic DNA. Complementary DNA is also advantageous because tissues producing significant amounts of the protein can be chosen as the source for the messenger RNA, a strategy that increases the chances of finding its complementary DNA. In the cloning of prokaryotic DNA encoding a protein of interest, genomic DNA is usually the starting point⁶⁴ because it is already double-helical DNA, and in prokaryotes there are no problems with introns. The genomic DNA of the bacterium is cut into restriction fragments long enough to contain all or most of the gene encoding the protein.

The complementary DNAs or fragments of genomic DNA in one of these complex mixtures are then usually incorporated into a library in which they can be stored, replicated, and screened. A **library** is a large population of bacteriophage or bacteria, each of which contains within its DNA one of the complementary DNAs or fragments of genomic DNA from the original mixture just as the usual library contains a large population of different books. Each piece of foreign DNA is integrated into the DNA of one of the bacteriophage or one of the bacteria in the library in such a way that it is replicated along with its genomic DNA, ensuring that all of the progeny of that one bacteriophage or bacterium contain the inserted complementary DNA or genomic DNA. Each of the fragments of foreign DNA is inserted into the same location in the DNA of the bacteriophage or bacteria in the library.

If the library consists of **bacteriophage**, the foreign DNA is inserted at the same site in the genomic DNA of each bacteriophage. These genomic DNAs containing the inserts can be biologically replicated to a high concentration by infecting a suspension of bacteria, usually *Escherichia coli*, with the bacteriophage.

Complementary DNAs or fragments of genomic DNA are incorporated into a population of **bacteria** by first inserting them into plasmids. A **plasmid** is a circular molecule of double-stranded DNA that is able to replicate independently of the chromosome in a bacterium. The species of bacteria usually used to carry a plasmid is *E. coli*. In addition to the inserted DNA, each of the various plasmids used for cloning contains a gene causing the bacterium that carries it to be resistant to a particular antibiotic. Consequently, when the plasmids have been incorporated into a population of bacteria, only the

bacteria carrying one of the plasmids will replicate in the presence of the antibiotic. In the library, each antibiotic-resistant bacterium contains a plasmid and most of the plasmids contain a copy of one of the original complementary DNAs or fragments of genomic DNA. Not only do plasmids and bacteriophage permit the inserted DNA to be replicated as they themselves are replicated, they also provide a way of storing the inserted DNA, because once it has been incorporated into the bacteriophage or its plasmid has been incorporated into a bacterium, it is stable for long periods of time if the bacteriophage or bacterium is stored in its dormant state.

Occasionally, the messenger RNA in a tissue producing mainly one protein is so enriched for the messenger RNA encoding that particular protein that the most of the individuals in the library carry complementary DNA for that one messenger RNA, and one of these can be picked out from the rest directly.⁶⁵ Usually, however, the library has to be screened to find an individual carrying the desired complementary DNA or fragment of genomic DNA. To **screen** a library is to isolate bacteriophage or bacteria that carry complementary DNA or fragments of DNA encoding one particular protein from the vast majority of the bacteriophage or bacteria that carry complementary DNA or fragments of genomic DNA encoding other proteins.

When the library is stored in bacteriophage, a continuous lawn of a particular bacterium growing on an agar plate is infected with a dilute solution of those bacteriophage carrying the inserted DNA. Small circular holes or **plaques** appear in the lawn. Each plaque results from the infection and lysis by bacteriophage of the bacteria that had been happily growing within the lawn. All of the bacteriophage in one of the plaques are offspring of a single bacteriophage from the original solution that fell upon the lawn at the position of the center of the plaque and then replicated outward by consecutive infections of the bacteria. Ultimately, each plaque contains millions of the progeny of that one bacteriophage, and each one of the progeny contains only the one inserted DNA its common ancestor contained.

When the library is stored in plasmids in a population of bacteria, a suitably diluted suspension of those bacteria is spread on a plate of agar containing the antibiotic. Only bacteria containing plasmids can grow, and each of these replicates until a round **colony** of bacteria appears on the plate at the location where the original one fell. Each of the bacteria in the colony contains a plasmid because it survived the antibiotic, and each of the plasmids within the same colony contains the same segment of inserted complementary DNA or genomic DNA because all the bacteria are offspring of the original one.

Each plaque or each colony contains copies of a different complementary DNA or fragment of genomic DNA or lacks an insert. The trick is to discover which of the plaques or colonies, respectively, clearly visible to the

naked eye but numbering in the thousands to hundreds of thousands, happens to contain the complementary DNA or genomic DNA that encodes the protein of interest.

The most rapid and unambiguous method of screening is to synthesize chemically or biologically a fragment of radioactive single-stranded or double-stranded DNA, referred to as a **probe**, the sequence of one strand of which encodes the amino acid sequence of the protein of interest (Figure 3-11). When the double-helical DNA in a plaque or a colony containing that particular short nucleic acid sequence is heated so that it unwinds and becomes single-stranded DNA, the sequence on the antisense strand or the sequences on the sense and the antisense strands that are complementary to the sequence or the two sequences of the probe will become accessible for hybridization. **Hybridization** is the formation in the laboratory of double-helical DNA from two complementary single strands of DNA. Because hybridization is usually performed in a complex mixture of single-stranded DNAs such as the denatured DNA from a plaque or colony, the mixture is cooled slowly or **annealed**, to give the pairs of complementary single-stranded molecules of DNA enough time to find each other and form a double helix. If the clone contains sequences of DNA that are complementary to those of the probe, those sequences, after the DNA has been denatured and probe has been added, will hybridize with the sequences of the probe to form short segments of double-helical DNA, and in this way the probe is captured. This trapping of the probe makes the plaque or the colony containing the desired complementary DNA radioactive, marking the position of the bacteriophage or bacteria carrying the desired complementary DNA and allowing that one plaque or colony to be isolated.

An example^{66,67} will illustrate this screening procedure. Factor VIII is one of the proteins that are together responsible for the cascade of events leading to the clotting of the plasma of mammalian blood. Human Factor VIII was digested with trypsin, and the peptides that resulted from the digestion were separated⁶⁶ on chromatography by adsorption. Several of these peptides were resolved cleanly from their neighbors, and they were submitted to Edman degradation. The amino acid sequence determined for one of these peptides was AWAYFSDVDLEK. A segment of radioactive, single-stranded DNA with the nucleic acid sequence CTTTTCCAGGTCAACGTCGGAGAAATAAGCCCAAGC (Figure 3-11), one of the many possible antisense sequences to that encoding the peptide, was synthesized chemically to act as a probe. Long restriction fragments (15 kb) of human genomic DNA were inserted into bacteriophage λ Charon, and these bacteriophage were used to produce plaques on lawns of *E. coli*. The DNA in the plaques was then denatured. During subsequent annealing and hybridization, the radioactive probe was captured by the denatured, single-stranded DNA in 15

plaques out of the 500,000 screened for DNA containing a nucleic acid sequence that would capture the probe.⁶⁷ Bacteriophage from each of these 15 clones were separately grown on a large scale, and the inserted DNA was cut out of the DNA of the bacteriophage that had been carrying it with site-specific deoxyribonucleases.

The **polymerase chain reaction**⁶⁸ can be used to produce probes for screening plaques or colonies or even a segment of the DNA encoding a significant portion of the protein of interest. This is a method for replicating to a high concentration only a specific segment from any source of DNA. To replicate only a particular segment of DNA in a complex mixture or within a much longer molecule of DNA by the polymerase chain reaction, all that is required is that the segment of double-stranded DNA to be replicated is flanked on either side by known sequences of nucleotides. Two short primers of single-stranded DNA are synthesized, one complementary to the flanking sequence at one end of the segment to be replicated and the other complementary to the flanking sequence at the other end. These two primers for the two ends, however, must be complementary to the sequences on opposite strands of the initial double-stranded DNA. The initial double-stranded DNA is melted, and the two primers are hybridized. DNA-directed DNA polymerase is then used to elongate from the 3'-end of each primer (Figure 3-10). This produces two copies of duplex DNA over the segment of interest. The new DNA is melted and rehybridized with the same two primers and elongation is performed again to produce four copies of duplex DNA for the segment of interest and so forth. If the heat-stable DNA-directed DNA polymerase from *Thermus aquaticus*⁶⁹ or *Pyrococcus furiosus*⁷⁰ is used for the elongation, new polymerase does not have to be added after each melting cycle. After repeated cycles of melting, annealing, and elongation, essentially all of the newly synthesized DNA is a copy of the double-stranded segment of the original DNA between and including the sequences of the priming DNA, and the concentration of this segment increases exponentially with each step.

An example of the use of this procedure is the synthesis of a probe for screening a library containing the gene for extensin from *Volvox carteri*.⁷¹ The amino-terminal sequence of the protein, AVSYSVSVYNNIAVT-GAP-, and the sequence of a tryptic peptide from the protein, IDPPSNFGNLPVK, were used to guide the synthesis of two primers, GT(T/C/A/G)TA(T/C)AA(T/C)-AA(T/C)AT(T/C/A)GC and GG(G/T)AGGTT(T/C/A/G)-CCGAA(G/A)TT, where letters in parentheses indicate that two or more nucleotides were coupled in that step of the synthesis to allow for the redundancy of the genetic code. When complementary DNA from sperm packets of *V. carteri* was amplified with these primers in a polymerase chain reaction, a segment of 410 bp of double-stranded DNA was produced beginning with the sequence GTCTACAACAACATCGC- and ending with the

sequence –AACTTTGGCAACCTGCC on its sense strand. This sequence encoded 136 aa of the amino acid sequence of the protein. This segment of DNA was inserted into a plasmid, replicated with radioactive precursors, and used successfully as a probe to screen a library of genomic DNA from *V. carteri*. By use of this probe, a clone of bacteria was identified that carried a plasmid containing a segment of complementary DNA 1392 bp long, encoding 464 aa from the amino acid sequence of extensin.

The complementary DNA or the fragment of genomic DNA encoding the protein of interest that has been produced by replicating the bacteriophage or bacterium identified by the screen, or the segment of DNA encoding a portion of the protein that has been amplified by the polymerase chain reaction, can be quite long, from thousands to tens of thousands of nucleotides. The sequence of a particular piece of single-stranded DNA can be read only to a certain length (300–400 nucleotides). Therefore, long DNAs must be cleaved into smaller restriction fragments with site-specific deoxyribonucleases, just as polypeptides have to be cleaved into peptides before they can be sequenced. By trial and error, a pattern of restriction fragments ideally suited to the demands of sequencing can be prepared.

The shorter double-helical restriction fragments produced from a longer double-helical DNA are rapidly separated by **preparative electrophoresis on gels of agarose**. They are usually visualized by use of fluorescent dyes. Their length can be estimated from their electrophoretic mobilities. The order in which a given set of restriction fragments is arranged in the original DNA is determined by **restriction mapping**. To produce a restriction map of a large piece of DNA, it is cleaved separately with several site-specific deoxyribonucleases. The restriction fragments produced in each of these separate digestions are isolated and assigned a length by electrophoresis. Each of these restriction fragments of DNA is then submitted to digestion by the other sets of site-specific deoxyribonucleases, and the shorter restriction fragments that result are separated and assigned a length. This dissection is continued until the restriction fragments observed, which are designated by the pedigree of the cleavages that produced them, are consistent with only one distribution of restriction sites through the original piece of long DNA as well as being of the desired length. This unique distribution of restriction sites, the restriction map, orders the different restriction fragments that have been obtained relative to the complete sequence.

An example will serve to illustrate the complete process.⁷² A clone containing the complementary DNA encoding the α polypeptide of the murine nicotinic acetylcholine receptor within the tetracycline-resistant plasmid pBR322 (Figure 3–12)⁷² was identified by screening. The cloned complementary DNA was cut from the plasmid as an intact double-helical polymer with the

site-specific deoxyribonuclease *Pst*I, which cleaves at CTGCA↓G. This DNA was digested with the following site-specific deoxyribonucleases: *Alu*I, which cleaves at the nucleic acid sequence AG↓CT; *Taq*I, which cleaves at T↓CGA; *Hpa*II, which cleaves at C↓CGG; *Hae*III, which cleaves at GG↓CC; *Rsa*I, which cleaves at GT↓AC; and *Hinc*II, which cleaves at GTPy↓PuAC, where Py is either pyrimidine and Pu is either purine.

The pattern of restriction fragments obtained when these enzymes were used in various combinations was consistent with only one restriction map (Figure 3–12). For example, the *Hpa*II restriction fragment between positions 478 and 1063 would give three restriction fragments about 60, 240, and 280 base pairs in length upon digestion with site-specific deoxyribonuclease *Alu*I. The order in which these three subfragments occur in the *Hpa*II restriction fragment could be determined by gathering the following observations. Deoxyribonuclease *Taq*I would cut only the *Alu*I restriction fragment that is about 280 base pairs in length to yield the same restriction fragment, about 120 base pairs long, that it would produce from one end of the *Hpa*II restriction fragment. Deoxyribonuclease *Hinc*II would cut only the *Alu*I restriction fragment that is about 240 base pairs in length to give a restriction fragment about 140 base pairs in length. This restriction fragment, together with the *Alu*I restriction fragment about 60 base pairs in length, would form the restriction fragment about 200 base pairs in length produced during the digestion of the *Hpa*II restriction fragment with deoxyribonuclease *Hinc*II alone.

When restriction fragments of a convenient size had been produced from this complementary DNA encoding the α polypeptide of the murine acetylcholine receptor, a group of single-stranded DNAs within the set were chosen for sequencing (arrows in Figure 3–12). These single-stranded DNAs were subcloned in the single-stranded bacteriophage M13, and each was submitted to sequencing from its 5'-end.

The property of denatured, single-stranded nucleic acids that allows them to be sequenced is that they behave with extraordinary **regularity upon electrophoresis**. For example, when 4.5S ribosomal RNA from the chloroplasts of spinach,⁷³ which is 107 bases long, is elongated with RNA ligase (ATP) from T4 bacteriophage by one nucleotide at its free 3'-hydroxyl group by use of [5'-³²P]cytidine 3',5'-bisphosphate and then submitted to partial alkaline hydrolysis, a random mixture of fragments of all possible lengths and all possible beginning and ending points within the sequence is produced. Only those fragments that begin at the original 3'-end, however, are radioactive. In the case of the 4.5S rRNA, these formed a set of 108 unique fragments that were of all the possible lengths between 1 and 108 nucleotides. When this mixture was submitted to electrophoresis under denaturing conditions on a gel cast from 12% acrylamide and the radioactive components

Figure 3-12: Restriction map of a fragment of DNA cut out of a plasmid.⁷² A large fragment of complementary DNA (17 kb) was removed with the site-specific deoxyribonuclease *PstI* from the circular plasmid pMARα15, which had been originally constructed from the circular plasmid pBR322. The plasmid contained a gene for resistance to the antibiotic tetracycline (TET) so that only bacteria carrying the plasmid would grow on a medium containing tetracycline. The origin of replication for the plasmid is indicated (O/I). The plasmid pMARα15 was isolated during a screening procedure for complementary DNA encoding the α-polypeptide of the murine acetylcholine receptor. The fragment of complementary DNA was purified by electrophoresis and submitted to a series of digestions with the noted site-specific deoxyribonucleases. The patterns of fragments established the restriction map displayed. The arrows below the restriction map indicate which restriction fragments were submitted to sequencing from which 5'-end. The positions in the nucleic acid sequence cleaved by each site-specific deoxyribonuclease are identified by numbers in parentheses. Reprinted with permission from ref 72. Copyright 1985 Oxford University Press.

were located by placing the polyacrylamide gel on a photographic film, a regular array of bands, referred to as a **ladder**, could be observed (Figure 3-13).⁷³ Each of these bands, with one interesting exception that will be discussed later, represents a single-stranded RNA that begins at the labeled 3'-end of the original 4.5S rRNA, because it is radioactive and is one nucleotide longer than the nucleic acid in the band below it in the figure.

The ability of electrophoresis on polyacrylamide gels to separate nucleic acids only on the basis of their length arises from the properties of these polymers and the nature of the electrophoresis. The free electrophoretic mobility of denatured single-stranded DNA at $I_c = 0.01$ M, pH 7.5, and 0°C is $(1.82 \pm 0.02) \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ and does not vary⁷⁴ with its length. The free electrophoretic mobility of denatured RNA under the same conditions is the same, $(1.77 \pm 0.05) \times 10^{-4} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$, and it also shows no tendency to vary with length.⁷⁴ The electrophoretic mobilities of single-stranded DNA and RNA on polyacrylamide gels also conform to Equation 1-81,⁷⁵ and the free mobilities extrapolated from their behavior on polyacrylamide gels are in reasonable agreement with those measured directly.⁷⁶ Because their free electrophoretic mobilities are all the same, it is only the resistance posed by the polyacrylamide, $\exp(-K_{r,i}T_a)$, that separates the nucleic acids of the various lengths. It is not

surprising that this sieving, accomplished at the molecular level by the strands of polyacrylamide, should be a regular, continuous, monotonic function of the lengths of the nucleic acids (Figure 3-13).

Suppose that a single-stranded deoxyribonucleic acid, labeled at its 5'-end by phosphorylation with [^{32}P]phosphate, has been cleaved in a low yield and randomly on the 5'-side of each of the deoxyguanosines in its sequence. This partial cleavage will have produced a series of radioactive fragments of different length, each of which ends at a nucleotide whose only distinction is that it preceded a deoxyguanosine in the original sequence. When the products of this **partial cleavage** are submitted to electrophoresis, a series of radioactive bands will appear the mobilities of which correspond to only those rungs in the ladder the 3'-terminal nucleotide of which precedes a deoxyguanosine. The knowledge that the cleavage occurred only at deoxyguanosines and the position of the products in the ladder identifies the relative positions of every deoxyguanosine in the original sequence.

Suppose further that four samples have been prepared from the original single-stranded deoxyribonucleic acid such that they contain radioactive fragments, all of which begin at the original 5'-end because they were made radioactive by phosphorylating only that

Figure 3-13: Separation of fragments of end-labeled RNA by electrophoresis on gels of polyacrylamide.⁷³ 4.5S Ribonucleic acid, isolated from spinach chloroplasts, was labeled at its 3'-end with [5'-³²P]cytidine 3',5'-bisphosphate by T4 RNA ligase (ATP). The end-labeled RNA was partially digested under alkaline conditions and then submitted to electrophoresis on slabs of 12% polyacrylamide cast in a buffered solution of 7 M urea. The two lanes in the figure were loaded with different amounts of sample and were run for different lengths of time. Reprinted with permission from ref 73. Copyright 1982 *Journal of Biological Chemistry*.

location, but which end at every nucleotide preceding a deoxyadenosine in one sample, preceding a deoxyguanosine in another sample, preceding a deoxycytidine in a third sample, or preceding a thymidine in the fourth sample. When these samples are submitted to electrophoresis, side by side, every band in the ladder will be represented in the four lanes, but each band in the ladder will be found in only one of the lanes. As one scanned the pattern, from the bands of greatest mobility to the bands of least mobility, one would encounter each band of the ladder in its proper succession. The lane in which each successive band was found would have been determined by the identity of the nucleotide that follows its actual 3'-terminal nucleotide in the complete sequence of the original DNA. By starting with the band of greatest mobility and noting its lane and the lane in which each successive band of lower mobility occurs,

one would be reading the sequence of the DNA in the direction from 5' to 3'.

The strategy for sequencing DNA illustrated by this simplified situation requires that a set of **end-labeled fragments** of single-stranded DNA be produced. Each of these fragments must have as its 5'-terminus the same nucleotide in the nucleic acid sequence to be determined, but this does not have to be the actual 5'-terminus of the original piece of DNA. For example, this result could be achieved by cleaving all of the molecules of the original DNA at the same nucleotide with a site-specific deoxyribonuclease. Every position in the portion of the complete nucleic acid sequence to be determined from the four lanes of a particular polyacrylamide gel must be represented by a labeled fragment that ends at this position and that has been produced in sufficient yield to be visualized. The observer must have enough information about each fragment visualized to associate its 3'-terminus with a particular nucleoside, deoxyadenosine, deoxyguanosine, deoxycytidine, or thymidine. In practice, this information is either that the 3'-terminus of a particular fragment precedes a particular nucleotide in the complete nucleic acid sequence or that its 3'-terminus is a particular nucleotide. There are two methods, chemical and enzymatic, for producing such a set of fragments. Neither corresponds exactly to the simplified illustration just described, but both satisfy the requirements of the strategy.

In the **chemical method** of Maxam and Gilbert,⁷⁷ reagents that take advantage of the hybrid nature of the nucleotide bases, which are partly aromatic heterocycles and partly acyl derivatives, are used to cleave chemically the single-stranded DNA, labeled at its 5'-terminus, at locations occupied by a particular base. The chemical cleavages used are based on reactions previously developed to remove selectively either purine bases or pyrimidine bases from DNA. Such reactions are depurinations⁷⁸ or depyrimidinations,⁷⁹ respectively. Reagents are used to depurinate the single-stranded DNA preferentially at deoxyguanosine^{80,81} or deoxyadenosine^{77,78} or to depyrimidinate single-stranded DNA selectively at both deoxycytidine and thymine^{79,82,83} or preferentially at deoxycytidine.⁷⁷ A position in DNA that has lost its nucleoside base by depurination or depyrimidination is susceptible to hydrolysis in base^{79,84} while normal DNA is not. In preparation for sequencing, the DNA is partially depurinated or depyrimidinated, respectively, at locations the identity of which has been controlled by the conditions of these reactions and is then hydrolyzed at each of these locations by treatment with base to produce fragments that have as their 3'-terminus a nucleotide that preceded, in the original nucleic acid sequence, a target for the depurination or depyrimidination.

In the **enzymatic method** of Sanger, Nicklen, and Coulson,⁸⁵ the properly terminated fragments required for the electrophoresis are made by synthesizing com-

plementary strands of DNA by use of the single-stranded DNA to be sequenced as a template in four separate elongations catalyzed by DNA-directed DNA polymerase (Figure 3-10). The nucleotides inserted by the polymerase are present in solution as their activated 5'-triphosphates. In the original method, the newly synthesized polymer of DNA is made radioactive by including [α - 32 P]dATP in the synthetic mixture. The successive fragments that have at their 3'-end only a particular nucleotide are produced by including a small amount of 3'-deoxythymidine triphosphate, 2',3'-dideoxycytidine triphosphate, 2',3'-dideoxyguanosine triphosphate, or 2',3'-dideoxyadenosine triphosphate, each in one of the four elongations, along with the thymidine triphosphate, 2'-deoxycytidine triphosphate, 2'-deoxyguanosine triphosphate, and 2'-deoxyadenosine triphosphate present in all of them. Occasionally, a **2',3'-dideoxynucleotide** is incorporated into one of the growing polymers by the DNA-directed DNA polymerase, and its incorporation terminates polymerization because that polymer then lacks the 3'-hydroxyl group necessary for further elongation. In this way fragments satisfying two of the requirements for electrophoretic sequencing are produced.

The last requirement, that every fragment have as its 5'-terminus the same position in the complete sequence, is satisfied by taking advantage of the requirement of DNA-directed DNA polymerase for a primer to provide a 3'-hydroxyl group from which the new strand can be elongated. To initiate the reaction, a primer that is complementary to a segment of the DNA to be sequenced is annealed to the template to provide the necessary 3'-hydroxyl group. Because the DNA-directed DNA polymerase starts at the primer when it synthesizes a complementary, radioactive single strand of DNA, the sequence of the primer can be chosen so that the newly synthesized DNA will begin at a particular point in the sequence of the template. The complementary sequence to which the primer is annealed can be a short piece of DNA of known sequence that has been deliberately attached to the 3'-end of the DNA to be sequenced,⁸⁶ or it can be any internal sequence for which a complementary fragment of single-stranded DNA happens to be available.⁸⁵ Often this complementary fragment is a probe that had been made for purposes of screening. It is also possible to use an oligonucleotide that has the same sequence as a segment near the 3'-end of the longest single-stranded fragment that provided readable nucleotide sequence in the last set of polyacrylamide gels, to extend the sequencing of the template further to its 5'-end. In this way, one can walk along a long template and read its entire sequence.

The polyacrylamide gels that result from the application of these two methods, the chemical and the enzymatic, are similar in appearance (Figure 3-14A, B).^{77,85} Sequence is read from the bottom (shortest fragments) to the top (longest fragments), 5' to 3'. In the chemical

method the sequence of the original single-stranded DNA is being read. In the enzymatic method the sequence of the complement of the original single-stranded DNA is being read. Since DNA is normally double-helical with two antiparallel strands of complementary sequence, either sequence is formally the sequence of the DNA, as long as the correct direction (5' \rightarrow 3') is assigned to the sequence by the observer.

These original methods, the chemical and the enzymatic, were both based on the use of fragments of nucleic acid made radioactive by incorporating [32 P]phosphate (Figure 3-14A, B), but in the **automated DNA sequencers** currently in use, **end-labeled fluorescent fragments** of nucleic acid are used. Although chemical methods have been developed⁸⁷ that may eventually be more efficient, the current automated procedures for sequencing DNA are based on the original enzymatic method of Sanger, Nicklen, and Coulson.⁸⁵ The products of the terminations by the dideoxynucleotides are all separated together on the same gel of polyacrylamide, which is continuously scanned by a fluorometer.⁸⁸ The products from the four respective termination reactions are end-labeled with four different fluorescent dyes that can be distinguished by the fluorometer on the basis of the colors of their fluorescence. The separate fluorescent tags are applied one of two ways.

Synthetic derivatives of 2',3'-dideoxyadenosine triphosphate, 2',3'-dideoxyguanosine triphosphate, 3'-deoxythymidine triphosphate, and 2',3'-dideoxycytidine triphosphate have been prepared that each have a different fluorescent dye covalently attached to their heterocyclic bases.^{89,90} When these derivatives are used to terminate the single-stranded fragments and thereby label them at their 3'-ends, the fluorometer can distinguish strands of DNA terminated at deoxyadenosines, deoxyguanosines, thymidines, or deoxycytidines from each other by their differences in fluorescence.

Alternatively, four distinguishable fluorescent dyes can be attached separately to the 5'-ends of four identical samples of the primer that will be used,⁸⁸ and a different one of the resulting fluorescent primers can be used in each of the four termination reactions. When the separate dideoxy terminations have been completed, the products of the four reactions are mixed. When the mixture is separated by electrophoresis, the fluorometer distinguishes each strand by the color of the fluorescence emitted by the fluorescent dye on its 5'-end, which identifies the termination mixture in which it arose.

The DNA-directed DNA polymerase used in these automated sequencers is an improved version. The original enzyme used, the Klenow fragment of DNA-directed DNA polymerase from *E. coli*, terminates the elongation at each position with a different yield that can vary significantly (Figure 3-14B). This variability can result in uncertainty in reading the sequence, especially when it is to be read by a machine. DNA-directed DNA polymerase from bacteriophage T7 produces a much more uniform

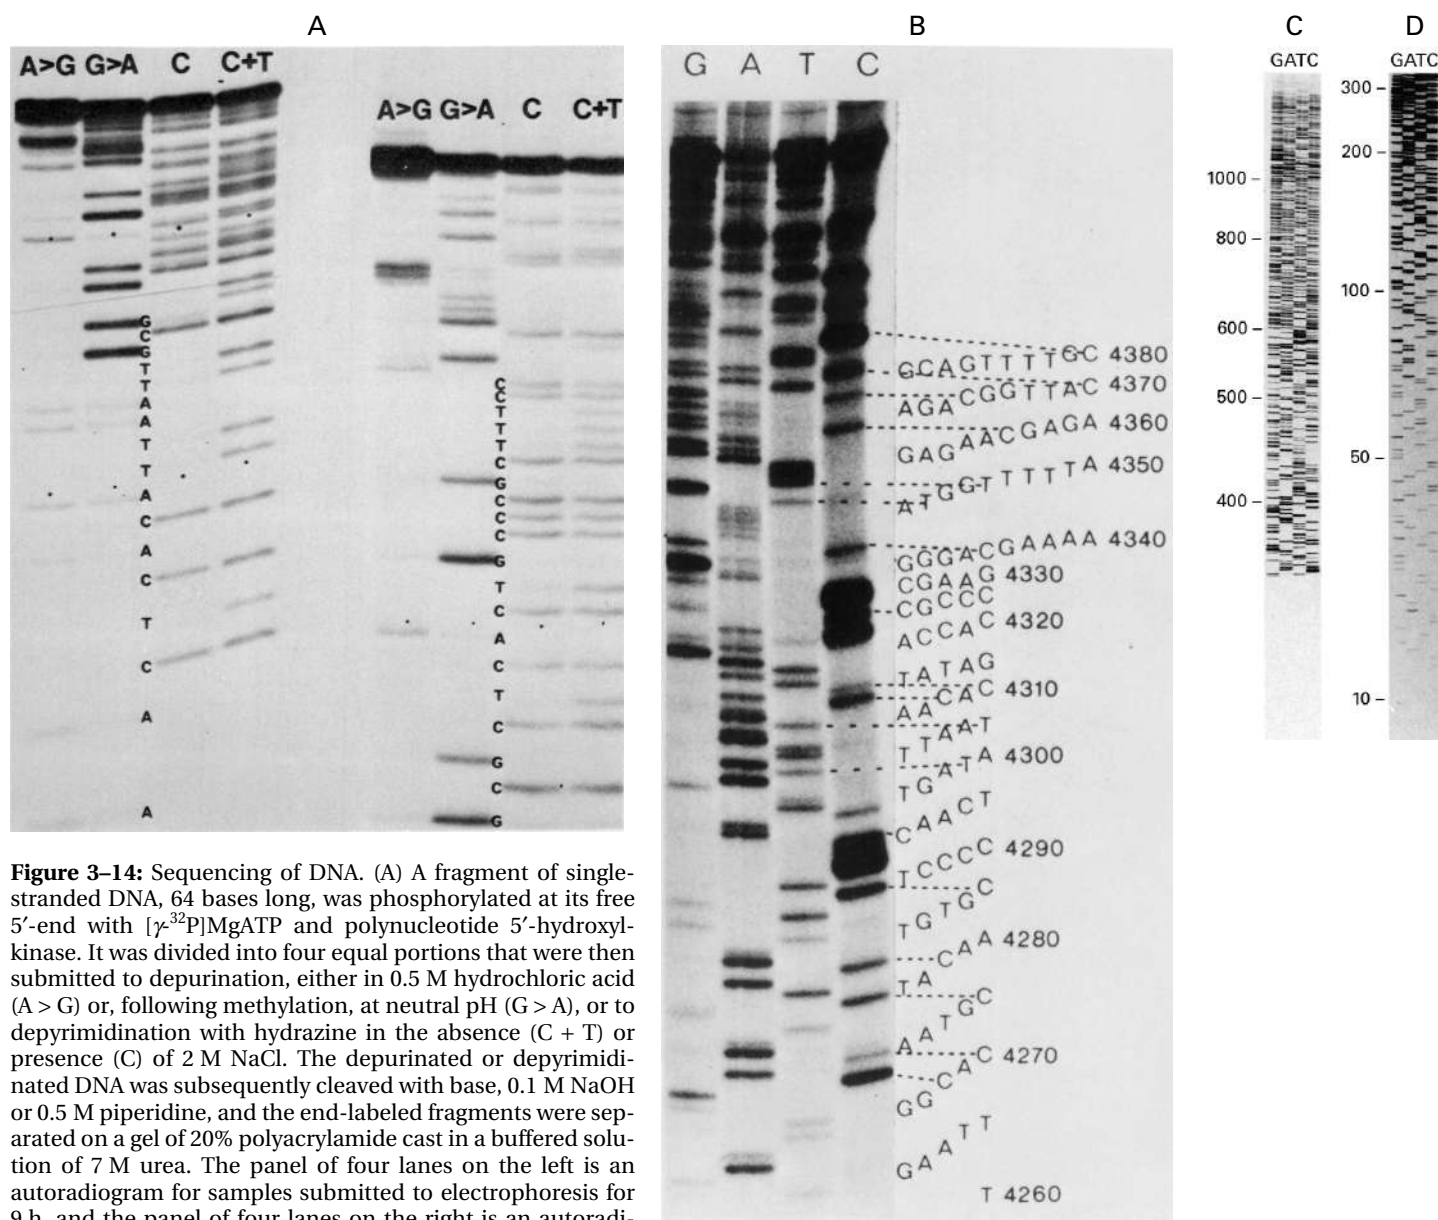

Figure 3-14: Sequencing of DNA. (A) A fragment of single-stranded DNA, 64 bases long, was phosphorylated at its free 5'-end with $[\gamma\text{-}^{32}\text{P}]\text{MgATP}$ and polynucleotide 5'-hydroxyl-kinase. It was divided into four equal portions that were then submitted to depurination, either in 0.5 M hydrochloric acid ($\text{A} > \text{G}$) or, following methylation, at neutral pH ($\text{G} > \text{A}$), or to depyrimidination with hydrazine in the absence ($\text{C} + \text{T}$) or presence (C) of 2 M NaCl. The depurinated or depyrimidinated DNA was subsequently cleaved with base, 0.1 M NaOH or 0.5 M piperidine, and the end-labeled fragments were separated on a gel of 20% polyacrylamide cast in a buffered solution of 7 M urea. The panel of four lanes on the left is an autoradiogram for samples submitted to electrophoresis for 9 h, and the panel of four lanes on the right is an autoradiogram for identical samples submitted to electrophoresis for 33 h. The sequence noted on the autoradiogram on the left, $-\text{TTTCCCGACTGG}-$, continues on the autoradiogram on the right.⁷⁷ Reprinted with permission from ref 77. Copyright 1977 National Academy of Sciences. (B) A fragment of DNA complementary to a short segment of the nucleic acid sequence of the single-stranded DNA from the bacteriophage ϕX174 was annealed to the template as a primer. The initiation complex was divided into four equal portions. Elongation of the primer in these separate samples was performed with DNA-directed DNA polymerase in the presence of 2',3'-dideoxyguanosine triphosphate (lane G), 2',3'-dideoxyadenosine triphosphate (lane A), 3'-deoxythymidine triphosphate (lane T), and 2',3'-dideoxycytosine triphosphate (lane C). Each sample contained a small amount of $[\alpha\text{-}^{32}\text{P}]\text{MgATP}$ to render the newly synthesized DNA radioactive. Following these respective reactions, each sample was digested with the *Hae*III site-specific deoxyribonuclease, which cut the DNA within the primer, so that all of the newly synthesized DNA would start with the same nucleotide at the 5'-end. The single-stranded, radioactive fragments of DNA in each sample were separated by electrophoresis on a slab of 12% polyacrylamide.⁸⁵ Reprinted with permission from ref 85. Copyright 1977 National Academy of Sciences. (C, D) A segment of single-stranded DNA 2707 bases long from the bacteriophage T7 was cloned in bacteriophage M13. The single-stranded genome of the M13 bacteriophage carrying the insert was used as template, and a short segment of synthetic DNA complementary to a region adjacent to the insert was annealed to the template as a primer. This initiation complex was labeled radioactively by mixing it with low concentrations (0.3 μM) of dGTP, TTP, dCTP, and $(\alpha\text{-}^{35}\text{S})\text{thio}(\text{dATP})$, as well as DNA-directed DNA polymerase from bacteriophage T7. After 5 min at room temperature, this mixture was divided into four equal portions to which were added high concentrations (150 μM) of dATP, dGTP, dCTP, and TTP. To each portion was added one of the dideoxynucleotides at 15 μM : 2',3'-dideoxyguanosine triphosphate (lanes G), 2',3'-dideoxyadenosine triphosphate (lanes A), 3'-deoxythymidine triphosphate (lanes T), or 2',3'-dideoxycytidine triphosphate (lanes C). The reaction was initiated by adding a high concentration of DNA-directed DNA polymerase from T7 bacteriophage. After 5 min at 37°C, the four samples were prepared for electrophoresis, the single-stranded radioactive fragments of DNA in each sample were separated on slabs of 7% polyacrylamide run for 12 h (C) or 2 h (D), and the gels were submitted to autoradiography. The numbers to each side indicate the lengths of the single-stranded fragments.⁹¹ Reprinted with permission from ref 91. Copyright 1987 held by authors.

yield of fragments terminated by 2',3'-dideoxynucleotides (Figure 3-14C, D).⁹¹ Certain mutants of the enzyme from *E. coli* are even more reliable than their parent.⁹²

The electrophoretic separations presented in Figure 3-13 illustrate an important artifact common to all methods of sequencing DNA. The thick band at the eleventh rung of the ladder on the electrophoretogram to the right is a **compression**. Within that one band, single-stranded RNAs from 24 to 27 nucleotides in length comigrate. The band above the compression is the single-stranded RNA 28 nucleotides long; and that below, 23 nucleotides long.⁷³ A compression usually occurs when the 3'-end of the fragment of single-stranded nucleic acid is rich in G and C, and it is caused by structures formed intramolecularly among these bases by the usual GC pairing.⁹¹ When a compression is not recognized as such by a person or by a machine, it is mistaken for a normal band representing a single polynucleotide and the sequence read will be missing one or more nucleotides. It is possible to eliminate such compressions by using 2'-deoxyinosine triphosphate instead of 2'-deoxyguanosine triphosphate in the elongation mixtures of the enzymatic method.⁹¹

Once the sequence of a segment of prokaryotic genomic DNA or eukaryotic complementary DNA is in hand, the complete sequence of the protein can be read from the open reading frame that encodes it. The sequence of nucleotides in the messenger RNA that encodes a polypeptide begins with the **initiation codon** -AUG-, which can be recognized in the sequence by its proximity to sequences encoding a binding site for a ribosome, and ends with a **termination codon**, -UAA-, -UGA-, or -UAG-. An **open reading frame** (ORF) is any sequence of nucleotides that begins with an initiation codon and ends with a termination codon. Because a sequence of DNA does not indicate the reading frame used to synthesize the protein nor which of the two complementary strands is the sense strand (Figure 3-11), there are six possible sequences of triplets that could encode the protein. These six different reading frames in any sequence of nucleotides obtained experimentally each contain open reading frames, and the open reading frame encoding an actual protein can be recognized only if some information about the protein is known, for example, its length or sequences from some of its peptides.

In the case of the α polypeptide of murine nicotinic acetylcholine receptor, each sequence of an individual single strand of DNA from the restriction mapping (Figure 3-12) began at the 5'-end of one of the two complementary strands of a double-helical fragment and was read as far as was possible. With the exception of two short segments, each region of the sequence was read at least twice. Together, all of these individual sequences produced the complete sequence of the complementary DNA (Figure 3-15).⁷² Of the six reading frames in the

completely sequenced double-helical complementary DNA, the one containing the open reading frame encoding the sequence of the α polypeptide of murine nicotinic acetylcholine receptor was easily identified by locating the one that encoded the amino acid sequences on which the probes used to screen the clones were based.

In the case of human Factor VIII, when the sequences of the different segments of DNA identified by the screen were translated into amino acid sequences, each segment was found to contain an overlapping region of the same open reading frame that encoded the sequence AWAYFSDVDLEK. The amino acid sequences of four of the other peptides of factor VIII that had been submitted to Edman degradation could also be found in the translation of this one complete open reading frame found in the nucleic acid sequences of the overlapping clones. Comparisons like these between directly determined amino acid sequences of a particular protein or its experimentally determined composition of amino acids^{93,94} and the amino acid sequence translated from an open reading frame in the complementary DNA or genomic DNA are often used to substantiate the identification of the complementary DNA or genomic DNA as that encoding a particular protein.

The sequences of peptides from the protein permit the proper open reading frame to be assigned, but if bases have been omitted by mistake during the sequencing of the nucleic acid, these omissions can produce a frameshift. A **frameshift** is the inadvertent shift into another reading frame as the sequence of nucleotides is being divided into triplets. It is caused by the omission of $3n + 1$ or $3n + 2$ bases in the sequence. One common mistake leading to a frameshift is the omission of several bases in the sequence that results when a compression goes unrecognized.⁹⁵ It is not unusual for an initial DNA sequence to contain errors, often quite a few,⁹⁶ but they are usually recognized and corrected by sequencing both the complementary strands or during further examinations of the protein it encodes.^{97,98}

When amino acid sequences of proteins were determined directly, the proteins chosen for sequencing were usually enzymes, and the sequences obtained were unremarkable. When the explosion of amino acid sequences from sequencing DNA commenced, so many more proteins were being sequenced that peculiar ones were discovered. The most obvious peculiarities were **enrichments** in a particular amino acid, such as a cell wall protein (465 aa) containing 60% glycine,⁹⁹ a 127 aa segment of chicken vitellogenin containing 75% serine,¹⁰⁰ a 655 aa segment of spider dragline silk containing 47% glycine and 28% alanine,¹⁰¹ a 246 aa segment of murine MP-2 containing 46% proline and 17% glutamine,¹⁰² a 71 aa segment of histidine-proline-rich glycoprotein containing 50% histidine,¹⁰³ a 30 aa segment of the Abdominal-B domain of the bithorax complex of *Drosophila melanogaster* containing 22 glut-

Figure 3–15: Nucleic acid sequence and deduced amino acid sequence for the α polypeptide of murine nicotinic acetylcholine receptor.⁷² The nucleotides are presented in the 5' to 3' direction for the coding strand. Both sequences are numbered starting with the first amino acid in the mature protein. The first eight amino acids in the presented sequence are removed posttranslationally. The initiation codon for translation was not on the cloned piece of complementary DNA. The asterisk marks the codon at which translation is terminated. The restriction sites that produced the restriction map (Figure 3–12) are identified in the nucleic acid sequence. The *Pst*I restriction sites situated at the two ends of the insert that were used to remove complementary DNA from the plasmid (Figure 3–12) are lost during the insertion of the restriction fragments of the complementary DNA into the M13 bacteriophage, but the sequence shown begins just after the initial *Pst*I site and ends just before the final *Pst*I site. Reprinted with permission from ref 72. Copyright 1985 Oxford University Press.

amines,¹⁰⁴ or a stretch of up to 37 successive glutamines in normal human HD protein.¹⁰⁵⁻¹⁰⁸ A protein induced by abscisic acid in maize has a segment 66 aa long containing only arginine, tyrosine, and glycine in which the sequence GYG₂G repeats 7 times,¹⁰⁹ and the repeating unit of rat filaggrin (406 aa) containing 15% glutamine but no asparagine, 14% arginine but no lysine, 2% isoleucine but no leucine, no cysteine or methionine, and no tryptophan or phenylalanine.^{110,111} In many of these enriched proteins, strings of 5-20 aa in length containing only one amino acid are common. Most of these proteins form flexible polymeric solids with physical properties appropriate to their function, and their peculiar sequences provide an intuition of the way in which they accomplish their roles.

The large majority of proteins, however, have sequences that in isolation say nothing about their structure or function, but the large number of sequences that have become available as a result of sequencing DNA permit proteins to be grouped into **families**. By the structure and function of its relatives, the structure and function of an unknown protein can often be revealed. The most obvious instance of such grouping of amino acid sequences is when a protein isolated from one organism is recognized to be the same protein, albeit with a somewhat different sequence, as one that is found in other species.¹¹² The most dramatic examples of such comparisons of amino acid sequences are those in which a protein responsible for one function is isolated and found to be identical to a protein isolated from the same species on the basis of its responsibility for another function.^{113,114}

The amino acid sequences of all the proteins in many prokaryotic species are now available. **Complete genomic sequences** have been determined for a number of those that are widely used in experimentation. These genomic sequences permit the amino acid sequence of a prokaryotic protein to be obtained without the need for sequencing its DNA. If enough amino acid sequence has been obtained from a protein to construct a probe to screen a library, one has enough amino acid sequence to search by computer the complete genome for the species from which the protein was isolated, identify the gene encoding that protein, and thereby obtain its complete amino acid sequence. Unfortunately, the existence of introns in the genes encoding eukaryotic proteins usually makes it impossible to obtain an accurate amino acid sequence of an unknown protein from the genomic sequence of the eukaryote from which it is derived. If, however, a set of already known amino acid sequences of proteins closely related to the protein of interest can be assembled, these sequences can be often be used to define the boundaries of the introns in the gene encoding the protein of unknown sequence.¹¹⁵ If the boundaries of the introns can be defined, the sequence of the protein can be read from the genomic DNA.

Once complementary DNA, if the protein is eukaryotic, or genomic DNA, if the protein is prokaryotic, encoding the complete, uninterrupted amino acid sequence of a protein has been cloned, it is possible to use that DNA to direct the production of the protein. This strategy provides a convenient and abundant source of the protein. It is also possible to cut out any piece of that DNA with the proper site-specific deoxyribonucleases and direct the production of the fragment of the protein encoded by the resulting fragment of the DNA. This strategy provides precisely designed pieces of the protein.

An **expression system** is any process by which foreign DNA encoding a protein of interest or a portion of that protein has been incorporated into a population of living cells and those cells have been induced to transcribe that foreign DNA into messenger RNA and translate that messenger RNA into usable quantities of the protein for which it encodes. The cells expressing the protein are usually not of the same species or even kingdom of the species from which the protein was first purified. *Escherichia coli*, a bacterium, is the organism most widely used to express proteins, often those from animals. For example, complementary DNA encoding the 5-aminolevulinate synthase from *Mus musculus* has been expressed in cells of *E. coli*, and when these bacterial cells were harvested, 50% of the protein in them was murine 5-aminolevulinate synthase. Each liter of culture medium yielded bacterial cells from which 5 mg of the pure enzyme could be isolated.¹¹⁶ Because the expression system is usually unrelated to the organism from which the DNA to be expressed was originally derived, that expression system is usually unable to splice introns out of the messenger RNA encoded by genomic DNA. Consequently, if a eukaryotic protein or a portion of a eukaryotic protein is to be expressed, its complementary DNA is used.

An **expression vector** is a molecule of DNA into which the DNA encoding the protein to be expressed is inserted and which compels the cells of the expression system to express the protein. When proteins are expressed in *E. coli*, the expression vectors are usually plasmids. There are many plasmids used as expression vectors, but each of them usually contains a gene conveying resistance to an antibiotic so that only cells carrying the plasmid will grow. The insertion is performed at a restriction site that occurs only once in the sequence of the DNA for the plasmid. The insertion is performed by cleaving that site with the appropriate site-specific deoxyribonuclease, adding the fragment of DNA encoding the protein, and ligating the pieces of DNA. The expression vector has been designed so that this restriction site for insertion is immediately adjacent to sequences of DNA that enforce the transcription and translation of the inserted DNA. To guarantee high levels of transcription, there is a **strong promoter**, for example, a T3 promoter, a T7 promoter, a *lacZ* promoter, an alka-

line phosphatase promoter, a *tacII* promoter, or a *trc* promoter. These promoters are segments of DNA that serve as unusually active sites for the initiation of the synthesis of messenger RNA by DNA-directed RNA polymerase. The DNA preceding the point of insertion on the plasmid must also have sequences necessary for the active translation of the messenger RNA into protein.

The DNA inserted into the **restriction site on the expression vector** is often complementary DNA or genomic DNA that has just been used for sequencing, and that DNA is cut out of the bacteriophage or plasmid in which it was screened and amplified. Occasionally, the inserted complementary DNA is from an organism the codon usage of which is so different from that of *E. coli* that poor expression occurs because of this mismatch. One solution to this problem is to synthesize the complementary DNA with compatible codons.¹¹⁷ The insertion into the expression vector is accomplished most effectively if the fragment has sticky ends that are compatible with the restriction site on the expression vector. One way this is accomplished is to use primers for the polymerase chain reaction that contain the sequences of DNA necessary to anneal to complementary sequences of the DNA at the beginning and end of the coding sequence but in addition contain sequences of DNA for the appropriate endonucleolytic cleavage sites^{64,118,119} and even sequences necessary for translation.¹²⁰ The final DNA produced in the polymerase chain reaction will incorporate these additional sequences even though they did not exist in the initial DNA used as the template. If the complementary DNA encodes a segment of amino acid sequence that is normally removed from the native protein by a posttranslational process absent from *E. coli*, the portion of the DNA encoding that segment sometimes has to be removed before a fully functional protein can be expressed.¹²¹

A piece of DNA encoding another amino acid sequence is often inserted ahead of the DNA encoding the protein of interest. For example, a portion of DNA encoding a strong promoter as well as a short segment of the protein that promoter usually controls, such as a segment of β -galactosidase or the λ cII protein, can be placed in front of the DNA to be expressed to guarantee that it is produced efficiently. In this instance, a stop codon followed by a start codon can be inserted between the two coding regions so that the fragment of DNA promoting transcription is not translated attached to the protein being expressed. It has been found in many instances, however, that **fusion proteins**, proteins in which the protein of interest is coupled during translation to another complete protein such as glutathione transferase, β -galactosidase, or ubiquitin, are expressed in much higher yield than the unfused, intact protein of interest. Often this is due to the fact that the fusion protein resists the endopeptidases of the *E. coli*^{122,123} that would otherwise degrade the protein of interest. To iso-

late the protein of interest without the associated fusion protein, an amino acid sequence is often introduced between the two proteins that is a target for an endopeptidase of stringent specificity, such as activated factor Xa or renin, so that the unwanted portion can be removed by cleavage with that endopeptidase.

A fusion protein can also be one between the protein of interest and a portion of a protein such as an enterotoxin that contains a signal for secretion from *E. coli*. In this case, the protein produced ends up in the medium rather than in the cells. In one instance, however, expression of a protein that is normally excreted from *E. coli* was toxic to the cells at the levels produced, and the sequences signalling excretion had to be removed to keep the protein inside the cells.¹²⁴

One problem with expression of a foreign protein in *E. coli* is its precipitation to form large **inclusion bodies**. In this precipitated form, the protein being expressed is inactive and indistinguishable from any other precipitated protein. It is often possible, however, to dissolve these precipitates in a solution of a salting-in solute such as urea or guanidinium chloride and renature functionally active, fully soluble protein from this solution.

Proteins can be expressed in cells other than those of *E. coli*. Expression plasmids containing promoters active in *Saccharomyces cerevisiae*¹²⁵ that can be incorporated into cells of this species of **yeast** are available for expressing proteins.¹²⁶ One of the difficulties of expressing animal proteins in bacteria or fungi is that these cells are unable to perform normal **posttranslational modifications**. An animal protein that is normally modified posttranslationally is usually expressed in animal cells capable of such modifications. One such animal system that provides high yields of protein is cells of the insect *Spodoptera frugiperda*. These **insect cells**, grown in culture, can be infected with virions containing an expression vector constructed from viral DNA of the nuclear polyhedrosis virus *Autographa californica*¹²⁷ just as a culture of *E. coli* can be infected with bacteriophage λ . If the DNA encoding the protein of interest is inserted at a point in the viral genome under the control of the promoter for the viral coat protein, high yields of the expressed protein are produced. Even higher yields can be produced if larvae (caterpillars) of *Trichoplusia ni* are infected with such a virus.¹²⁸ These insect expression systems produce proteins with many of the normal posttranslational modifications of animals.¹²⁹

To ensure that posttranslational modifications of mammalian proteins that are foreign to insects are correctly made or to express a mammalian protein in the biological context of a mammalian cell, proteins are often expressed in cultured **mammalian cells** by use of an expression vector carrying a promoter from an animal virus, such as cytomegalovirus or simian virus. Such expression vectors can be inserted into the genomic DNA

of an animal cell such as Chinese hamster ovary cells or murine L cells by transfection.

When a protein is expressed in any of these expression systems, the final product of the expression is usually a pellet of cells that is then homogenized, producing a complex mixture of proteins. Even if the expression has been so successful that the protein that has been expressed accounts for the majority of the protein in this mixture, it still must be purified. This **purification** is usually performed by the standard procedures because they are simple to implement, but it is possible to design the expressed protein to ease its purification. For example, the protein can be expressed with a string of six histidines attached at its carboxy terminus or amino terminus. An affinity adsorbent to which Ni^{2+} has been attached through a covalently bound iminodiacetic acid¹³⁰ binds such **histidine tails** with high specificity, and the expressed protein can be eluted, often in pure form, with a gradient of imidazole.¹³¹ It is also possible to purify expressed proteins specifically if they have been designed to contain a short amino acid sequence on one of their termini recognized by a specific **immunoglobulin** immobilized on a solid phase. Fusion proteins between the protein of interest and **glutathione transferase** can be purified by using an affinity adsorbent on which glutathione has been covalently attached and eluting with glutathione. All of these strategies require that a short sequence of amino acids or even another protein be fused with the protein of interest, but if a short sequence recognized by a stringent endopeptidase is incorporated between the two, the protein of interest can be released in its unmodified form by digestion.

One advantage of expressing a protein in a system in which it is produced as a major fraction of the cellular protein or it has been tagged for affinity adsorption is that its purification often requires fewer steps than purification from its natural source. Because the steps of a purification are often accompanied by slow degradation of the protein, the fewer the steps, the more homogeneous will be the final purified protein. Crystals are more readily obtained from a protein the purification of which has been simple and rapid. For this reason, if they are available in high yield, expressed proteins are usually used in **crystallographic studies** in preference to the same proteins purified from natural sources. Often, however, expressing a protein in cells, even in *E. coli*, provides far less of the purified protein than can be obtained by starting with 10 kg of liver, heart, blood, or skeletal muscle. In such instances, if all that is desired is the pure protein, using an expression system is inefficient and costly. If, however, one experimental goal is to mutate specific amino acids in the sequence of the protein, an expression system is unavoidable.

Site-directed mutation^{132,133} converts one particular amino acid in the sequence of a polypeptide into another of the 20 amino acids. It is also possible to delete

amino acids from the sequence of a polypeptide or insert extra amino acids at a particular location with this technique. The method requires that the complementary DNA or genomic DNA for the protein of interest has been cloned and that the encoded protein can be expressed, in quantities sufficient for the contemplated experiments. The site-directed mutation is incorporated into the DNA, and the mutated DNA is used to direct the production of the modified polypeptide in which one particular amino acid has been deliberately changed. For example, a collection of 13 mutated versions of the lysozyme from T4 bacteriophage, in which Threonine 157 had been changed to 13 of the other 19 amino acids, was produced by site-directed mutation. Each of these 13 different proteins was obtained as a pure crystalline product in quantities sufficient for crystallographic analysis.¹³⁴

A site-directed mutation can be introduced into a particular segment of DNA by annealing a short piece of synthetic DNA, the **mutagenic oligonucleotide**, to one of the two strands of the unmutated DNA to form a short section of double-helical DNA in which one or more of the nucleotide bases are mismatched.¹³² The mutagenic oligonucleotide is designed so that the desired mismatches occur in the middle of the duplex formed by the annealing and there are sufficiently long regions of complementary nucleotide sequence on each flank to guarantee that a stable and specific duplex is formed. The original way this was accomplished is the following.

A restriction fragment of the DNA encoding the protein of interest and containing the site to be mutated is inserted into the genome of an M13 bacteriophage, a bacteriophage that carries its genome as single-stranded DNA. Infection of a suspension of *E. coli* with the altered bacteriophage produces virus particles containing the enlarged genome on a closed, single-stranded circle of DNA.¹³⁵ Closed, single-stranded circles containing the strand of the inserted DNA complementary to the mutagenic oligonucleotide are selected¹³³ for hybridization. The mutagenic oligonucleotide is complementary to sequences on this single-stranded DNA except at the central, mismatched positions, chosen to produce the desired change in a particular codon. For example, the deoxyribonucleotide sequence –CTCTACTGCGGGTT–TG– occurs in DNA encoding the sequence of tyrosyl-tRNA synthetase from *Bacillus stearothermophilus*. It encodes the amino acid sequence –LYCGF–, which contains amino acids 33–37 in the sequence of the intact protein. The mutagenic oligonucleotide –CAAACCCGC–CGTAGAG– was chemically synthesized.¹³⁶ It is complementary to the coding sequence of the unmutated complementary DNA except at its tenth residue, which is a C instead of the complementary A. When it was annealed to a single-stranded, circular DNA containing DNA with the unmutated sequence, it formed a short self-complementary segment of double-stranded DNA in which its C was mismatched with the T of the unmutated

sequence. It was this mismatch that eventually produced the mutated DNA with the sequence –CTCTACG-GCGGGTTTG–, encoding the mutated protein sequence, –LYGGF–.

The short mutagenic oligonucleotide sits upon the single-stranded, circular M13 DNA as a primer offering a free 3'-hydroxyl group. This hydroxyl is used to initiate the synthesis of DNA by DNA-directed DNA polymerase.^{132,133} The enzyme synthesizes a single strand of DNA upon the circular template until it comes around the circle to the 5'-end of the mutagenic oligonucleotide where it stops. The newly synthesized, single-stranded circle is then closed with DNA ligase to produce a closed, double-stranded circle of DNA, completely complementary except at the designed mismatch. This double-stranded circular DNA is then replicated in a suspension of *E. coli*. Half of the resulting viral DNA should contain the mutated sequence of the segment of the inserted DNA because it is the progeny of the single strand into which the mutagenic oligonucleotide was incorporated originally.

Plaques produced by the viruses are screened to locate ones producing the mutated DNA,¹³³ double-stranded DNA is produced from one of these mutants and amplified, and the desired restriction fragment containing the mutation is isolated and reintroduced into the original DNA to create full-length DNA incorporating the mutation. The mutant protein expressed from this full-length, mutant DNA should contain the designated substitution. For example, in the case of the mutated tyrosyl-tRNA synthetase, it was shown by direct sequencing of the purified protein that it had a glycine rather than a cysteine at position 35.¹³⁶ That the modification has occurred, however, is usually verified by sequencing the mutated DNA rather than the protein itself.

Several **improvements** in the original method for site-directed mutation just described have been made. The most important is the adaptation of the procedure so that double-stranded plasmids, rather than single-stranded M13 DNA, can be mutated directly.¹³⁷ Another improvement has been the development of strategies permitting the removal of the parental unmutated strands of DNA that served as the template for the mutation so that all of the newly synthesized DNA carries the mutated sequence,^{138–141} increasing the percentage of the product that bears the mutation. A related method that also selects for DNA bearing the mutation is to use two primers, one that mutates the position of interest and the other that mutates a unique restriction site on the plasmid outside of the DNA inserted into it. In this way only the DNA containing the desired mutation, which also has the mutated restriction site, is immune to cleavage at the restriction site.¹⁴² Finally, the PCR method has been applied to produce mutated DNA.^{143–145} Because of its importance, many different procedures are now available for site-directed mutation, and each investigator believes that the one she is using is the best.

Site-directed mutations can also be produced by insertion of **cassettes** of synthetic double-stranded DNA into a particular complementary DNA. In this method, preexisting or purposely designed restriction sites for site-specific deoxyribonucleases that flank the region to be mutated are chosen. These restriction sites are designed or chosen so that the piece of double-stranded DNA produced by the site-specific deoxyribonucleases is short and has single-stranded, sticky ends, such as those produced by *Pst*I (CTGCA↓G). A double-stranded segment of DNA is synthesized so that it has the appropriate sticky ends and incorporates complementary nucleotide sequences that encode the desired mutation. This is the cassette, which is then inserted into the hole in the original complementary DNA produced by the site-specific deoxyribonucleases. The advantage of the cassette is that the mutation is produced directly by insertion of synthetic double-stranded DNA. The disadvantage is that two complementary pieces of synthetic single-stranded DNA have to be synthesized. Nevertheless, mutation with cassettes has particular advantages when sets of mutants are prepared in which all of the possible 19 substitutions need to be made at a particular location.¹⁴⁶ A similar but much more ambitious strategy is to synthesize fragments of DNA that when ligated together constitute the entire coding sequence for a protein. In this way a mutation can be introduced anywhere by synthesizing the corresponding fragment that has the altered sequence at the position to be mutated and ligating it with the remaining unmutated fragments.¹⁴⁷

One of the supposed drawbacks of site-directed mutation is that only the 19 other natural α amino acids are available for substitution at the mutated site. It is rather easy to synthesize an α amino acid. A large number are available commercially and if one that has been drawn on a piece of paper is not available commercially, it can usually be synthesized. It is now possible to replace an amino acid at any position in a polypeptide with any one of these **unnatural amino acids**. To do this, advantage is taken of the fact that there are three stop codons for translation: UAA (ochre), UAG (amber), and UGA. A rare tRNA, the amber suppressor tRNA, reads the codon UAG and normally inserts phenylalanine at that position. The triplet encoding the chosen amino acid in the coding sequence of the protein is mutated by usual site-directed mutation to TAG, and an amber suppressor tRNA (tRNA_{CUA}) to which the unnatural amino acid to be inserted has been synthetically attached is used to effect the desired substitution in a cell-free system for transcription and translation.^{148,149} The requirements for chemically synthesizing the derivative of the suppressor tRNA and the low yields of protein from the cell-free translation system have limited the application of these procedures, but in at least one instance protein sufficient for crystallographic studies has been prepared.¹⁵⁰

Natl Acad. Sci. U.S.A.* 96, 10039–10044.

Problem 3-7: Draw the complete structures of 2'-deoxyadenosine 5'-triphosphate (dATP), 2'-deoxyguanosine 5'-triphosphate (dGTP), thymidine 5'-triphosphate (dTTP), 2'-deoxycytidine 5'-triphosphate (dCTP), and the single-stranded deoxyribonucleic acid AGTC.

Problem 3-8: Write out, in the three-letter abbreviations for the amino acids, the amino acid sequences of the amino terminus and the internal tryptic peptide of extensin from *V. carteri* that guided the synthesis of the two primers used to make the probe by the polymerase chain reaction. Look up the genetic code. Below these two amino acid sequences, write out the nucleic acid sequences of the 5'- and 3'-ends of the sense strand of the segment of 410 bp amplified by the polymerase chain reaction aligned by the genetic code with the respective sequences of the amino acids. Below these two sequences of nucleic acid, write out their complementary sequences. Below each of the appropriate positions in these two blocks of aligned sequences, write out all of the redundant codons that the probe was designed to include. How many polynucleotides of different sequence resulted from each of the two syntheses?

Problem 3-9: A fragment of single-stranded RNA, 488 nucleotides long, was obtained from one of the ribosomal RNAs of rat liver, 28S rRNA, by treatment with α -sarcin.¹⁵¹ It was treated with alkaline phosphatase to remove any phosphate from its 5'-end and then with [γ -³²P]MgATP and T4 polynucleotide 5'-hydroxyl-kinase to attach a radioactive phosphate to its 5'-end. The sample was then split into five separate portions. They were treated with the following reagents, respectively:

- (I) NaOH
- (II) ribonuclease T₁, which cleaves on the 3'-side of G
- (III) ribonuclease U₂, which cleaves on the 3'-side of A
- (IV) ribonuclease PhyM, which cleaves on the 3'-sides of A and U
- (V) ribonuclease BC, which cleaves on the 3'-sides of U and C

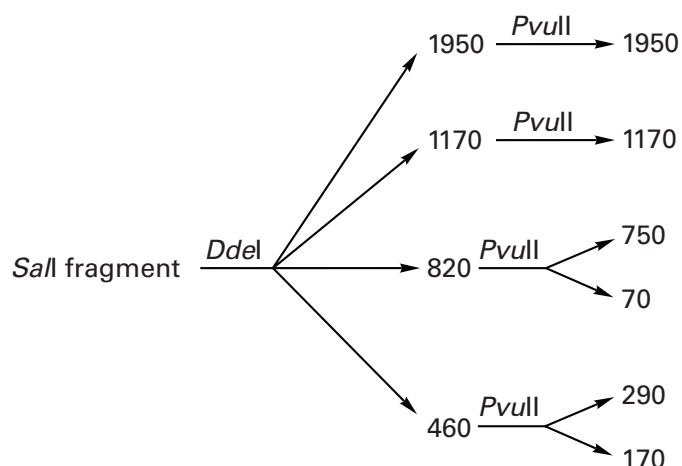

The alkaline hydrolysis (I) and the enzymatic digestions (II–V) were carefully controlled so that only a small amount of cleavage occurred at each sensitive position. The five mixtures were then placed in adjacent lanes on a polyacrylamide gel and submitted to electrophoresis followed by autoradiography. A tracing of that autoradiogram is presented below. An autoradiogram only registers radioactive fragments.

Each lane is labeled with the appropriate roman numeral. The most rapidly migrating bands were mononucleotides.

- (A) Starting with the nucleotide on the 5'-end, write the sequence of the α -sarcin fragment covered by the gel. Indicate clearly 5' \rightarrow 3' polarity.
- (B) Look carefully at the gel and then give a reason for including the digest in lane I.

Problem 3-10: A piece of double-stranded DNA about 4360 base pairs in length was produced by the site-specific deoxyribonuclease *SalI*. When this was digested with the site-specific deoxyribonucleases *DdeI* and *PvuII*, the fragments described in the diagram below were obtained. The numbers are the approximate lengths of the fragments.

Construct a restriction map.

Problem 3-11: A piece of double-stranded DNA about 5300 base pairs in length has been produced by the action of the site-specific deoxyribonuclease *EcoRI*. When this fragment was digested with the site-specific deoxyribonucleases *HindIII*, *KpnI*, and *BamHI*, the following results were obtained. The numbers are the approximate lengths of the fragments.

Construct a restriction map.

Posttranslational Modification

With the exception of the evanescent N^α -formyl group on its amino terminus and perhaps the 21st primary amino acid, selenocysteine,¹⁵² the infant polypeptide as it emerges from the peptidyltransferase site on the ribosome is a polymer containing only the 20 natural amino acids. Each amino acid is coupled to its neighbors by the amides of the peptide backbone, and the amino acids are arranged in the sequence encoded by the particular messenger RNA. It is this covalent structure and only this covalent structure that can be read by the investigator from the sequence of the messenger RNA or genomic DNA. The covalent structures of many proteins, however, do not remain in this untouched state but are biologically modified. A **posttranslational modification** is any change in the covalent structure of a polypeptide that occurs after its emergence from the ribosome.

Although a thiopeptide bond

has been observed at Glycine 445 of coenzyme-B sulfoethylthiotransferase,^{153,154} most posttranslational modifications of the polypeptide backbone result from endopeptidolytic cleavage or covalent rearrangements.

Modifications of the original covalent structure of the polypeptide are performed naturally by cellular **endopeptidases**. Such normal editing of the amino acid sequence of the protein must be distinguished from artifactual degradation by endopeptidases that can occur, for example, during the purification of a protein. In the course of a normal, natural modification, the polypeptide of a particular protein is cleaved internally, either as a mechanism for controlling its enzymatic activity or for architectural purposes. An example of the former is the

activation of endopeptidases in the pancreatic secretions or the serum by internal cleavages by endopeptidases.¹⁵⁵ An example of the latter is the trimming of folded proinsulin to produce insulin. As in the production of insulin from proinsulin, a number of other hormones are produced by endopeptidic cleavage at –Lys–Lys– or –Arg–Lys– positions in the sequence of longer precursors.¹⁵⁶ For example, corticotrophin, β -lipotropin, γ -lipotropin, β -endorphin, α -melanocyte-stimulating hormone, and γ -melanocyte-stimulating hormone are all cut from the same precursor 265 aa in length.^{157,158} Following the initial endopeptidolytic, posttranslational cleavage, the new amino terminus and carboxy terminus can be further digested by exopeptidases.¹¹¹

Almost all of the proteins of animals are posttranslationally shortened by the removal of one or more of the amino acids from their amino terminus, but some proteins have particular segments removed from their amino termini as they are passed from one compartment in the cell to another compartment. These amino-terminal **signal sequences**¹⁵⁹ address the proteins to the proper locations, and their removal is presumably involved in keeping them there. These successive removals of portions of the amino-terminal sequence have led to the terms pre-proprotein and proprotein.

There is a set of posttranslational modifications involving cysteines, serines, threonines, asparagines, and aspartates that result in **rearrangements in the covalent structure of the polyamide backbone** of a protein or **self cleavage** of its backbone. These five amino acids promote these modifications because they place either a nucleophile or an electrophile four atoms away from either an electrophilic acyl carbon or a nucleophilic amide nitrogen, respectively. Thus, the chemistry involved is the chemistry of five-membered heterocycles. Almost all of these posttranslational modifications are catalyzed intramolecularly by the protein itself.

Cysteines, serines, and threonines have their nucleophilic oxygens or sulfurs four atoms away from the acyl carbon of their amino-terminal neighbor. One example of a consequence of this spacing is the posttranslational modifications that produce thiazolines

and oxazolines in microsin.^{160,161} Another is the self-catalyzed posttranslational modification that cleaves the polypeptides of human *S*-adenosylmethionine decarboxylase¹⁶² between Glutamine 67 and Serine 68', histidine decarboxylase from *Lactobacillus*^{163,164} between Serine 81 and Serine 82, and aspartate 1-decarboxylase from *E. coli*¹⁶⁵ between Glycine 24 and Serine 25, in each case producing a pyruvated amino terminus.

The first step in this reaction is a five-membered tetravalent intermediate as in the first step of Equation 3-8, but the amine leaves the intermediate rather than water to produce the intermediate ester, which has been observed crystallographically.^{162,165} This step is an example of an **N \rightarrow O acyl migration**. The next step in this reaction utilizes the superior ability of carboxylate as a leaving group to effect the dehydration ultimately producing the pyruvyl group. The oxygen of the original serine ends up in the carboxylate of the new carboxy terminus produced in the reaction.¹⁶⁶ An α -ketobutyryl group¹⁶⁷ is found as an acyl substituent at the amino terminus of one of the two polypeptides composing threonine dehydratase, and it presumably arises by a similar mechanism (Equation 3-9) from a threonine in the protein rather than a serine.

An N \rightarrow O acyl migration also occurs in the self-catalyzed¹⁶⁸ cleavage of the peptide bond on the amino-terminal side of Threonine 206 in human *N*⁴-(β -*N*-acetylglucosaminy)-L-asparaginase.¹⁶⁹ In this case, the ester produced by the migration (Equation 3-9), rather than providing a leaving group, hydrolyzes to

produce the break in the polypeptide between amino acids 205 and 206. In hedgehog protein from *D. melanogaster*, the thioester resulting from an **N → S migration** of the polypeptide at Cysteine 258 is transesterified onto the hydroxyl group of cholesterol, which takes the place of the water that would hydrolyze the ester.¹⁷⁰ In the process, the polypeptide is cleaved between Glycine 257 and Cysteine 258, and the cholesterol ends up as a posttranslational modification esterified to the new carboxy terminus.

An **asparagine or aspartic acid** places an electrophile four atoms away from the amide nitrogen of its carboxy-terminal neighbor. This can lead to the production of an aspartyl imide, an isoaspartyl peptide bond, or an aspartate where there was an asparagine.^{171,172}

It is the production of aspartyl imides between asparagines and adjacent glycines ($R = H$), promoted by alkaline pH and elevated temperature, that is thought to be the first step in the chemical cleavage of a polypeptide by hydroxylamine.³⁷ The preference, in this case, for asparaginylglycyl peptide bonds is thought to be due to a steric effect on the initial cyclization that is minimized when the amido nitrogen that attacks the acyl carbon of the side chain of the asparagine is that of a glycine. It is thought that the aspartyl imide is then cleaved by the nucleophilic hydroxylamine to produce the chemical cleavage used experimentally to produce large fragments of a polypeptide.³⁸

The formation of aspartyl imides, aspartates, and isoaspartyl peptide bonds also seems to occur spontaneously but slowly at many of the asparagines, as well as at aspartic acids,¹⁷¹ in most proteins in their natural environment to produce a low level of isoaspartyl peptide bonds,¹⁷³ which are more stable than normal aspartyl or

asparaginyl peptide bonds.¹⁷² Both an aspartylimide and an isoaspartyl peptide bond have been observed crystallographically at the position of Aspartate 101 in hen lysozyme, which precedes Glycine 102,¹⁷⁴ and an isoaspartyl peptide bond has been observed crystallographically at the position of Asparagine 67 in bovine pancreatic ribonuclease, which precedes Glycine 68.¹⁷⁵ Because the hydrolysis of an aspartyl imide can lead to the replacement of an asparagine with an aspartate still in a normal peptide bond, this reaction may be responsible for the deamidation observed at particular sites in some proteins.^{176,177} Because the aspartylimide racemizes more rapidly at its α carbon than does either of the amides,¹⁷² this process also introduces D-aspartates into the polypeptide.

Both the unnatural isoaspartyl peptide bonds and the D-aspartates are recognized by a repair enzyme that methylates their free carboxylates. This **methylation** reinitiates the formation of the aspartyl imide, which can spontaneously racemize and hydrolyze to produce L-aspartate in a normal peptide bond, thus repairing the problem.¹⁷⁸⁻¹⁸¹ Only a fraction of the imide racemizes before it hydrolyzes, and when it hydrolyzes the isoaspartyl peptide bond is the favored product, but if only the D-aspartates and the isoaspartates are methylated and if they are recycled often enough, significant repair can be accomplished.¹⁸⁰⁻¹⁸²

The ultimate exploitation of this class of posttranslational modifications involving five-membered rings is self-catalyzed rearrangements of an amino acid sequence. There is a group of proteins, such as vacuolar adenosinetriphosphatase,^{183,184} certain RecA proteins,¹⁸⁵ and certain DNA polymerases¹⁸⁶ that contain an internal sequence called an intein that is 400–550 aa in length. The **intein** is spliced out of these proteins coincident with the formation of a peptide bond connecting the carboxy terminus of the amino-terminal segment of the protein that precedes the intein to the amino terminus of the carboxy-terminal segment following it.

The intein can be one continuous folded polypeptide connecting the amino-terminal segment preceding it to the carboxy-terminal segment following it, or it can be the carboxy-terminal segment of one folded polypeptide that is bound noncovalently to the amino-terminal segment of a second folded polypeptide.^{187,188} In the latter instance, the intein, after it has been spliced out, is two folded polypeptides bound to each other but the other product is still one continuous, spliced polypeptide formed from the amino-terminal segment of the first folded polypeptide and the carboxy-terminal segment of the second. The intein always begins with a serine, threonine, or cysteine and ends with a histidiny asparagine, and the carboxy-terminal segment always begins with a serine, threonine, or cysteine.¹⁸⁹

An even more extensive set of similar self-catalyzed posttranslational rearrangements occurs in concanavalin A from *Canavalia ensiformis*. After the initial polypeptide is produced by the ribosome, the α -amido group of Serine 30 couples to the α -acyl group of Asparagine 281 in place of the α -amido group of Glutamate 282, releasing the amino-terminal 29 amino acids preceding Serine 30 and the carboxy-terminal nine amino acids following Asparagine 281 as two short peptides, and the polypeptide is cleaved to the carboxy-terminal sides of Asparagines 148 and 163, releasing the intervening 26 amino acids as another short peptide.¹⁹⁰ The final intact product of the splicing begins at Alanine 164 of the precursor and ends at Asparagine 148.

The two spontaneous cleavages to the carboxy-terminal sides of Asparagines 148 and 163 in concanavalin A are thought to result from an attack of the amide nitrogen of the asparagine on its own acyl carbon

in a reaction analogous to that involving the acyl oxygen of aspartate under acidic conditions (Figure 3-5). In the case of concanavalin A, this cleavage would be catalyzed by other amino acids in the protein and the product would be the imide.

The first step in intein splicing is an $N \rightarrow O$ or $N \rightarrow S$

acyl migration (Equation 3-9) of the amino-terminal segment of the protein occurring at the serine, threonine, or cysteine on the amino-terminal side of the intein (Equation 3-11).^{191,192} The amino-terminal segment is then passed by a transesterification to the oxygen or sulfur of the serine, threonine, or cysteine on the carboxy-terminal side of the upstream splice site (Equation 3-11) to form a branched intermediate in which the intein and the carboxy-terminal segment are still joined together and the amino-terminal segment is esterified to the serine, threonine, or cysteine.^{193,194} In the next step of the reaction, the peptide bond to the carboxy-terminal side of the asparagine is cleaved (Equation 3-12) to produce the free intein with an unsubstituted aspartyl imide at its carboxy terminus.¹⁸⁹ The peptide bond between the amino-terminal segment and the carboxy-terminal segment is then formed by the respective $O \rightarrow N$ or $S \rightarrow N$ acyl migration. The amino-terminal and carboxy-terminal splice sites sit next to each other in the folded protein to permit all of these rearrangements to occur in close proximity.^{188,195,196}

In the rearrangement of concanavalin A, Glutamate 282 in the asparaginyglutamate is replaced by Serine 30 to produce an asparaginyserine. The first step in this reaction is probably the cleavage of the peptide bond of the asparaginyglutamate at positions 281 and 282 to produce the aspartyl imide at the resulting carboxy terminus (Equation 3-12). The following steps in the reaction would then be, by analogy to those of intein splicing, $N \rightarrow O$ migration at Serine 30, attack of the α -amino group of Serine 30 on the aspartyl imide of Asparagine 281, and hydrolysis of the ester between the α -carboxyl group of Serine 29 and the hydroxyl group on the side chain of Serine 30.

The posttranslational modifications of the backbone of the initially synthesized polypeptide that are produced by endopeptidolytic cleavage, self-catalyzed cleavage, the formation of aspartyl imides or isoaspartyl peptide bonds, or intein splicing have usually been identified by electrophoresis of complexes between the polypeptide and dodecyl sulfate, a procedure that registers the lengths of constituent polypeptides; by electrospray mass spectrometry, a procedure that registers decreases in mass caused by loss of portions of the polypeptide; by amino-terminal sequencing, a procedure that registers newly formed amino termini; by digestion with carboxypeptidases, a procedure that identifies new carboxy-terminal sequences; and by digestion with exopeptidases, which digest the normal peptide bonds but not imides or isopeptide bonds. These analyses rely heavily on the complete amino acid sequence of the unmodified polypeptide that is the immediate product of protein synthesis. This sequence is learned from sequencing the nucleic acid encoding it. For example, even though the complete amino acid sequence of mature concanavalin A was known from direct sequencing,¹⁹⁷ the extensive rearrangements producing the final

protein went unrecognized until the complementary DNA encoding it had been sequenced.^{190,198}

The **amino terminus** of a polypeptide can be *N*-methylated,^{199,200} *N*-2-pyruvylated,²⁰¹ or *N*-acylated, either intramolecularly, as in pyroglutamate (Figure 3-16), or externally, as when it is *N*-formylated,²⁰² *N*-acetylated,²⁰³ or *N*-glucuronylated.²⁰⁴ Enzymes are available that hydrolyze pyroglutamyl groups²⁰⁵ or remove acetyl groups.²⁰⁶ In a murein lipoprotein from bacterial outer membrane²⁰⁷ and ubiquinol oxidase (cytochrome *bo*₃) from *E. coli*,²⁰⁸ each of the respective amino-terminal cysteines is *N*-acylated by a fatty acid at its α -amino group and its sulfur forms a thioether with carbon 3 of a 1,2-diacylglycerol. *n*-Tetradecanoyl amides of amino termini (Figure 3-16)²⁰⁹ were first found on protein kinases. The existence of these fatty acylated amino termini was established by isolating an amino-terminal peptide, CH₃(CH₂)₁₂COHNGly-Asn-Ala, from cAMP-dependent protein kinase and confirming its structure by chemical degradation and by mass spectrometry with fast-atom bombardment.²¹⁰ By similar procedures it was shown that recoverin was acylated at its amino terminus with a mixture of *n*-dodecanoic acid, *cis*-*n*-tetradec-5-enoic acid, and *cis,cis*-*n*-tetradeca-5,8-dienoic acid in

addition to *n*-tetradecanoic acid.²¹¹ Such chemical demonstrations of a modification at the amino terminus of a polypeptide should be distinguished from an unsupported conjecture that the amino terminus is blocked when the Edman degradation fails.

The **carboxy terminus** of a polypeptide can also be modified, for example, as the primary amide (Figure 3-16), the tyrosyl amide,²¹² or the methyl ester.²¹³ In at least one instance,²¹⁴ the primary amide at a carboxy terminus is produced from a carboxy-terminal glycine that is first monooxygenated and then decomposes with the loss of glyoxylate to leave behind its former amino group as the carboxy-terminal amide.

Figure 3-16: Posttranslational modifications that occur at the termini of a polypeptide.

During the posttranslational modification of several polypeptides with the carboxy-terminal sequence CXYZ (where X, Y, and Z each represent one of many possible amino acids),²¹⁵ the last three amino acids are removed,²¹⁶ and the cysteine at the new carboxy terminus is doubly modified (Figure 3-16) by **isoprenylation** and methylation. A farnesyl group²¹⁷ or a geranylgeranyl group^{218,219} is added to the sulfur of the cysteine in an allylthioether, and the new carboxy terminus is methylated to form the methyl ester.^{215,220} It is thought that these modifications make the carboxy terminus sufficiently hydrophobic to bind to biological membranes.^{221,222} There are also proteins in which the polypeptide synthesized from the messenger RNA has the carboxy-terminal sequence Cys-Cys or Cys-X-Cys, and each of the cysteines in these carboxy-terminal sequences is then geranylgeranylated.^{223,224} The geranylgeranylated proteins with the carboxy-terminal sequence Cys-X-Cys are then methylated on their terminal carboxylates,^{223,225} but those with the carboxy-terminal sequence Cys-Cys are not.²²⁵

An extensive posttranslational modification of the carboxy terminus occurs in certain proteins that are bound tightly to the extracellular surface of protozoal and animal cells.²²⁶⁻²²⁸ It has the effect of covalently connecting the carboxy terminus of the protein to a phosphatidylinositol dissolved within the bilayer of the plasma membrane. The carboxy terminus is linked directly through an amide to an ethanolamine, which is linked through a phosphate diester to the mannose of an oligosaccharide, which, in turn, is linked by a glycosidic linkage to phosphatidylinositol, a phospholipid (Figure 3-17).²²⁸⁻²³⁵ Because this

Figure 3-17: Structure of the linkage between phosphatidylinositol and the carboxy terminus of a polypeptide in a phosphatidylinositol-linked protein.²²⁸⁻²³² The carboxy-terminal amino acid sequence shown is that for the linkage at the end of the variant surface glycoprotein MITat.1.4 from *Trypanosoma brucei*.²³³ The phosphatidylinositol shown is in the ditetradecanoyl form, but saturated and unsaturated fatty acids from 12 to 22 carbons in length can be esterified at either position in place of either or both of the tetradecanoyl groups. A variant in which a tetradecanoyl group is also attached to the inositol has been reported,²³⁴ as well as one in which a ceramide replaces the diacylglycerol.²³⁰ The phosphatidylinositol is coupled to an unacetylated D-glucosamine, which is coupled in turn through a trisaccharide of D-mannoses to ethanolamine phosphate, the primary amine of which is attached in amide linkage to the carboxy terminus of the protein. A variant of the more common structure displayed here has the phosphoethanolamine attached through the 3-position of the middle mannose rather than the 6-position of the end mannose.²³⁵ Within the tetrasaccharide, the position marked (Gal)_n is either a hydrogen or an oligosaccharide of one or more galactosyl groups; the position marked Man is either a hydrogen, an α 1-mannosyl group, or a mannosyl disaccharide; the position marked (Gal X) is either a hydrogen, a β 1-galactosyl group, or a β 1-N-acetylgalactosamyl group; and the position marked E is either a hydrogen or an (O-ethanolamino)phosphoryl group.

posttranslational modification causes the protein to adhere to membranes, it is called a **glycosylphosphatidylinositol (GPI) anchor**.

In addition to the polypeptide itself and its amino and carboxy termini, **posttranslational modification of the side chain of an amino acid** can occur. When it does, the derivative remains an L- α -amino acid residue because its carboxyl group and its α -amino group are protected by the amides of the backbone. There are many posttranslationally modified amino acids that have been identified in naturally occurring polypeptides (Table 3-1, Figure 3-18).

The length of Table 3-1 gives the erroneous impression that posttranslational modifications are common. Aside from glycosylation and the phosphorylation of serines, threonines, and tyrosines, the incidence of any of these modifications is quite **limited**, often being confined to only one protein or one small family of proteins. For example, two of the earliest recognized posttranslational modifications were the 5-hydroxylysine and 4-hydroxyproline (Figure 3-18) that, with few exceptions, are formed in the posttranslational monooxygenation of only prolines and lysines that are found in segments of amino acid sequence in which every third amino acid is a glycine.⁴¹⁰ Such sequences

occur in the various collagens and proteins related to the collagens. The modifications producing covalently bound coenzymes occur only in proteins using these coenzymes to assist in catalysis of particular reactions. Some of the other posttranslational modifications, for example, the quinones of 2,5-dihydroxytyrosine (Figure 3-18),³¹² 6,7-dioxo-4-(2-tryptophanyl)tryptophan (Figure 3-18), and dehydroalanine,³⁴⁹ occur only in the active sites of particular enzymes and are designed for specific functions. 4-Carboxyglutamate (Figure 3-18)^{252,253,385,411} is found only in a few of the proteins that bind calcium strongly or that are involved in calcium metabolism.⁴¹² Thyroxine,²⁶¹⁻²⁶³ O-(3,5-diiodo-4-hydroxyphenyl)-3,5-diiodotyrosine (Figure 3-18), is found only in the protein thyroglobulin,²⁶⁶ wherein it is formed at two positions by the intramolecular condensation of two pairs of 3,5-diiodotyrosines.⁴¹³ The sole function of this large protein (2769 aa) is to produce the thyroxine, which is then liberated from the protein by its complete digestion. Diphthamide, 2-[3-carboxamido-3-(trimethylammonio)propyl]histidine (Figure 3-18), is found only in one of the elongation factors (elongation factor 2) involved in eukaryotic translation.^{267,269} The attachment of ADP-ribosyl groups to diphthamide, arginine, and asparagine side chains in one or the other of a

small group of proteins is catalyzed by bacterial toxins, and only proteins in individuals infected with these bacteria are modified in this way. There also seem to be enzymes in normal cells, however, that are capable of ADP-ribosylating a small number of proteins as part of their normal operation.^{331,414-417}

Mass spectrometry is often used to identify these posttranslational modifications on the side chains of amino acids. Electrospray mass spectrometry of a purified, intact protein is often the first indication that it contains a posttranslational modification. Because the unmodified amino acid sequence of a protein as it is produced by the ribosome is often known even before it has been purified but usually soon after, any difference between the molecular mass observed by electrospray mass spectrometry and the mass calculated from the unmodified amino acid sequence indicates a posttranslational modification. Such results were the first indications that the protein *Ner* of bacteriophage *Mu* was modified at its amino terminus with a pyruvate²⁰¹ and that bovine recoverin was modified at its amino terminus by one of several different fatty acids.²¹¹ Electrospray mass spectrometry of peptides purified from a digest of rat profilaggrin identified nine phosphopeptides by the fact that their molecular masses were 80 Da greater than those predicted from their amino acid sequences.⁴¹⁸

Normal direct probe, high-resolution mass spectrometry and mass spectrometry with electron ionization have been used to provide molecular ions and fragment ions of posttranslational modifications such as polyisoprenoids^{219,296} or 5-mercaptopuracil³⁴² that can be removed chemically from the amino acid to which they are attached. Electrospray mass spectrometry in the negative ion mode has been used in a similar way to identify the ceramide released from the GPI anchor of the arabinogalactan proteoglycan from *Pyrus communis*.²³⁰ Fast-atom bombardment feeding a conventional mass spectrometer has been used to vaporize a bispeptide containing the semicarbazide derivative of 6,7-dioxo-4-(2-tryptophanyl)tryptophan and obtain a **high-resolution mass spectrum** with a molecular ion of 940.3262 Da which was of sufficient precision to calculate a molecular formula for the modification.³⁸⁵

Fast-atom bombardment or matrix-assisted-laser-desorption ionization feeding a tandem mass spectrometer can be used to vaporize posttranslationally modified peptides purified from a digest of a protein, sort the molecular ions in the first mass spectrometer, fragment those ions, and then separate the fragments in the second mass spectrometer. The resulting pattern of fragments is often sufficient to identify the posttranslational modification. Peptides containing an α -hydroxyglycine,³²⁴ an 8 α -(*N*³-histidyl)flavin mononucleotide,⁴¹⁹ and an *N*-acetyl-*O*-phosphothreonine⁴²⁰ were analyzed in this way. Matrix-assisted-laser-desorption ionization feeding a time-of-flight mass spectrometer in either the positive-ion mode^{304,305,350} or negative-ion mode⁴²¹ has

been used to identify posttranslational modifications in peptides that have been purified from digests of proteins. The negative-ion mode is used for phosphopeptides.⁴²²

Electrospray can also be used to produce ions to feed a tandem mass spectrometer.^{161,270} Although some difficulty arises with the multiply charged ions emitted by the electrospray, they can usually be sorted out successfully in the first mass spectrometer because peptides are short enough that only a few ions are produced from each of them.¹¹¹ For example, a peptide containing covalently bound flavin from fructosyl-amino acid oxidase of *Aspergillus* was vaporized by electrospray ionization, the ionic molecule of *m/z* 659 Da was selected in the first quadrupole mass spectrometer, it was fragmented by collision-induced dissociation, and the fragment ions produced a mass spectrum in the second quadrupole mass spectrometer of the tandem. The pattern of fragments demonstrated that the flavin was covalently attached to Cysteine 342 of the protein.⁴²³ Such a system can also be used to identify the locations in the sequence of a protein at which it is phosphorylated.⁴²⁴

If the posttranslational modification cannot be identified by its mass or its pattern of fragmentation, it is usually possible to hydrolyze the polypeptide and liberate the modified amino acid. Usually the hydrolysis is performed enzymatically to avoid destruction of the modified amino acid that might occur in strong acid or strong base. Enough of the peculiar amino acid is purified to perform a proof of its structure by chemical analysis.

One way in which two or more of the amino acid side chains in a polypeptide can be modified coincidentally is during the formation of a **covalent cross-link** between them or among them. The cross-link can be intramolecular, connecting two or more amino acid side chains in the same polypeptide, or intermolecular, connecting two or more amino acid side chains in different polypeptides. There is no formal distinction between these two outcomes because the linkage is invariably made after the polypeptides have folded into their native structure and, subsequently, formed specific intermolecular complexes among themselves. This folding and intermolecular assembly is what brings the two or more amino acid side chains that will be cross-linked into atomic contact with each other. Therefore, it is irrelevant whether the amino acid side chains started out on the same polypeptide or different polypeptides or whether they are at positions within the amino acid sequence of the same polypeptide that are close to or distant from each other. The only deciding factor is that they are immediately adjacent to each other in the final structure of the mature protein.

A simple example of a covalent cross-link is an amide between a lysine side chain and a glutamate side chain. Such a cross-link is formed from a glutamine side chain and a lysine side chain, both within a

Table 3–1: Posttranslational Modifications of the Side Chains of Amino Acids in Proteins²³⁶

type of modification	derivative of side chain
phosphorylation	<i>O</i> -phosphoserine, ^{237–239} <i>O</i> -phosphothreonine, ^{238–240} <i>O</i> -phosphotyrosine, ^{239,241,242} <i>N</i> -phospholysine, ²⁴³ <i>N</i> -phosphohistidine, ^{243–245} <i>N</i> -phosphoarginine, ²⁴⁵ <i>S</i> -phosphocysteine, ²⁴⁶ <i>O</i> -phosphoaspartate, ^{247–249} <i>O</i> -phosphoglutamate ²⁵⁰
sulfation	<i>O</i> -sulfotyrosine ²⁵¹
carboxylation	4-carboxyglutamate, ^{252,253} 3-carboxyaspartate ²⁵⁴
aromatic substitution	3,5-diiodotyrosine, ^{255–257} 3-iodotyrosine, ^{255,257,258} 3,5-dibromotyrosine, ^{255,259} 3-bromotyrosine, ^{255,258} 3-bromo-5-chlorotyrosine, ^{255,260} 3-chlorotyrosine, ²⁵⁵ 3,5-dichlorotyrosine, ²⁵⁵ <i>O</i> -(3,5-diiodo-4-hydroxyphenyl)-3,5-diiodotyrosine (thyroxine, T ₄), ^{261–263} <i>O</i> -(3-iodo-4-hydroxyphenyl)-3,5-diiodotyrosine (triiodothyronine, T ₃), ^{264–266} 2-[3-carboxamido-3-(trimethylammonio)propyl]histidine (diphthamide), ^{267–269} 2-(1-mannosyl)tryptophan, ^{270,271} <i>o</i> -bromophenylalanine ²⁷²
methylation	<i>N</i> -methyllysine, ^{273–275} <i>N,N</i> -dimethyllysine, ^{274–276} <i>N,N,N</i> -trimethyllysine, ^{274,275,277} <i>N</i> ^ω -methylarginine, ^{278,279} <i>N</i> ^ω , <i>N</i> ^ω -dimethylarginine, ^{278,280} <i>N</i> ^ω , <i>N</i> ^ω -dimethylarginine, ^{281,282} <i>N</i> ^δ -methylarginine, ²⁸³ <i>N</i> ³ -methylhistidine, ²⁸⁴ <i>N</i> ¹ -methylhistidine, ¹⁵⁴ <i>O</i> -methyl-D-aspartate, ¹⁷⁸ <i>O</i> -methylglutamate, ²⁸⁵ <i>O</i> -methylisoaspartate, ²⁸⁶ <i>S</i> -methylmethionine, ²⁸⁷ <i>S</i> -methylcysteine, ¹⁵⁴ <i>N</i> -methylasparagine, ^{288,289} <i>N</i> -methylglutamine, ²⁹⁰ 2-(<i>S</i>)-methylglutamine, ^{153,291} 5-(<i>S</i>)-methylarginine ^{153,291}
alkylation	<i>N</i> -(4-amino-2-hydroxybutyl)lysine (hypusine), ^{292–294} <i>S</i> -farnesylcysteine, ^{217,295} <i>S</i> -geranylgeranyl cysteine ^{219,296}
acylation	<i>N</i> -acetyllysine, ^{297,298} <i>O</i> -palmitoylthreonine, ²⁹⁹ <i>S</i> -palmitoylcysteine, ^{300–302} <i>S</i> -stearoylcysteine ³⁰³
amidation	γ -poly(α -glutamyl)glutamate, ³⁰⁴ γ -poly(glycyl)glutamate ³⁰⁵
monooxygenation	5-hydroxylysine, ³⁰⁶ <i>N,N,N</i> -trimethyl-5-hydroxylysine, ³⁰⁷ <i>N,N,N</i> -trimethyl- <i>O</i> -phospho-5-hydroxylysine, ³⁰⁷ 4-hydroxyproline, ^{308–310} 3-hydroxyproline, ³¹¹ 2,5-dihydroxytyrosine, ³¹² β -hydroxyaspartate, ^{313–315} β -hydroxyasparagine, ³¹⁶ β -hydroxytryptophan, ^{317,318} <i>m</i> -hydroxyphenylalanine, ³¹⁹ 3-hydroxytyrosine (3,4-dihydroxyphenylalanine, DOPA), ^{320–323} α -hydroxyglycine ³²⁴
oxidation	6-deamino-6-oxolysine (allysine), ^{306,325} 6-deamino-5-hydroxy-6-oxolysine, ³⁰⁶ cysteinesulfenic acid, ³²⁶ cyteinesulfenic acid, ³²⁶ β -dethio- β -oxocysteine, ³²⁷ methioninesulfone ³²⁸
free radical	tyrosyl free radical, ³²⁹ glycyl free radical ³³⁰
ADP-ribosylation	<i>N</i> ^ω -(ADP-ribosyl)arginine, ^{331–333} <i>N</i> -(ADP-ribosyl)asparagine, ³³⁴ <i>S</i> -(ADP-ribosyl)cysteine, ³³⁵ poly(ADP-ribosyl)glutamate, ^{336,337} 1-[<i>N</i> -(ADP-ribosyl)]-2-[3-carboxamido-3-(trimethylammonio)propyl]histidine ^{338,339}
nucleotidylation	<i>O</i> -(5'-adenylyl)tyrosine, ³⁴⁰ <i>O</i> -(5'-uridylyl)tyrosine, ³⁴¹ <i>O</i> -[5'-(5-mercapto)uridylyl]tyrosine ³⁴²
hydrolysis	citrulline from arginine, ³⁴³ ornithine from arginine, ³⁴⁴ aspartate from asparagine, ^{176,345,346} glutamate from glutamine ³⁴⁶
dehydration	dehydroalanine from serine, ^{347–349} α,β -dehydrotyrosine ^{350,351}

folded polypeptide, by the enzyme protein-glutamine γ -glutamyltransferase.⁴²⁵ Thioethers between a cysteine side chain and the aromatic ring of either a tyrosine side chain (3-3)³⁷³ or a histidine side chain (3-4)³⁷²

are cross-links that have been identified in galactose oxidase,³⁷⁴ and in hemocyanin,⁴²⁶ and monophenol monooxygenase,^{371,372} respectively.

A large number of cross-links form in both collagen and elastin as the direct result of the posttranslational oxidative deamination of lysine side chains in these proteins to the corresponding aliphatic 6-deamino-6-oxolysyl aldehydes in a reaction performed by the enzyme protein-lysine 6-oxidase.⁴²⁷ These aldehydes are formed in the vicinity of each other as well as in the vicinity of other lysines and of 5-hydroxylysines and 5-hydroxy-6-deamino-6-oxolysyl aldehydes, all also derived from lysine side chains. A dazzling array of aliphatic carbonyl chemistry is initiated by the formation of the reactive aldehydes in this environment, including aldol condensations, imine formations, dehydrations of β -hydroxyaldehydes, dehydrations of aliphatic alcohols, Michael additions, and oxidations (Figure 3-19). Only four out of the more than 25 cross-links that result from this uncontrolled flurry of reactions³⁰⁶ are displayed in the figure. The purpose of these cross-links is to strengthen fibers of collagen. Cross-links between tyrosine side chains, such as 3-(3-tyrosyl)tyrosine (Figure 3-18) and the other examples listed in Table 3-1, also serve to strengthen the biological fibers, films, and coatings in which they are found.

One of the most common posttranslational cross-links in a protein is the disulfide that forms when two cysteine side chains are oxidatively coupled to form one **cystine** side chain (Figure 3-20). While cysteine is unstable under the conditions necessary to hydrolyze proteins in strong acid, cystine is stable, and its appearance on the standard ion-exchange chromatogram between alanine and valine (Figure 1-3) establishes the presence of cystine side chains in a protein.

The interior of most cells has a high concentration of a small, free thiol, such as **glutathione**

that reduces back to cysteine any cystine that forms in cytoplasmic proteins in a reaction known as disulfide interchange (Figure 3-20). The net effect of disulfide interchange is to set the cystine side chains in a protein in equilibrium with the disulfide of the small thiol such that

$$K_{eq} = \frac{[RS-SR][\text{prot}(SH)_2]}{[RSH]^2[\text{prot}(S-S)]} \quad (3-14)$$

where RSH is the small thiol, RS-SR its disulfide, $[\text{prot}(SH)_2]$ is the molar concentration of a particular reduced pair of adjacent cysteine side chains in the folded polypeptide, and $[\text{prot}(S-S)]$ is the concentration of cystine between these same two side chains, also in the folded polypeptide. The reaction as written is first-order in reduced protein because the oxidation of the reduced protein is intramolecular. Equation 3-14 can be rearranged:

$$\frac{K_{eq}[RSH]^2}{[RS-SR]} = \frac{[\text{prot}(SH)_2]}{[\text{prot}(S-S)]} \quad (3-15)$$

The point made by this equation is that the greater the ratio $[RSH]^2/[RS-SR]$, the less cystine will be found in proteins.

In the cytoplasm, $[RS-SR]$ is kept at a low level enzymatically. For example, when RSH is glutathione, GSH, the enzyme glutathione reductase accomplishes this:

This reaction drives the equilibrium of Equation 3-14 in the direction of the reduced protein by coupling it to the level of reduction of NADPH. The result of all these facts is that proteins confined to the cytoplasm usually⁴²⁸ do not contain cystine, while proteins removed from the cytoplasm often do contain cystine.

A protein is usually prepared for sequencing by **reducing** any cystine side chains it may contain with a small thiol such as 2-mercaptoethanol (Figure 3-20, $R = HOCH_2CH_2-$) and then **alkylating** all of its cysteines with a reagent such as iodoacetic acid

Figure 3-19: Examples of the formation of four of the more than 25 cross-links initiated by the formation of 6-deamino-6-oxolysine in collagen by protein-lysine 6-oxidase. Shown is an aldol condensation to produce the first cross-link. The β-hydroxyaldehyde can then form an imine with a lysine that dehydrates to an α,β-unsaturated imine, a product that cross-links three amino acids. The enol of another aldehyde can add to the α,β-unsaturated imine, and the initial enamine can condense to an imine with the carbonyl of the aldehyde. This forms a dihydropyridine that cross-links four amino acid residues. The pyridinium cation formed upon oxidation of the dihydropyridine is a desmosine linking the four amino acid residues. Upper right corner: 6-Deamino-5-hydroxy-6-oxolysine formed by the consecutive action of procollagen-lysine 5-dioxygenase and protein-lysine 6-oxidase produces an α-hydroxyaldehyde, which is susceptible to an even more complicated set of modifications.

Figure 3-20: Reduction of a cystine side chain by disulfide interchange. The cystine connecting two segments of polypeptide is exposed to an external thiolate (RS^-) that displaces the cysteinyl anion by nucleophilic substitution and is in turn removed by another thiolate.

iodoacetamide, *N*-ethylmaleimide, 4-vinylpyridine, or 2-vinylpyridine to prevent their reoxidation. This creates the stable amino acid side chains *S*-(carboxymethyl) cysteine (Equation 3-17), *S*-(carboxamidomethyl) cysteine, *S*-(*N*-ethyl-2-succinimidyl)cysteine, *S*-[2-(4-pyridyl)ethyl]cysteine, or *S*-[2-(2-pyridyl)ethyl]cysteine, respectively, in place of the unstable cysteine. *S*-[2-(2-Pyridyl)ethyl]cysteine absorbs at 254 nm, and its absorption can be used to identify peptides containing cysteine.

In experimental situations where cystines in a protein must be reduced, a problem arises. If the protein remains folded, its cystine side chains are generally more stable, relative to the adjacent cysteine side chains that would be produced upon its reduction, than is the disulfide of a small reducing agent such as 2-mercaptoethanol, relative to its thiol form. This results from the fact that the reaction in the protein is intramolecular in the direction of oxidation, but the reaction of the 2-mercaptoethanol is intermolecular in the direction of oxidation (Equation 3-14). The problem is solved either by using an intramolecular dithiol such as 2,3-dihydroxy-1,4-dithiobutane (**dithiothreitol**, DTT)⁴²⁹

which produces a stable disulfide as a product, or by unfolding the protein with urea or guanidinium chloride, which causes the reaction of the cysteine side chains in the protein to be formally intermolecular in the direction of oxidation, or by simultaneously applying both of these strategies.

There are a few examples in which a protein contains a cystine connecting two cysteines that are adjacent to each other in the amino acid sequence.⁴³⁰⁻⁴³³ The eight-membered ring that results, however, is unstable for steric reasons.^{432,434,435} Cystines connecting two cysteines from different folded polypeptides are also occasionally encountered,⁴³⁶ but in the majority of the extracytoplasmic proteins that contain cystine side chains as a posttranslational modification, the two cysteine side chains that are connected to each other are in the same folded polypeptide but far from each other in the amino acid sequence. For example, in ribonuclease, a protein formed from a polypeptide of 124 aa, the cystines are formed from Cysteine 96 and Cysteine 40, Cysteine 58 and Cysteine 110, Cysteine 26 and Cysteine 84, and Cysteine 65 and Cysteine 72. When the polypeptide folds to form the native structure of ribonuclease, these pairs of cysteine side chains, which were distant from each other in the unfolded polypeptide, are juxtaposed.

It is the **juxtaposition** that not only determines what cystines form but also brings the two sulfurs close enough to each other that they can react at an appreciable rate.^{437,438} They are then oxidized to cystine by molecular oxygen⁴³⁹

or by **disulfide interchange** (Figure 3-20) with cystines in protein disulfide-isomerase.⁴⁴⁰⁻⁴⁴³ Protein disulfide-isomerase⁴⁴⁴ contains a cystine so unstable that the

equilibrium constant^{445,446} for disulfide interchange between its disulfide (taking the place of RS-SR in Equation 3-14) and the disulfide in a normal extracytoplasmic protein [prot (S-S) in Equation 3-14] is about 10^{-3} . Unlike synthetic 2,3-dihydroxy-1,4-dithiobutane or the natural protein thioredoxin, both of which can cleave disulfides in native proteins, protein disulfide-isomerase forms them.

The identification of the two cysteine side chains that are connected in a particular cystine in a native protein requires that a peptide containing only those two cysteines still joined as the cystine be isolated from a digest of the protein.⁴⁴⁷⁻⁴⁵⁰ Before the protein is unfolded or digested, however, it must be treated with an alkylating agent such as *N*-ethylmaleimide under conditions capable of **capping off** all the free sulfhydryls in the preparation, which if left unalkylated would catalyze disulfide interchange (Figure 3-20) and thereby **scramble the disulfides**.⁴⁴⁸ Ideally, the peptides with intact cystine side chains used to identify the cysteines involved should be two short peptides held together by the cystine itself. For example, one of the peptides from ribonuclease isolated from a digest of the protein performed with pepsin, trypsin, and chymotrypsin was composed of the two smaller peptides NGQTNCYH and NVACK, covalently coupled by a cystine between the two cysteine side chains.⁴⁴⁷ From this result it could be concluded that, in native ribonuclease, Cysteine 65 is coupled as a cystine with Cysteine 72.

The three digestions used in the experiments just described served the purpose of producing bispeptides containing cystine that were as small as possible. This precaution avoids the confusion of having several large peptides interlaced by multiple disulfides⁴⁵¹ into one large, intractable peptide. This problem, however, is sometimes unavoidable, as in the case of thrombomodulin, in which three cystines occur within a short sequence of 14 amino acids and from which individual peptides containing each of them could not be obtained. In this case, the linkages were assigned⁴⁵² by following the rates at which the individual cysteines appeared as the cystines were slowly cleaved with the nucleophile tris(2-carboxyethyl)phosphine.⁴⁵³

Because oxidation states of cysteine (Figure 2-8) other than cystine as well as covalent modifications of cysteine⁴⁵⁴ revert to yield free cysteine upon addition of a thiol such as 2,3-dihydroxy-1,4-dithiobutane, the **indirect assignment** of a cystine based solely upon the appearance of free cysteine after the addition of a thiol cannot be trusted.^{455,456}

Procedures have been developed to assist in the **analysis of peptides containing cystine**. Sensitive methods have been described for continuously monitoring chromatograms of digests performed with endopeptidases to detect peptides containing intact cystine side chains either electrochemically after they have been reductively cleaved on the surface of an elec-

trode⁴³⁰ or colorimetrically after they have been nucleophilically cleaved with tributylphosphine.⁴⁵⁷ The bis(phenylthiohydantoin) of cystine (Figure 3-1) displays a unique relative mobility on the high-pressure liquid chromatograms used to identify the products from the steps of automated Edman degradation.^{458,459} Peptides containing cystine that have been purified from a digest of a protein can also be positively identified by mass spectrometry.^{460,461} The advantage in this instance is that the gaseous molecular ion of the bis-peptide, necessarily containing the intact cystine, is observed directly. The presence of a cystine within a peptide can be established by mass spectrometry because the mass of the peptide gradually increases by 2 Da as a result of photoreduction during successive shots from the laser during its vaporization.⁴⁶²

Problem 3-12: Assume that a protein containing an intein has a cysteine at the amino terminus of the intein and a serine at the amino terminus of the carboxy-terminal segment. Write the mechanism for intein splicing involving the initial N → S migration, an S → O migration, cleavage of the peptide bond between the intein and the carboxy-terminal segment to produce the unsubstituted aspartyl imide, and the final O → N migration to produce the new peptide bond.

Problem 3-13: Draw the structure of a polypeptide with an amino-terminal cysteine residue the α-amine of which is acylated with palmitate and the sulfur of which forms a thioether with C3 of a 1,2-dipalmitoyl-3-deoxyglycerol.

Problem 3-14: A remarkable feature of the enzyme glutamate-ammonia ligase from *E. coli* is that its catalytic properties depend on the conditions of growth under which the *E. coli* from which it is purified were grown. The enzyme purified from *E. coli* grown on NH₄Cl and glucose (Type I) is less sensitive to inhibition by AMP than is the enzyme purified from *E. coli* grown on glutamate and glycerol (Type II). The Type II enzyme can be converted into Type I enzyme if it is treated with snake venom phosphodiesterase.⁴⁶³

When Type II enzyme was digested with snake venom phosphodiesterase and subsequently precipitated out of solution with trichloroacetic acid, the super-

natant solution contained material having a maximum absorbance at 260 nm.

Hydrolysis of the Type I and Type II enzymes was performed by a series of endopeptidases. Both enzymes were split into the same number of peptides, but one decapeptide from the Type II enzyme differed in chromatographic behavior from the similar decapeptide from the Type I enzyme. The single different peptide isolated from the Type II enzyme had the following composition after acid hydrolysis:

D	2
E	2
P	3
G	1
L	1
T	1
adenine	1
D-ribose	1
phosphate	1

From an acid-base titration, the following pK_a values were measured for the decapeptide isolated from Type II enzyme before and after treatment with snake venom phosphodiesterase.

number of groups	pK_a	
	before	after
1	3.4	3.4
1	3.7	3.7
4	4–4.5	4–4.5
1	7.8	7.8
1		6.0
1		10.0

How does the covalent structure of the Type II enzyme differ from that of the Type I enzyme? Explain each result described above on the basis of the proposed structure.

How are the cysteines linked to form the two cystines in the peptide? What unexpected cleavage did trypsin produce?

Oligosaccharides of Glycoproteins

Living organisms are formed from three types of covalent polymers: proteins, nucleic acids, and polysaccharides. **Polysaccharides** used biologically for structural purposes

or for the storage of carbohydrate occur as long, often branched, uniform polymers of monosaccharides (sugars). Examples of polysaccharides would be agarose (Figure 1-7), cellulose (Figure 1-2), starch,⁴⁶⁷ hyaluronic acid, chitin, and glycogen. Although the reducing ends of these polysaccharides are sometimes attached covalently to particular proteins,⁴⁶⁸ this fact is secondary to their biological roles. **Oligosaccharides** are shorter, more heterogeneous oligomers of monosaccharides. Oligosaccharides are frequently attached to recently synthesized polypeptides as posttranslational modifications of serines, threonines, or asparagines. Such posttranslational modifications produce glycoproteins.

A **glycoprotein** is any protein to which one or more oligosaccharides are covalently attached. To define the complete covalent structure of a glycoprotein, not only the amino acid sequence of the protein but also the points of attachment and the sequences of the monosaccharide in the oligosaccharides must be established. Some of the rarely occurring oligosaccharides and their sites of attachment have been listed along with the other posttranslational modifications in Table 3-1. The more commonly encountered oligosaccharides in glycoproteins from animals and plants, however, are branched oligomers attached through *N*-acetylglucosamine to asparagine side chains or through *N*-acetylgalac-

Figure 3-21: Covalent structure of one of the oligosaccharides attached through asparagine to human immunoglobulin D.⁴⁶⁹ This is an example of a high-mannose oligosaccharide.

Figure 3-22: Covalent structure of one of the oligosaccharides attached through asparagine to human immunoglobulin D.⁴⁶⁹ This is an example of a complex *N*-linked oligosaccharide.

tosamine to serine and threonine side chains (Figures 3-21, 3-22, and 3-23).⁴⁶⁹⁻⁴⁷²

The monomers from which these oligosaccharides are constructed are **monosaccharides**. The eleven major monosaccharides that are found in the oligosaccharides of glycoproteins are D-mannose, D-galactose, D-glucose, N-acetyl-D-glucosamine, N-acetyl-D-galactosamine, the sialic acids, D-glucuronic acid, L-fucose, L-rhamnose, D-xylose, and L-arabinose (Figure 3-24). Several of the monosaccharides in glycoproteins can be O-sulfated,^{473,474} and mannoses and N-acetylglucosamines can be O-(2-aminoethyl)phosphonylated.⁴⁷⁵

A variety of different sialic acids are known (greater than 40) that are derivatives of either D-neuraminic acid (Figure 3-24) or the closely related D-5-deamino-5(S)-hydroxyneuraminic acid (2-keto-3-deoxy-D-glycero-D-galacto-noninic acid; 3-deoxy-D-glycero-D-galacto-nonulosonic acid).^{476,477} These two anionic monosaccharides are modified variously by N-acetylation, N-glycolylation, O-lactylation, O-sulfation, O-methylation, O-phosphorylation, and O-acetylation.⁴⁷⁸

The covalent bonds that link the monosaccharides together are those of acetals and occasionally ketals. **Glycosidic linkages** are the bonds in these acetals and ketals formed between the only carbonyl carbon on each monosaccharide, enclosed within a pyranose ring or a furanose ring as a hemiacetal, and one of the hydroxyl groups of the preceding monosaccharide in the oligomer. A glycosidic linkage is formed between the oxocarbenium cation of the pyranose or furanose and a lone pair of electrons on a nitrogen or an oxygen. An example would be

Figure 3-23: Covalent structure of one of the oligosaccharides attached through serine and threonine to human colonic mucin.⁴⁷⁰ This is an example of an O-linked oligosaccharide.

Branching of the oligosaccharide (Figures 3-21 to 3-23) occurs whenever two or more of the hydroxyl groups on one of the monosaccharides participate in glycosidic linkages.

Each of the oligosaccharides on a glycoprotein can be thought of as beginning at the monosaccharide that is attached to the polypeptide (the reducing end). The point of attachment is either an **O-glycosidic linkage**, formed between the carbonyl carbon of this initial monosaccharide and the hydroxyl group of a serine or threonine side chain, or an **N-glycosidic linkage**, formed between the carbonyl carbon of this initial monosaccharide and the amide nitrogen of an asparagine side chain. The first monosaccharide in an oligosaccharide attached to a serine or a threonine is usually N-acetylgalactosamine; the first sugar in an oligosaccharide attached to asparagine is almost always N-acetylglucosamine. Peripheral to this initial monomer, the oligomer will be found to branch at several points and end at each of several unsubstituted monosaccharides that occupy the last positions on the branches (the nonreducing ends). There are usually 2-8 monosaccharides counting from the initial monosaccharide to the end of a branch and

Figure 3-24: Eleven most common monosaccharides composing the oligosaccharides of glycoproteins.

1–4 branches in a typical oligosaccharide on a glycoprotein. Often a branch has only one monosaccharide.

Writing the **sequences** of the oligosaccharides on glycoproteins is complicated by the requirements that each monosaccharide must be noted, the particular

hydroxyl group in the preceding monosaccharide to which it is attached through its carbonyl carbon must be noted, and the anomeric state of its carbonyl carbon must be noted. It is usually assumed that unless otherwise stated the monosaccharides in the oligosaccharide are of the *D* stereochemistry, where, for example, L-fucose, L-rhamnose, and L-arabinose would be exceptions to be noted, and in the pyranose form, where, for example, galactofuranose and arabinofuranose would be exceptions to be noted. To confuse matters further, the sequences of oligosaccharides are usually written from right to left beginning at the right with the monosaccharide attached directly to the protein. The anomeric state of the carbonyl carbon and the hydroxyl group to which it is attached are noted to the right of the name of each monosaccharide. For example, GlcNAc(β 1,4) states that an *N*-acetylglucosamine is attached through its carbonyl carbon, carbon 1, to the 4-hydroxyl group of its immediate predecessor to the right in the written sequence by a β -anomeric acetal. In addition, any modifications of the monosaccharides, such as *O*-acetylation, *O*-sulfation, *O*-phosphorylation, de-*N*-acetylation, or *O*-methylation, must be noted. The actual structure of the oligosaccharide in Figure 3-23 can be compared to its written sequence (Table 3-2, entry 7).

There is yet a further peculiarity of oligosaccharides, that of **microheterogeneity**. Because serious biological problems do not seem to arise when unfinished oligosaccharides are produced, in contrast to the devastation that would occur if unfinished proteins and nucleic acids were produced, natural selection has not enforced uniformity on the synthesis of oligosaccharides. It may even be the case that the existing lack of uniformity has advantages for which natural selection has selected. Although a few finished glycoproteins are homogeneous, in most instances the synthesis of the oligosaccharides is an apparently haphazard stochastic process, and each oligosaccharide that ends up attached at a particular site in a glycoprotein is usually unfinished. Each, however, is unfinished in a different way. Each is missing a different set of monosaccharides. As a result, 10 or 15 different oligosaccharides may be found on the amino acid side chain at the same position in the amino acid sequence of different molecules of the same protein.

Once they have been separately identified and individually sequenced, each of these oligosaccharides can be recognized as a different, incomplete realization of only one complete sequence. This prototypical sequence is often longer than any one of the sequences of the actual oligosaccharides, but each of the sequences of the actual oligosaccharides is a piece of the prototype and every sugar in the prototype is represented in one of the actual oligosaccharides. Whether the prototype including all of the actual sequences is the most complete sequence that could have been produced or is itself only an incomplete realization of a longer sequence can never be decided unequivocally. As an example, 13 different

^aOnly 7 of the 13 oligosaccharides isolated are tabulated. ^bFor abbreviations see Figure 3-27.

oligosaccharides were isolated from human colonic mucin.⁴⁷⁰ All of the other 12, of which six are presented in Table 3-2, were incomplete realizations of the largest (Table 3-2, entry 7). It is possible, however, that this largest one may be an incomplete realization of an even larger oligosaccharide that escaped detection.

Another view of microheterogeneity, in opposition to the view that it is haphazard and purposeless, is that it has a role in producing many different **glycoforms** of the same protein. This would increase the functional range of these proteins and would be advantageous in particular situations. For example, the microheterogeneity observed in the set of oligosaccharides isolated from human colonic mucin (Table 3-2) may permit the oligosaccharides on this glycoprotein to ensnare many different species of bacteria, each of which binds specifically to only one or a few oligosaccharide sequences. It is probably the case that microheterogeneity is relevant in some instances and irrelevant in others. For example, the length and amount of branching in the oligosaccharides on erythropoietin determines its biological activity,⁴⁷⁹ but the presence or absence of oligosaccharide on channel-forming intrinsic protein has no effect on its function.⁴⁸⁰ Unlike most proteins, most oligosaccharides do not assume a fixed conformation so the involvement of microheterogeneity in their biological specificity would be based mainly on differences in sequence. As the oligosaccharides, however, become more crowded⁴⁸¹ or more branched,⁴⁸² local steric effects become more numerous, and their confinement of the conformation of the oligosaccharide may contribute to differences in biological function.

From an examination of the sequences of the oligosaccharides attached to glycoproteins from animals and plants, several generalizations can be drawn. The

most common of these oligosaccharides can be divided into three classes (Table 3-3). The high-mannose oligosaccharides begin with two *N*-acetylglucosamines linked (β 1,4) to each other, the first attached to an asparagine in the protein. These oligosaccharides contain 5-9 mannoses (Figure 3-21). The complex *N*-linked oligosaccharides, because they are biosynthetically derived from the high-mannose oligosaccharides, also begin with two *N*-acetylglucosamines linked (β 1,4) to each other, followed by three branched mannose residues. Beyond this structural core, variable amounts of *N*-acetylglucosamine, galactose, fucose, various sialic acids, and occasionally *N*-acetylgalactosamine⁴⁸⁶ are attached (Figure 3-22). The *O*-linked oligosaccharides begin with an *N*-acetylgalactosamine linked to a serine or threonine on the protein and contain variable amounts of *N*-acetylglucosamine, galactose, *N*-acetylgalactosamine, fucose, and various sialic acids (Figure 3-23).

High-mannose oligosaccharides occur in all eukaryotes, but those in fungi have differences in linkage and branching patterns⁴⁸⁷ from those in plants and animals and often contain significantly more mannose.⁴⁸⁸ Most, if not all,⁴⁸⁹ of the high-mannose oligosaccharides from the proteins of plants and animals are incomplete realizations of one complete, basic structure (Table 3-3, entry 1).⁴⁷¹ This uniformity results from the fact that this unit is transferred in its entirety to the targeted asparagine side chain on the glycoprotein.⁴⁸⁴ Then, in a specific sequence of steps, catalyzed by three exomannosidases, it is shortened until all of the mannoses in (α 1,2) linkage have been removed. When only five mannoses remain, the oligosaccharide is then elongated in a highly specific sequence of steps by specific glycosyltransferases to produce complex *N*-linked oligosaccha-

rides. After the last step of this elongation, other mannosidases remove two more mannoses to leave the three found in the mature complex *N*-linked oligosaccharide.

At the end of this process, most of these **complex *N*-linked oligosaccharides** are also incomplete realizations of one basic structure (Table 3–3, entry 2),^{471,485,490} but minor differences in the positions on the peripheral *N*-acetylglucosamines and galactoses at which the linkages are made have been noted^{491–493} as well as substitution of the peripheral galactoses with *N*-acetylgalactosamines.⁴⁹⁴ Short, repeating units of *N*-acetylglucosaminyl(β1,3)galactose have also been observed inserted between the peripheral galactoses and *N*-acetylglucosamines of some complex *N*-linked oligosaccharides.⁴⁹⁵ Fucoses are found attached to many of the complex *N*-linked oligosaccharides from animals in (α1,6) or (α1,3) linkage to one or the other of the *N*-acetylglucosamines in their cores⁴⁹⁶ or in (α1,3) or (α1,4) linkage to *N*-acetylglucosamines in their peripheries. Xyloses are found attached to a few of the complex *N*-linked oligosaccharides from animals⁴⁹⁷ but many of the complex *N*-linked oligosaccharides from plants⁴⁷¹ in (β1,2) linkage to the central mannose in the core.

It seems that, within the same protein, the oligosac-

charides on certain asparagine side chains will remain as high-mannose oligosaccharides exclusively, while the oligosaccharides on other asparagine side chains are completely converted to complex *N*-linked oligosaccharides.⁴⁶⁹ Occasionally, however, a **hybrid *N*-glycan** is encountered, in which one of the branches in one of these oligosaccharides is of the complex structure while the other remains of the high-mannose structure,⁴⁹⁴ presumably because the processing on the latter branch was specifically blocked.

The ***O*-linked oligosaccharides** display less uniformity than the *N*-linked. This may result from the fact that they are built up one sugar at a time rather than as intact units.⁴⁹⁸ The *O*-linked oligosaccharides drawn in Figure 3–23 and presented in Table 3–3 include some of the common structural features of this class. By far the most common monosaccharide forming the linkage to the serine or threonine is *N*-acetylgalactosamine, but oligosaccharides *O*-linked through other monosaccharides have been reported.^{499,500} The branches are constructed from the basic repeating unit, Gal(β1,3 or β1,4)GlcNAc(β1,3 or β1,4 or β1,6). Branching usually occurs at a galactose or at the initial *N*-acetylgalactosamine, rarely if ever at an *N*-acetylglucosamine. The

basic repeating unit of each branch can begin with either an *N*-acetylglucosamine (Figure 3–23) or a galactose (Table 3–3). Fucose is found in (α 1,4) and (α 1,3) linkages to penultimate *N*-acetylglucosamines in addition to (α 1,2) linkage to peripheral galactoses. The branches either end with a galactose of the repeating unit or are capped by an *N*-acetylgalactosamine in (α 1,3) or (α 1,4) linkage. Sialic acids are found in (α 2,6) or (α 2,3) linkage to galactoses or the initial *N*-acetylgalactosamine. Many variations on these patterns are observed.^{470,483,501–508} Often *O*-linked oligosaccharides are quite short. An example would be NeuNAc(α 2,3)Gal(β 1,3)[NeuNAc(α 2,6)]GalNAc.^{501,503} All these regularities seem to result from the fact that the sugars are added one at a time from the initial *N*-acetylgalactosamine outward by a limited set of glycosyltransferases. These enzymes are specific for particular sugars and attach them only to particular hydroxyl groups on particular sugars within the growing oligosaccharide.

Two of the most heavily glycosylated glycoproteins found in animals are the mucins and the proteoglycans. These two types of glycoproteins can contain up to 80% or 90% carbohydrate by mass, respectively.

The **mucins** are the glycoproteins that constitute mucus and also coat the surfaces of many types of cells.

The human intestinal mucin MUC2 is a polypeptide 5159 aa long.² Between Cysteine 1375 and Cysteine 1762 and between Cysteine 1858 and Isoleucine 4299, there are two regions of amino acid sequence that are rich in threonine (58% of the amino acids) and proline (24%) and are thought to contain the majority if not all of the sites for the *O*-linked glycosylation (Table 3–2), which occurs mainly on threonine.⁵⁰⁹ The larger of these two regions is made up almost exclusively of 101 consecutive repeats of the sequence –TTTTTVTPPTPTGTQTPTTTPI– with only a few substitutions over the entire length of 2323 aa. There are about 1100 *N*-acetylgalactosylthreonyl linkages in the entire protein,⁵⁰⁹ and if all of these are confined to the two regions rich in threonine, about 85% of the threonines in these regions carry oligosaccharides. From an examination of the repeating sequence and the fact that each oligosaccharide contains an average of four monosaccharides,⁵⁰⁹ one can gain an appreciation of how closely packed these oligosaccharides must be. Other mucins also have similar regions rich in threonine and serine, usually found in repeating sequences^{510–512} that are also heavily glycosylated.

Proteoglycans are proteins to which particular types of regular polysaccharides are attached. Proteoglycans are secreted as extracellular matrix and

^aThis is the disaccharide monomer constituting the newly synthesized polymer before postsynthetic modification.

^bEpimerization of glucuronic acid at carbon 5 to form iduronic acid, the presence of which distinguishes dermatan sulfate from chondroitin sulfate. ^cDeacetylation and *N*-sulfation (–NSO₃[–]) are both incomplete so that *N*-acetylglucosamine, glucosamine, and *N*-sulfoglucosamine coexist in the same proteoglycan. ^dEpimerization of glucuronic acid at carbon 5 to form iduronic acid, the presence of which distinguishes heparan sulfate from heparin.

are the main constituents in such structures as cartilage, vascular wall, and tendon. Although they often carry the usual *N*-linked and *O*-linked oligosaccharides, by definition, they also carry at least one of a class of long polysaccharides formed from repeating disaccharides (Table 3–4). Each proteoglycan is defined by the repeating disaccharide that forms the polysaccharide that is attached to it. These polysaccharides of repeating units are heterogeneous because of a collection of postsynthetic modifications (Table 3–4) that are only partially accomplished, often concentrated within randomly spaced blocks of consecutive monosaccharides along the length of the polymer. One constant feature of the covalent structure of a proteoglycan is that each of its defining polysaccharides, except for keratan sulfate,⁵¹⁵ is *O*-linked to the protein through the oligosaccharide –GlcA(β 1,3)Gal(β 1,3)Gal(β 1,4)xylosylserine.⁵¹⁶

As with those of the mucins, the polypeptides of proteoglycans can be quite long. The polypeptide of one of the human chondroitin sulfate proteoglycans is 2293 aa in length⁵¹⁷ and has on average, 12,000 monosaccharides in its covalently attached oligosaccharides and polysaccharides.⁵¹⁸ Unlike the mucins, which contain short oligosaccharides densely packed together because they are on long strings of adjacent threonines, the proteoglycans contain long polysaccharides that can be attached to serines at isolated –Gly-Ser– or –Ser-Gly– sites scattered randomly over the sequence at intervals of about 50 aa.^{517,519} In at least one of the proteoglycans, however, there is the sequence –YS(GS)₂₄L–, to the serines of which heparin and chondroitin sulfate are attached.⁵²⁰

The **sequence of the monosaccharides** in an oligosaccharide or polysaccharide on a glycoprotein is established by chemical analysis. The starting material in this analysis is a purified preparation of the glycoprotein itself. Often, to facilitate the analysis, the oligosaccharides on the glycoprotein have been made radioactive by growing cells producing it in the presence of one or two radioactive monosaccharides, for example, [³H]mannose and [¹⁴C]glucosamine.⁵²¹ Oligosaccharides attached to a glycoprotein are isolated by digesting the protein with endopeptidases, purifying the resulting glycopeptides, and releasing the oligosaccharides from these glycopeptides by chemical or enzymatic cleavage. The **glycopeptides** produced by the digestion are usually separated on a chromatographic system, such as chromatography by reverse-phase adsorption, to separate them on the basis of only their amino acid sequence. In this way all of the oligosaccharides attached to a particular amino acid side chain in the sequence of the glycoprotein are isolated together.⁵²² From an examination of the amino acid sequences of a large number of such glycopeptides, it has been concluded that *N*-linked oligosaccharides from plants and animals are always attached to asparagines that have either a serine or a threonine two amino acids further on in the amino acid sequence (Asn-X-

Ser/Thr).^{471,523} The serines and threonines to which *O*-linked oligosaccharides are attached, however, are evidently not designated by any pattern in the surrounding sequence of amino acids⁵⁰¹ but tend to be clustered in regions of the polypeptide rich in serines, threonines, and prolines. The ultimate example of this would be the mucin MUC2.

The chemical or enzymatic cleavage used to release the several microscopically heterogeneous oligosaccharides from a particular glycopeptide depends upon the glycosidic linkage. For *N*-linked oligosaccharides, **endo-glycosidases** specific for cleavage within the common segment GlcNAc(β 1,4)GlcNAcAsn are usually used. For example, mannosyl-glycoprotein endo- β -*N*-acetylglucosaminidase (endoglycosidase H) catalyzes hydrolysis of the glycosidic linkage between two *N*-acetylglucosamines and releases the oligosaccharide missing its initial monosaccharide, while peptide-*N*⁴-(*N*-acetyl- β -glucosaminy)asparagine amidase (peptide-*N*-glycosidase F) cleaves the *N*-glycosidic linkage between an *N*-linked oligosaccharide and the asparagine on a glycoprotein or glycopeptide.⁵²⁴ Oligosaccharides in *N*-glycosidic linkage to asparagine can also be released from the glycopeptide by hydrazinolysis⁵²⁵ and reacylated with acetic anhydride. Regardless of the method by which it is released, the aldehyde at C1 of the initial *N*-acetylglucosamine in the oligosaccharide is usually reduced to the primary alcohol with Na[³H]BH₄ (Figure 3–25).⁴⁶⁹ This reduction eliminates the aldehyde, simplifies the subsequent chemistry, and makes the oligosaccharide radioactive, if it is not so already. Oligosaccharides in *O*-glycosidic linkage to serine and threonine are usually released from the glycopeptides by treatment with base, which promotes **β -elimination** (Figure 3–25). The treatment with base is performed in the presence of Na[³H]BH₄ to prevent, by reduction of the aldehyde at C1, the destruction of the oligosaccharide from its reducing end and to make the released oligosaccharide radioactive.

It is at this point that the technical consequences of microheterogeneity are experienced. Instead of one pure oligosaccharide released in a quantity equimolar to the amount of glycopeptide, a mixture of many oligosaccharides is produced, each present in a correspondingly small quantity. This mixture is first separated into neutral and anionic oligosaccharides chromatographically.⁴⁹¹ **Chromatographic systems** that separate the oligosaccharides by molecular exclusion or by anion exchange⁵²⁶ are then used to perform further separations. Chromatography by molecular exclusion provides an indication of the size of each oligosaccharide in the set. After the sialic acids have been removed from the anionic oligosaccharides by hydrolysis in mild acid and separately analyzed, the composition of each oligosaccharide is determined. This can be done by methanolysis under acidic conditions to cleave the acetals and coincidentally form methyl glycosides (Figure 3–26) that are

Figure 3-25: β -Elimination of an *N*-acetylgalactosamino oligosaccharide from serine by strong base. The initial step in the reaction is the removal of the proton α to the amide to produce the 1,2-diaminoenolate, which in turn ejects the alcohol to form a dehydroalanine. The reducing end of the oligosaccharide is then reductively labeled with $\text{Na}[^3\text{H}]\text{BH}_4$.

identified by their mobilities on gas chromatography. It is also possible to analyze the composition of the oligosaccharide directly by submitting it to hydrolysis in acid and separating the resulting monosaccharides and deacetylated amino sugars on chromatography by anion exchange (Figure 3-27),^{480,527} the effluent from which is monitored electrochemically.⁵²⁸

The sequence of each of the purified oligosaccharides is determined by indirection. A series of chemical and enzymatic reactions is performed on the oligosaccharide and the outcome of each of these reactions is assessed either directly or by determining the change in composition of the oligosaccharide that occurs. The results of these various reactions are gathered until in their entirety they are consistent with only one of the many possible structures for the oligosaccharide. This one structure is then considered to be the actual structure. The reactions used in this process are periodate oxidation, Smith degradation, treatment with glycosidases, and methylation. The results from these chemical analyses are often supplemented with nuclear magnetic resonance spectroscopy and mass spectrometry.

When sodium metaperiodate (NaIO_4) is dissolved in water at acidic pH (pH 3–6) it forms a mixture of acidic hydrates referred to as periodic acid (HIO_4). **Periodic acid** cleaves polyalcohols such as monosaccharides at the carbon–carbon bonds between vicinal diols and produces two carbonyls from the two hydroxyl groups (Figure 3-28). Both of the hydroxyl groups in the vicinal diol must be free for periodic acid to cleave the carbon–carbon bond between them. The disappearance of a monosaccharide during treatment with periodic acid demonstrates that, in the intact oligosaccharide, the sugar that disappeared had at least two adjacent hydroxyl groups unbonded in glycosidic linkages. It is also possible to identify the actual products of the perio-

date cleavage by mass spectrometry.²²⁸ Oxidation by periodic acid can be performed sequentially by the Smith degradation (Figure 3-28). This series of reactions takes advantage of the lability to acid of a glycosidic linkage at carbon 1 of a sugar that has been cleaved by periodic acid and the resulting aldehydes of which have been reduced with sodium borohydride. In theory this reaction should be able to cleave sugars sequentially from the ends of the branches inward, but in practice only one cycle is usually successful because the selectivity for acyclic acetals is not great.

A more informative sequence of cleavages can often be performed with **exoglycosidases**. These are enzymes that remove particular sugars from the ends of branches. They are highly specific for the sugar removed, the anomeric state of the glycosidic linkage, and sometimes the location of the hydroxyl group from which the bond has been formed. Examples of such exoglycosidases would be β -galactosidase, α -L-fucosidase, β -*N*-acetylglucosamidase, and exo- α -sialidase. An example of the specificity for the hydroxyl group would be the exo- α -2,3-sialidase from Newcastle disease virus. The release of a monosaccharide after exposure of the oligosaccharide to an exoglycosidase is evidence that that monosaccharide was at the end of a branch and attached to it by a glycosidic linkage of the designated anomeric stereochemistry. The digestions are usually performed sequentially. After each of the monosaccharides at the ends of the branches has been catalogued, each of the shortened products of the first round of digestions is then submitted to a round of digestion to identify the penultimate monosaccharides on each branch and so on until the last sugar is released. The products of each round of digestion are monitored either chromatographically⁵²⁹ or by mass spectrometry.⁵³⁰ Several specific endoglycosidases, which cleave an oligosaccharide internally at particular

Figure 3-26: Acidic methanolysis of oligosaccharides. Protonation of the exocyclic acetal oxygen produces a leaving group, the departure of which gives the planar oxacarbenium cation. Addition of methanol to either face of the oxacarbenium cation produces a mixture of the α - and β -anomers of the methyl glycoside.

bonds with high specificity, are also available. Examples of these enzymes are endo-1,4- β -galactosidase and endo- α -sialidase. Many of the complementary DNAs isolated from the original sources of these glycosidases have been transferred to expression vectors, and the proteins are expressed in high yield by transfected bacteria. One advantage to these expression systems is that these enzymes purified from recombinant bacteria are uncontaminated by other glycosidases.

An oligosaccharide can be **chemically methylated** on all of its free hydroxyl groups. This is done by forming the sodium alkoxides of the hydroxyl groups in a solution of dimethyl sulfoxide by using the sodium salt of the dimethyl sulfoxide anion as the base. The alkoxides are then methylated with methyl iodide.⁵³¹ The methylated oligosaccharide is then hydrolyzed in acid, and the resulting monosaccharides are reduced with NaBH_4 . The

Figure 3-27: Chromatographic analysis of the hydrolysate of a glycopeptide to quantify its composition of monosaccharides.⁵²⁷ A sample (300 pmol) of a purified, homogeneous glycopeptide (with the composition $\text{Gal}_3\text{GlcNAc}_5\text{Man}_3$) was hydrolyzed for 4 h at 100°C in 4 M trifluoroacetic acid. The acid was removed by evaporation, and the hydrolysate was submitted to chromatography (panel A) on a column ($0.46\text{ cm} \times 25\text{ cm}$) of a medium for anion exchange equilibrated and eluted with 22 mM NaOH. The strong base makes the sugars sufficiently anionic to be separated by the chromatographic medium. The concentration of monosaccharide was monitored continuously with a pulsed amperometric detector (PAD). The detector responds to the current resulting from the uptake of electrons at a gold electrode (PAD response). The electrode is poised at +50 mV, which is a sufficiently positive potential to oxidize the polyols of the monosaccharides. It is this oxidation at the surface of the electrode that produces the current. Standards (25 pmol) were run (panel B) under the same conditions and separately identified as the following monosaccharides: 1, fucose; 2, galactosamine; 3, glucosamine; 4, galactose; 5, glucose; 6, mannose. From the areas of the peaks of the standards it could be calculated that the original hydrolysate contained 1.1 nmol of glucosamine, 0.79 nmol of galactose, and 0.75 nmol of mannose. The glucose observed was a contaminant. Reprinted with permission from ref 527. Copyright 1988 Academic Press, Inc.

resulting alditols are acetylated both at the hydroxyl groups produced by the hydrolysis of the glycosidic linkages and at the hydroxyl groups produced by the reduction of the aldehydes. The various methylated alditol acetates that result from this treatment are identified chromatographically. In this way, the hydroxyl groups at which the various monosaccharides were bonded in the glycosidic linkages of the original oligosaccharide can be identified because they are acetylated rather than methylated in the products.⁴⁹⁴ For example, upon methylation, the oligosaccharide drawn in Figure 3-21 yielded 1,5-diacetyl-2,3,4,6-tetramethylmannitol, 1,2,5-triacetyl-3,4,6-trimethylmannitol, 2,4-dimethyl-1,3,5,6-tetraacetylmannitol, and smaller amounts of 1,3,5-triacetyl-2,4,6-trimethylmannitol and 3,6-dimethyl-1,4,5-triacetyl-N-acetylglucosaminitol.⁴⁶⁹ The appearance of each of these products is consistent with the structure ultimately proposed for the intact oligosaccharide.

Figure 3-28: Periodate oxidation and Smith degradation. Periodate oxidation (HIO_4) cleaves the carbon-carbon bond between any two unbonded vicinal hydroxyl groups. The products are most readily understood by first putting a hydroxyl group at each position on a carbon that was involved in the carbon-carbon bond and then turning hydrates to aldehydes and orthoacids to acids. Following periodate oxidation, the aldehydes are reduced with borohydride anion, and the acetals containing the degraded monosaccharides are cleaved selectively in weak acid. This frees hydroxyl groups that were previously in glycosidic linkages and makes certain monosaccharides, which were resistant before, now susceptible to periodate oxidation.

Although it is limited by the amounts ($0.5 \mu\text{mol}$) of oligosaccharide needed, **nuclear magnetic resonance spectroscopy** has been applied to solving the sequence of oligosaccharides. The analysis has been most successful in cases where the oligosaccharide is a member of a class, such as high-mannose or complex oligosaccharides, the

structures of which are predictable and for which many well-characterized standards are available to assist in the assignments of the various resonances.^{485,489,491,507,508,532,533}

In at least one instance, however, the structures of a nested set of oligosaccharides of increasing length, from a less well-characterized class of oligosaccharides, were determined entirely by nuclear magnetic resonance spectroscopy.⁵⁰² If a standard oligosaccharide of exactly the same structure as the oligosaccharide isolated from the glycoprotein is available, the coincidence of the nuclear magnetic resonance spectrum of the standard and that of the unknown is proof of the structure of the unknown.⁵³⁴ In the nuclear magnetic resonance spectrum of an oligosaccharide, the chemical shift for the resonance of each of the various hydrogens attached to the carbons of the monosaccharides is characteristic of the monosaccharide itself, the carbon it is attached to, and whether or not the hydroxyl group on that carbon is glycosidically linked.⁵⁰⁶ Two-dimensional spectra are used to assign the set of resonances from hydrogens on the same monosaccharide.^{506,535}

Mass spectrometry has also been applied to structural studies of oligosaccharides and glycopeptides. Oligosaccharides and glycopeptides can be transferred to the gas phase as ionic molecules by fast-atom bombardment,⁵³⁶ electrospray,⁵³⁷ or matrix-assisted-laser-desorption ionization.⁵³⁸ A mass spectrometer cannot distinguish mannose, galactose, and glucose from each other, nor *N*-acetylglucosamine from *N*-acetylgalactosamine. When used without collision-induced dissociation, it can provide information only about the number of hexoses, *N*-(acetylamino)hexoses, and sialic acids present in a given glycopeptide⁵³⁹ because the molecular mass of an oligosaccharide is the same regardless of how the monosaccharides are connected and which epimers are present. Because of the unusual molecular mass of fucose, oligosaccharides containing different amounts of fucose can be distinguished by mass spectrometry.⁵⁴⁰ When mass spectrometry is combined with chemical modifications such as methylation, more information can be gathered by using mass spectra to analyze the products of the reactions.⁵⁴¹ One significant advantage of mass spectrometry is that mixtures of glycopeptides or oligosaccharides can be analyzed because each component in the mixture produces a different molecular ion.⁵⁴²

When a tandem mass spectrometer is used with an intermediate step of collision-induced dissociation, the molecular ion of the oligosaccharide can be selected by the first mass spectrometer, and the fragment ions can be registered by the second.⁵³⁷ In this way a clean sequence of fragments, each missing an additional monosaccharide, can be observed. The sequence in which the fragmentation occurs can provide information about the sequence of monosaccharides in the oligosaccharide, but because the monomeric units are usually not arranged linearly in an oligosaccharide but as branches, the order in which hexoses and *N*-acetylhexosamines are lost upon

fragmentation is not sufficient to define the sequence in which they occur in the oligosaccharide. In the case of the linear, unbranched oligosaccharides of proteoglycans (Table 3-4), however, because the masses of glucuronic acid and iduronic acid differ from those of *N*-acetylgalactosamic and *N*-acetylglucosamine and because the various postsynthetic modifications change the masses of the monosaccharides, spectrometry provides significant information about sequence.⁵³⁸

Problem 3-18: Complete the following reactions:

Problem 3-19: A polysaccharide, which is a polymer of glucose only, is treated in the following way:

Z is a mixture containing the following distribution of methylated glucitol acetates.

methylated glucitol acetate	mole percent
1,4,5-triacetyl-2,3,6-trimethylglucitol	81.9
2,3-dimethyl-1,4,5,6-tetraacetylglucitol	9.0
1,5-diacetyl-2,3,4,6-tetramethylglucitol	8.8
4-acetyl-1,2,3,5,6-pentamethylglucitol	0.2

- On average, how many monosaccharides does each molecule of the polysaccharide contain, how many branch points are there, and how many nonreducing ends are there?
- Draw structures of the linkages in the main linear polymer and the structure of a branch point.
- If the polysaccharide were treated with periodic acid, what percentage of the glucose would be destroyed?

Problem 3-20: A glycopeptide has been isolated following exhaustive pronase digestion of phytohemagglutinin from lima beans.⁵⁴³ Determine its structure from the following information. The compositions of single, intact, homogeneous glycopeptides or oligosaccharides are enclosed within parentheses.

- Composition: (mannose₄, *N*-acetylglucosamine₂, Asp)
- Exhaustive methylation, acid hydrolysis, reduction, and acetylation

methylated acetylated sugar alcohol	mol (mol of dimethyltetraacetylmannitol) ⁻¹
1,5-diacetyl-2,3,4,6-tetramethylmannitol	1.95
1,2,5-triacetyl-3,4,6-trimethylmannitol	1.10
2,4-dimethyl-1,3,5,6-tetraacetylmannitol	1.00
3,6-dimethyl-1,4,5-triacetyl- <i>N</i> -acetylglucosaminitol	1.90

- Periodate oxidation followed by mild acid hydrolysis yields a smaller glycopeptide and no free sugar of any kind. The composition of the smaller

- glycopeptide is (mannose₁, *N*-acetylglucosamine₂, Asp)
- (D) Mannosidase treatments of initial glycopeptide produced

mannosidase	mol of mannose released (mol of glycopeptide) ⁻¹
α -mannosidase (<i>Arthrobacter</i> GJM-1)	0.9
(α 1,2)-mannosidase (<i>Aspergillus niger</i>)	1.1
α -mannosidase (jack bean)	3.0
α -mannosidase (jack bean) followed by β -mannosidase (<i>A. niger</i>)	3.8
β -mannosidase (<i>A. niger</i>) alone	< 0.2

- (E) Glycopeptide core remaining after digestion with α -mannosidase (jack bean) and β -mannosidase (*A. niger*) was GlcNAc(β 1,4)GlcNAc-Asn.
- (F) The glycopeptide remaining after α -mannosidase (*Arthrobacter* GJM-1) digestion was isolated, exhaustively methylated, and hydrolyzed, and the resulting methylhexoses were reduced and acetylated. 1,5,6-Triacetyl-2,3,4-trimethylmannitol, 1,2,5-triacetyl-3,4,6-trimethylmannitol, and 1,5-diacetyl-2,3,4,6-tetramethylmannitol were obtained in approximately equal amounts.

Draw a structure for this glycopeptide that is consistent with all of these observations.

Problem 3-21: A glycopeptide has been purified from thyroglobulin⁵⁴⁴ that had been digested with pronase. From the following information, determine its complete structure. Draw the linkage to the amino acid side chain in the peptide portion. The compositions of single, intact, homogeneous glycopeptides or oligosaccharides are enclosed within parentheses.

- (A) Composition
(Asp, Gly, Val, mannose₃, acetate₂, glucosamine₂)
- (B) Pronase + α -mannosidase
Gly
Val
3 mannose
(Asp, glucosamine₂, acetate₂)
- (C) Chick oviduct extract
(mannose₃, glucosamine₂, acetate₂)
(Asp, Gly, Val)
- (D) Exhaustive methylation, acid hydrolysis, reduction, and acetylation (amounts not determined)
3,6-dimethyl-1,4,5-triacetyl-*N*-acetylglucosaminitol
1,5-diacetyl-2,3,4,6-tetramethylmannitol
2,X-dimethyl-1,Y,5,6-tetraacetylmannitol (X = 3 or 4; Y = 4 or 3)
- (E) Periodate oxidation, acid hydrolysis
(Asp, Gly, Val, mannose₁, glucosamine₂, acetate₂)

- (F) Reduction followed by acid hydrolysis of oligosaccharide from step C
3 mannose
1 glucosamine
1 glucosaminitol
2 acetate
- (G) α -Mannosidase treatment of oligosaccharide from step C
3 mannose
[di-*N*-acetylglucosaminyl(β 1,4)glucosamine]*

Chapter 4

Crystallographic Molecular Models

To this point, it has been described how proteins are composed of long polymers of amino acids and how these polymers are posttranslationally modified by processes that alter the backbone of the polypeptide or the side chains of the amino acids or that add oligosaccharides to the polypeptides. All of the specific covalent bonds connecting all of the atoms in each of the posttranslationally altered polypeptides composing a particular protein can be defined by chemical analysis. The bond lengths and fixed bond angles of the monomers, amino acids and monosaccharides, and of the bonds coupling the monomers into polymers, amides and acetals, are known precisely. With these values, every bond length, the hybridization of every atom, and every fixed bond angle in each complete, posttranslationally modified polypeptide can be assigned unambiguously. From this information a long flexible molecular model of a particular posttranslationally modified polypeptide can be constructed with high precision.

The problem with defining the complete structure of any polymer, polypeptides included, is the rotational degrees of freedom about the large number of exocyclic, unconjugated single bonds that are present in the polymer. In a finished polypeptide there are from hundreds to tens of thousands of such single bonds. In a commercial polymer, such as polystyrene, rotation about its many single bonds causes each molecule of the polymer, even though it may be covalently identical to other molecules of the polymer in the sample, to assume a different three-dimensional structure, and if the polymer is in solution, the structure of each molecule usually changes constantly and randomly with time. The polypeptides in a protein, however, assume only one unchanging structure, or a small number of interchanging structures, uniquely determined by the amino acid sequences of those polypeptides. Each molecule of the same protein assumes the same or one of a small number of three-dimensional structures. This structure or these few structures are exclusively assumed because almost all of the exocyclic single bonds composing the backbones of the polymer and most of the exocyclic single bonds of the side chains of the amino acids are confined to particular dihedral angles. It is crystals of proteins that have provided both this insight and the opportunity to observe molecular models representing these structures.

The existence of a crystal of any protein permits certain conclusions to be drawn about that protein. As in

organic chemistry, it can be concluded that the molecules in the crystal are all covalently identical or almost identical to each other. Furthermore, if a crystal exists, the covalently identical molecules can be present only in a small number of specific three-dimensional conformations. In the case of proteins, all of the molecules in the crystal usually have the same structure or one of a small number of almost identical structures. It is now also known that the structure of a molecule of protein in a crystal is essentially identical to its only structure or one of its few structures when it is free in solution. When the crystal is submitted to X-ray crystallography, that unique structure can be observed.

*Maps of Electron Density*¹

Suppose that one could see X-radiation. If one were to pick up a crystal of a purified protein and tumble it in his hand under a beam of X-radiation of one wavelength, it would glitter as does a jewel in a ray of sunlight. There would be, however, a peculiarity to this glitter. A jewel glitters because its facets reflect the sunlight as small individual mirrors. This means that if one follows a facet carefully as the jewel turns, one would see that it is always reflecting the sunlight and realize that the glittering sensation only arises because the eye is at rest with respect to the moving reflected beam. The glitter from a crystal of protein, however, arises because its facets produce flashes, and these flashes occur only when a facet is aligned in one precise direction relative to the direction of the incident beam of X-radiation. The reason for this is that the flashes are produced by the summation in phase of the reflections from a stack of evenly spaced, parallel mirrors. This summation in phase is **diffraction**. It is only at certain angles that the reflections sum in phase.

If one played with the crystal of protein long enough, it would become clear that there were axes running through it. Rotation about any one of these axes would produce flashes that were regularly arrayed. This regular array of flashes would be reminiscent of the array of reflections that emanates from one of the rotating mirrored spheres in a ballroom. One difference, however, would be that while each mirror on the sphere continuously reflects the spotlight when it is on the illuminated side, as can be discerned by following the reflected beams on the walls, each of the mirrors in the crystal of

protein reflects only when it passes through certain precise orientations, as could also be discerned by watching the patterns of the flashes on the walls. In addition, the mirrors in the rotating crystal, referred to as the **reflecting faces**, reflect onto the walls behind the crystal as well as in front of the crystal because the crystal is not opaque to X-radiation, as is the ballroom sphere to light, and both sides of each mirror can reflect.

The easiest way to verify this behavior is photographically. A crystal is mounted on the end of a rotating shaft the axis of which is coincident with the axis of a cylinder of photographic film. The crystal is attached to the shaft in an orientation such that one of its principal axes is parallel to the axis around which the shaft is rotating. The cylinder of film has a slot through which a beam of X-radiation perpendicular to the axis of rotation can be directed upon the crystal (Figure 4-1A).² After an appropriate exposure, the film is developed. The image observed is that of reflected flashes arrayed on lines of latitude (Figure 4-1B). Each line of latitude, referred to as a **layer line**, arises from all of the mirrors that are tilted at the same angle with respect to the beam of incident X-radiation. Because the spots on the film produced by the flashes occur along layer lines, the tilt of the mirrors relative to the axis of the crystal must be able to assume only certain values. Because the layer lines are made up of discrete spots, each the result of one flash, each mirror must reflect only when the angle between its face and the incident beam assumes unique values.

The profound insight into this curious phenomenon was the realization that the remarkable variations in the intensities of the flashes (Figure 4-1B) contained information and that, from the information they contained, the atomic structure of the molecules from which the crystal was formed could be deduced. With the promise that this is the reward, one can now ask, what are these mirrors, why do they flash, and why does each one flash with a different intensity?

A **crystal of protein** is a solution to a warehousing problem. It is a solid object formed from a huge number of the same protein molecules, neatly stacked as the boxes or barrels in a warehouse, with the vacancies between the molecules of the protein filled with water. It is, for all intents and purposes, an **infinite, three-dimensional array of identical enantiomeric objects**. It can be shown that there are only 71 ways to arrange enantiomeric objects to form an infinite array. Each crystal represents a particular one of these 71 solutions.

Each of these 71 different arrangements can be divided in its entirety into a stack of boxes, each of which is identical in its size, shape, contents, and the arrangement of its contents to every other one. These boxes are always parallelepipeds, and they are referred to as unit cells. A **unit cell** is the smallest parallelepiped of matter that, by only simple translational movements along the three axes of the crystal, can be stacked to create and fill completely the whole crystal. Keep in mind that each of these parallelepipeds is filled with molecules of protein,

Figure 4-1: (A) Schematic drawing of a camera used to take an oscillation photograph of a crystal turning about one of its crystallographic axes. (B) A photograph from such a camera.² The crystal was aligned such that one axis of the unit cell was perpendicular to the beam of X-radiation, and the crystal was then rotated back and forth around this vertical axis back. Each of these oscillations covered the same excursion of about 20°. The axis of rotation was aligned vertically with respect to the film as it is displayed. The white shadow in the center of the photograph is of a beam stop used to protect the film from the majority of the X-radiation, which passes through and around the crystal. The beam was pointed at the circular top of the beam stop. The five layer lines are labeled as if the rotation had occurred around the **a** axis of the crystal. The middle layer line $(0,k,l)$ is the equator. Reprinted with permission from ref 2. Copyright 1968 Macmillan.

and surrounding water, that are necessarily arranged in space in certain positions and orientations. It is this arrangement of molecules that exists, not the unit cells or the planes about to be discussed.

In any crystal, three sets of planes can be constructed. Within each of these three sets, all of the constituent planes must be equidistant and parallel to each other. Every one of the planes in each of the three sets must intersect planes from both of the other two sets, and every one of the parallelepipeds that results from these intersections must be the same unit cell containing the same distribution of matter. The partition of space accomplished by three sets of planes so defined is accompanied by the creation of a network of lines, each of which is the intersection of two of these planes. This network of lines is a **lattice** (Figure 4-2) encaging a set of unit cells.

Unfortunately, each crystal can be divided into several different lattices, each of which satisfies the definition. In addition, any translational movement, no matter how small, of any one of these lattices produces another equally satisfactory lattice. Usually crystallographers follow certain conventions in choosing the fundamental lattice that will be used. These conventions are designed in part to reveal any underlying symmetry that

Figure 4-2: A triclinic lattice. This lattice is the most general because none of the sides of the unit cells (a , b , or c) is the same length and none of the three angles (α , β , or γ) is 90° or 120° . If $\alpha = \beta = 90^\circ$, the lattice would be **monoclinic**. If $\alpha = \beta = \gamma = 90^\circ$, the lattice would be **orthorhombic**. If $a = b$ and $\alpha = \beta = \gamma = 90^\circ$, the lattice would be **tetragonal**. If $a = b = c$ and $\alpha = \beta = \gamma \neq 90^\circ$, the lattice would be **rhombohedral**. If $a = b$, $\alpha = \beta = 90^\circ$, and $\gamma = 120^\circ$, the lattice would be **hexagonal**. If $a = b = c$ and $\alpha = \beta = \gamma = 90^\circ$, the lattice would be **cubic**. The axes are defined by the right-hand rule. The hand is reprinted with permission from ref 2. Copyright 1968 Macmillan.

Figure 4-3: Fundamental unit cell in a triclinic lattice showing the relationship between the distribution of matter and the boundaries of the fundamental unit cell. Even if the fundamental unit cell has not been chosen to enclose one of the repeating objects, it contains a total of one complete object.

may be present within the crystal and in part to simplify the extensive calculations that are involved in producing a map of electron density. One lattice is chosen, however, during a procedure known as indexing, and this choice defines the **fundamental unit cell** (Figure 4-3). The three **axes** of the fundamental unit cell are conventionally designated a , b , and c by the right-hand rule (Figure 4-2). The length of the fundamental unit cell along each axis, in nanometers, is designated a , b , or c , respectively.

There are other ways to divide the space occupied by the crystal into different sets of unit cells by using other **sets of parallel planes**. This can be most easily seen by starting with a two-dimensional lattice (Figure 4-4). Each set of parallel lines in the figure is constructed so that its members pass through the origins of the fundamental unit cells, and the origin of each fundamental unit cell is contained in one of the lines of each set. This two-dimensional lattice can then be thought of as one of the lattice planes in a three-dimensional monoclinic crystal. In this case, the view presented in the figure would be down the c axis, and each line would be the intersection of a plane perpendicular to the page. Each set of planes parallel to each other and perpendicular to the two-dimensional lattice would create a new array of unit cells (Figure 4-5), and within a particular crystal, every one of these arrays would contain the same number of unit cells. Most of these arrays do not produce lattices because their unit cells are not formed from three intersecting sets of parallel planes, but they are arrays of genuine unit cells nevertheless. By extension it is clear that there is an infinite number of ways to divide a lattice into a set of unit cells that are bounded by at least one set of parallel planes (Figure 4-5).

Each of these sets of parallel planes is identified by giving it an **index**, (h, k, l) . The index is referred to the axes of the fundamental unit cell. From an examination of Figure 4-5, it can be seen that the parallel planes perpendicular to the page that define a given set of unit cells always intersect the axes of the fundamental unit cell at intervals that are the quotient of the length of the fundamental unit cell along that axis (a , b , or c , respectively) and an integer. As the tilt of the planes relative to that axis

Figure 4-4: Sets of parallel lines, defining sets of unit cells, that pass through a two-dimensional lattice with axes **a** and **b**. The sets of parallel lines with indices (1,1), (2,1), and (3,1) and (-1,1), (-2,1), and (-3,1) are presented.

increases, so does the magnitude of this integer, monotonically and continuously. A given set of parallel planes (Figure 4-6) is assigned three integers, h , k , and l . The magnitude of the integer h is the number of segments into which the planes divide the length of the fundamental unit cell along its **a** axis. The magnitude of the integer k is the number of segments into which the planes divide the length of the fundamental unit cell along the **b** axis; and the magnitude of the integer l , along the **c** axis. When the set of planes is parallel to one of the axes of the fundamental unit cell, as all of the planes in Figure 4-5 are to the **c** axis, it is assigned 0 for the respective index.

The **signs of the integers** assigned to each reflection are determined by the relative progressions of the planes along the three axes. If, as one progresses from one plane to the next along the **a** axis in a positive direction, the intersections of the successive planes with the **b** axis progresses also in a positive direction, as they do in Figure 4-6, then the signs of the integers h and k are the same. If, however, as one progresses from one plane to the next along the **a** axis in a positive direction, the intersections of the successive planes with the **b** axis progress in a negative direction, as they do in Figure 4-5, then the signs of the integers h and k are opposite each other. The same holds for the relationship between the signs of the integers h and l .

Each plane in a set of parallel planes has two **faces**, and either can reflect X-radiation. The two reflections, one from each of the two sides of that set of reflecting planes, are a **Friedel pair**.² In the indices (h,k,l) assigned respectively to the two reflections of the Friedel pair, the signs of the integers h , k and l are opposite. For example, the two reflections with indices (3,-2,4) and (-3,2,-4), respectively, are from the opposite faces of the same set of parallel planes and are a Friedel pair.

The reflections from the faces of the sets of reflecting planes are produced by the electrons in the crystal and they are emitted by diffraction.

Electrons **scatter X-radiation**, and molecules are clouds of electrons confined within atomic and molecular orbitals. The molecule or molecules of protein and the molecules of water distributed through any unit cell in a crystal are clouds of electrons, and they will scatter X-radiation. Electrons scatter X-radiation by being excited to vibrate by the oscillating electric field of the incident beam and then radiating X-radiation of the same wavelength in all directions.

Cut a crystal of protein across its entire width with any plane parallel to the set of planes of a given index (Figure 4-5). Examine one of the two smooth, flat faces produced by that random transection of the crystal. That face contains a particular amount of electron density

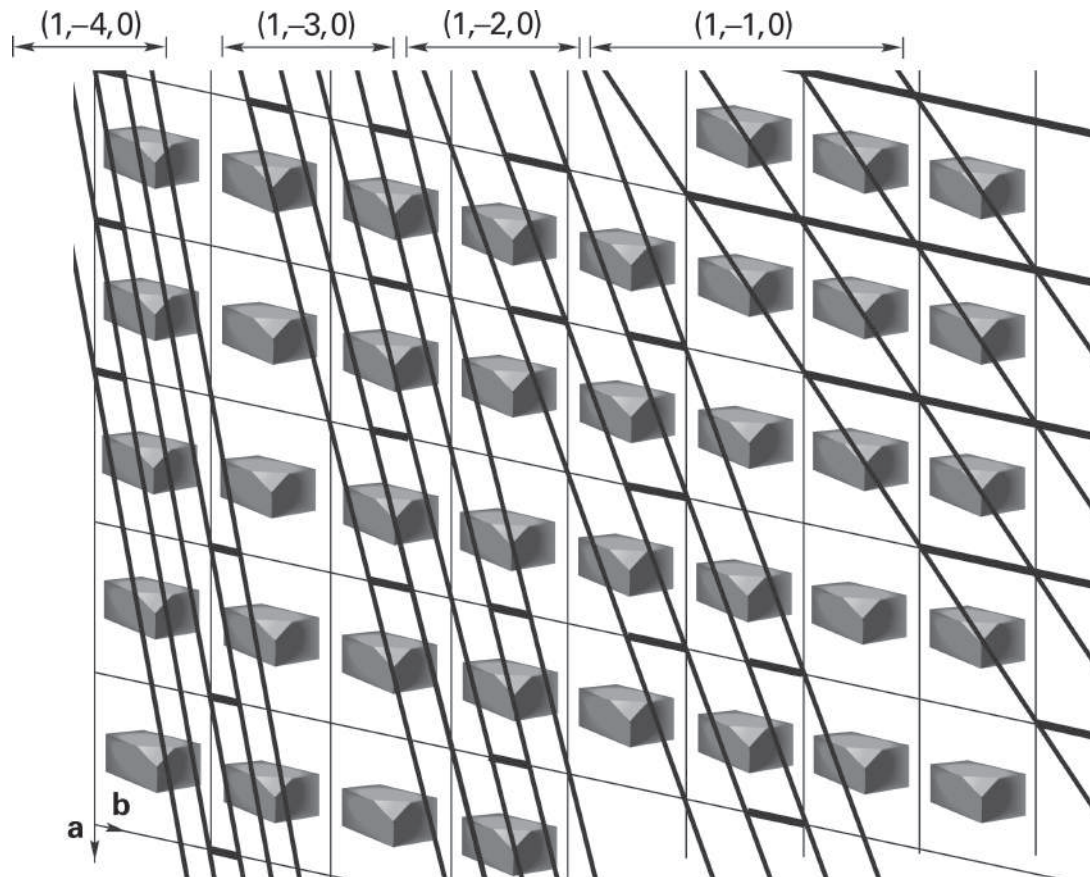

Figure 4-5: Sets of unit cells created by sets of parallel planes. Assume this to be a monoclinic lattice viewed down the c axis and each line the intersection of a perpendicular plane $(h,k,0)$ with the page. Each new set of parallel planes produces a new set of unit cells. The index of each set is given at the top. Each type of unit cell cuts the repeating object into different segments, but in each unit cell in each set of parallel planes, the segments, if put together, form one complete object.

from those atoms within each unit cell that were transected by the plane. Each unit cell defined by the set of planes parallel to the transection contributes exactly the same amount of electron density to the face because it is sliced at exactly the same angle and at exactly the same level. All of the electron density in the entire face will scatter X-radiation. The electron density in the face scatters the X-radiation just as the silver on the smooth, flat surface of a mirror scatters light, and the face is therefore **a mirror for X-radiation**. All of the quanta of X-radiation reflected by that mirror at a certain angle will be reflected

Figure 4-6: Assignment of an index to a set of planes creating the reflecting faces. The index h , k , or l relative to a given axis, a , b , or c , respectively, is the number of segments into which the respective axis is intersected by the set of planes over the length of the fundamental unit cell. The index of this set of parallel planes is $(4,2,3)$.

in phase as is the case with any planar mirror (Figure 4-7). As a result, the scattering elements can be anywhere in the reflecting face and the regularly arrayed, repeating pattern of electron density can be translated along axes parallel to the plane, without affecting either the amplitude or the phase of the reflection. It is this insensitivity of reflected electromagnetic radiation to translation that creates the requirement that a unit cell be only a translational repeating unit. The **amplitude of the reflection** produced by this mirror will be proportional to the quantity of electron density it contains, which is equal to the amount of electron density contributed by each unit cell times the number of unit cells it transects.

Consider the two planes parallel to the one just described at a distance the width of one unit cell above it and at a distance the width of one unit cell below it. Each of these two planes creates a reflecting face with an

Figure 4-7: Incident electromagnetic radiation at an angle ϕ to a plane of reflection emerges from the reflection in phase regardless of the locations of the points on the plane at which reflection occurs.

identical orientation and an identical repeating pattern of electron density to the one just described. The three reflecting faces considered so far, however, are undistinguished members of a set of reflecting faces evenly spaced throughout the entire crystal that each contain an identical repeating pattern of electron density, that are each the distance of a unit cell above and below their neighbors, and that together include identical transections through all of the unit cells of the same index in the crystal. Each of the members in this set of faces will produce a reflection. If the crystal is being rotated in a beam of X-radiation, when the angle of the incident beam of X-radiation assumes one of a set of particular values, θ_{hkl} , with respect to the set of planes that produced this set of reflecting faces, the reflections from all of the reflecting faces in the set will add in phase to produce a burst or flash of X-radiation by **diffraction** (Figure 4-1B).

The values of θ_{hkl} at which this diffracted reflection occurs is defined by Bragg's law²

$$\theta_{hkl} = \sin^{-1} \left(\frac{n\lambda}{2d_{hkl}} \right) \quad (4-1)$$

where n is any integer, λ is the wavelength of the incident X-radiation, and d_{hkl} is the perpendicular distance, or **Bragg spacing**, between the reflecting faces, which is the width of the unit cells between the planes. Only diffracted reflections are emitted by the crystal because when the incident angle of the X-radiation on a set of faces is not equal to one of these values θ_{hkl} , there are so many reflections from that set of faces that are out of phase with each other that all of them cancel completely. From Equation 4-1 it follows that X-radiation is diffracted by every set of reflecting faces for which the spacing between the planes is larger than $\lambda/2$. The distance $\lambda/2$ is the diffraction limit. Sets of faces with spacings less than the **diffraction limit** do not diffract the X-radiation, and therefore their reflections cannot be observed.

Now consider a plane transecting the crystal parallel to one of the reflecting faces just described, so that it has the same index but at a distance ds above it (Figure 4-8). Consider the reflecting face created by this plane that faces the same direction as the reflecting faces just described. This new reflecting face is a member of a second set of reflecting faces each a distance d_{hkl} apart and each a distance ds above a member of the first set. This second set of reflecting surfaces will diffract the X-radiation at the same incident angle that the first set did because its spacing and angular disposition is the same. But the amplitude of the diffraction from the second set will be different from the amplitude of the diffraction from the first set because even though all of the unit cells are also sliced by the second set, a reflecting face in the second set transects a different region of the unit cell and therefore contains a different amount of electron density from each unit cell than did a reflecting

face in the first set. The phase of the diffraction from the second set will also be different from the phase of the diffraction from the first set of reflecting faces because the second set is displaced a distance ds from the first.

This process of slicing the crystal with sets of reflecting faces each displaced from the set before it by a distance ds can be repeated until the entire unit cell, and hence the entire crystal, has been sliced (Figure 4-8). Each one of these different sets of reflecting faces will diffract at the same angle, θ_{hkl} , because they all have the spacing of the planes of the given index. The single amplitude and single phase of the total diffracted reflection produced by the complete set of all of these reflecting faces will be the sum of the individual amplitudes and individual phases of all of the component sets. The diffracted reflection from the complete set will be observed at the angle θ_{hkl} to the incident beam of X-radiation, and its amplitude and phase will necessarily contain information concerning the distribution of electron density within the crystal. Each complete set of faces of a given index passing through the lattice will produce its own diffracted reflection. Each of the spots on the film in Figure 4-1 is the diffracted reflection from the complete set of reflecting faces of a particular index.

The phase of the reflection from the set of faces hkl is designated α_{hkl} . The **phase of the reflection** is the distance between a crest of the emitted wave and a point of reference common to all of the emitted X-radiation. The phase is expressed in units of wavelength so that, were its value 1, there would be an integral number of wavelengths between the point of reference and the crest. Because the wave is periodic, the phase is expressed as a dimensionless fraction between 0 and 1. Because the

Figure 4-8: Reflecting faces within three consecutive unit cells of height d each a distance ds apart from its neighbors. The first 11 reflecting faces in the unit cell in the middle are shown. The top three faces of that same set of 11 in the bottom unit cell are also shown as well as the bottom face of the same set in the top unit cell. Each reflecting face extends over the whole crystal but only its intersection with the respective unit cell is shown in the figure. Each reflecting face in the set represented here is parallel to two of the axes of the unit cell. Each reflecting face in the stack within each unit cell has a different two-dimensional distribution of electron density because each plane producing a reflecting face cuts a different section through the unit cell.

wavelength of the X-radiation used is usually less than 0.2 nm, the differences in phase among the different reflections are less than 0.2 nm, and because coherent sources are unavailable, they are immeasurable.

Because the choice of the lattice used to define the fundamental unit cell was arbitrary, the choice of the **boundaries of the fundamental unit cell** is arbitrary. Because every plane passing through the unit cell parallel to its boundaries (Figure 4-8) is no better than any other, the plane chosen as the upper boundary of the fundamental unit cell can be anywhere so long as the plane below it chosen for the lower boundary is the one at the level where the pattern repeats. Crystals are seldom cooperative and the molecules packed within them almost never fit as intact entities into a neat box. But this is irrelevant because the solution to a crystallographic calculation gives the distribution of electrons in the fundamental unit cell. The distribution of electrons in any number of adjacent fundamental unit cells can be constructed by simply stacking fundamental unit cells next to each other. If a large enough pile of fundamental unit cells is made, a complete molecule will be found somewhere in the pile.

Each of the thousands of diffracted reflections emerging from the rotating crystal must be assigned an index. For example, each reflection in Figure 4-1B originated from one of the complete sets of reflecting faces, and the index of that set must be assigned to that reflection. The problem of **indexing** is a game of mirrors. As with all games, it is captivating and takes on a life of its own. The crystallographer plays the game in **reciprocal space**; and, as such, learning to live in reciprocal space is a rite of passage. But it is not necessary to live in reciprocal space unless one is a crystallographer; it is enough to know that this can be done with certainty. The concept of reciprocal space simplifies this process of assignment. A familiarity with reciprocal space also permits an engineer to design an X-ray camera that can display the reflections on a sheet of photographic film in the order of their index number. A precession photograph (Figure 4-9) is the product of such a camera.

The intensities of all of the reflections the values of h , k , and l of which fall within chosen limits are measured and indexed. From the measured intensity of each reflection, the amplitude of the structure factor of that reflection can be calculated. The **structure factor** of a reflection is a vector. The phase of that vector is the phase of the reflection, and the square of the amplitude of that vector is a number directly proportional to the measured intensity of the reflection. The constant of this proportionality can be calculated from a consideration of the geometry and the dimensions of the instrument used to measure the reflection. The **amplitude of the structure factor** is the quotient of the square root of the measured intensity of the reflection and this constant of proportionality. In this way, the amplitude of the structure factor is the amplitude of the reflection that has

Figure 4-9: Precession photograph of the diffraction of X-radiation by a crystal of egg-white lysozyme from *Gallus gallus* and its isomorphous replacement both in the same triclinic lattice.¹² This is a section through the full three-dimensional pattern of reflections, taken with a Buerger precession camera. Only reflections with an index h of 0 were arrayed by the camera in this particular section. Two photographs are superimposed slightly out of horizontal register to show changes in intensities produced by isomorphous introduction of heavy atoms into the crystal. Left spot of each pair, native lysozyme; right spot, crystal after HgBr_4 has diffused in. This is a photograph of an array of the $0kl$ set of reflections mechanically arranged by the camera with the l axis horizontal and k axis nearly vertical. The index of each reflection can be assigned by inspection from its position in the array. One can consider this photograph as an array of all of the reflections in an equatorial layer line from a rotation photograph about the a axis, such as the one in Figure 4-1B, laid out by the precession camera systematically upon the field. The photograph contains all reflections needed to compute a projection of the structure down the a axis to Bragg spacings of 0.4 nm. Reprinted with permission from ref 12. Copyright 1964 Academic Press.

been corrected for the geometric and instrumental details involved in the measurement. Consequently, it is a property only of the unit cell itself and not of the method by which the measurement was made. Together the amplitudes of the properly indexed structure factors produce a data set. A **data set** is a three-dimensional matrix centered on an origin (0,0,0) in which is entered the amplitudes of all the structure factors calculated from the intensities of the respective reflections that have been measured from a given crystal. Each amplitude is entered at the location in the matrix that has an index identical to the index of its reflection. The amplitude entered at position hkl in this matrix is designated as F_{hkl} and is a positive number.

The rectangular sheet of photographic film that was once used to record the amplitudes of the diffracted reflections (Figure 4-1B) has been replaced by a **charge-coupled device**, which is a rectangular plate that can

measure simultaneously the magnitude of the flux of X-radiation through each pixel on its surface. If the density of pixels is constant, the larger the surface area of the detector, the greater the number of reflections that can be measured simultaneously, and the less will be the damage to the crystal caused by the X-radiation.³

The greater the flux of X-radiation from the source, the shorter will be the interval needed to collect a complete data set. The sources of X-radiation with the greatest fluxes are the large **synchrotrons** located at national laboratories around the world.⁴ The additional advantage to X-radiation from synchrotrons is that these sources produce a broad spectrum of wavelengths so that any narrow range of wavelength within this spectrum can be chosen for the experiment. If the crystal diffracts effectively, it is now possible to collect hundreds of thousands^{3,5} of unique reflections* to Bragg spacings of less than 0.1 nm,^{5,6} which approaches the diffraction limit of the available wavelengths.

The size and shape of the fundamental unit cell can be defined from the angles at which the reflections emerge from the crystal and hence the spacings of the reflections over the surface of the detector (Figure 4-1B). The size and shape of the fundamental unit cell and the indexed data set itself are the only directly measurable quantities available to the crystallographer, and they are ultimately the information used to calculate the distribution of electrons in the crystal of a protein. The unobservable phases, the values of which are inescapably required for the calculation, must be ascertained indirectly by comparing several data sets, each obtained from an altered form of the original crystal.

At this point it is possible to explain the **pattern of reflections in the oscillation photograph** in Figure 4-1B. The central layer line, which intersects at its midpoint the axis of the collimated beam of X-radiation in the camera, is referred to as the equator. Assume that the axis of the crystal chosen for rotation is the **a** axis and that the axis of the beam of X-radiation is perpendicular to the axis about which the crystal is rotated. Define the angle ν , which is the angle between the axis of rotation and a diffracted reflection (Figure 4-10). The complete sets of reflecting faces with an index h of 0, referred to as the $(0,k,l)$ sets of faces, contain only faces parallel to the axis of rotation. As the rotation of the crystal brings each set of these $(0,k,l)$ faces into the proper angle θ_{0kl} with respect to the beam of X-radiation, diffracted reflection occurs. Because each set of these faces is parallel to the axis about which the crystal is rotated and because the angle of reflection equals the angle of incidence, each flash emerges at an angle $\nu = 90^\circ$. The reflections from the $(0,k,l)$ sets of faces are the layer line of reflections on the equator. There is, however, no easily explained pattern in which the reflections with particular values for k

Figure 4-10: Definition of ν , the angle between the axis of rotation and the diffracted reflection.

and l are distributed along the equator. Now consider all the sets of faces with an index h of 1, referred to as the $(1,k,l)$ sets of faces. Each of the faces in these sets makes an angle with the axis of rotation such that all values of ν for these sets are the same and all the reflections lie on the first layer line. The same argument can be made for the other layer lines. Therefore, in a crystal rotated about the **a** axis, all of the reflections with the same first index lie on the same layer line, and each successive layer line out from the equator is of successively higher or successively lower first index. In each layer line, however, the pattern in which the reflections with successive second or successive third indices occur is complex. Each of these reflections, however, can be assigned a full index unambiguously by the crystallographer.

Any piece of matter, at a given instant ($<10^{-12}$ s), has a particular distribution of molecules, and this distribution of molecules causes the matter to have a **distribution of electron density**, $\rho(x,y,z)$. If the matter is a gas or a liquid, the rapid redistribution of the molecules causes $\rho(x,y,z)$ to change over its full extent with time. The collection and measurement of the intensities of the reflections necessary to perform a determination of molecular structure usually takes hours, and the distribution of electron density of a liquid or a gas averaged over the period of the measurement is absolutely uniform. The liquid regions of aqueous solvent within a crystal of protein, which account for 40–75% of its volume,⁷ are, as a result, featureless. Any portion of the protein the position of which fluctuates over dimensions greater than those of an atom, for example a flexible segment of polypeptide, is also featureless. To the extent that the matter in a crystal is a solid, its molecules remain fixed in space, and solids have well-defined distributions of electron density. The fixed portions of the molecules of protein in the crystal remain in place, except for thermal vibrations,

* Unique reflections count only those not duplicated by the symmetry of the crystal and count only one of the Friedel pairs.

and the experimentally measurable distribution of electron density in the regions of the crystal that contain the fixed portion of the protein is the average over these small vibrational displacements. Within these limits, it is featured. The distribution of featured electron density in a crystal is a periodic function, by definition, and it is this periodicity that leads to the reflections.

It can be shown² that for a crystal of protein

$$\rho(x, y, z) = \frac{1}{V} \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} \sum_{l=-\infty}^{\infty} F_{hkl} \exp[-2\pi i(hx + ky + lz - \alpha_{hkl})] \quad (4-2)$$

where V is the volume of the fundamental unit cell, F_{hkl} are all of the amplitudes, properly indexed, and α_{hkl} are all of the properly indexed phases of the structure factors of the reflections. The coordinates x , y , and z in Equation 4-2 are referred to the major axes **a**, **b**, and **c**, respectively, of the fundamental unit cell (Figure 4-11). This usually produces a **coordinate system** that is not orthogonal. The lengths a , b , and c of the fundamental unit cell along the three major axes **a**, **b**, and **c** are expressed in absolute length (nanometers). The three distances x , y , and z that are the coordinates of a point within the fundamental unit cell are measured along the three major axes (Figure 4-11), but the units in which these three distances are expressed in Equation 4-2 are relative distances along these axes, where $x = Xa^{-1}$, $y = Yb^{-1}$, and $z = Zc^{-1}$, and X , Y , and Z are the absolute distances (nanometers) along each respective axis. The integers h , k , and l ; the coordinates of a point in the unit cell, x , y , and z ; and the phase of each structure factor, α_{hkl} , are all dimensionless numbers. The 2π by which they are multiplied in Equation 4-2 converts these dimensionless numbers to units of radians. This is the purpose that 2π serves in all of the remaining equations of this section.

Figure 4-11: Assignment of coordinates x , y , and z to a point within a fundamental unit cell. The coordinate axes for the distances x , y , and z are the crystallographic axes **a**, **b**, and **c**, respectively. The distances in each direction are measured along these axes regardless of the angles between them. The numbers in parentheses are the values for x , y , and z , respectively, at the respective corners of the unit cell.

The **imaginary portion** of Equation 4-2 is somewhat disconcerting because the intention of the equation is to calculate a real electron density. This conundrum is solved by noting that

$$\exp(iw) = \cos w + i \sin w \quad (4-3)$$

and that, because a complete data set is a complete set of Friedel pairs, all terms in $i \sin w$ cancel in pairs.² As a result

$$\rho(x, y, z) = \frac{1}{V} \sum_h \sum_k \sum_l F_{hkl} \cos[2\pi(hx + ky + lz - \alpha_{hkl})] \quad (4-4)$$

The value of examining Equation 4-2 is that it demonstrates that the electron density at any point in the fundamental unit cell can be calculated explicitly by inserting the amplitudes of the structure factors, properly indexed; the coordinates of that point; and the respective phases. The way that the **calculation of a map of electron density** is performed is to divide the fundamental unit cell into a large number of points with coordinates x_p , y_q , z_r . Insertion of all available values for F_{hkl} , α_{hkl} , h , k , l , and the coordinates of the point x_p , y_q , z_r into Equation 4-2 produces the value of $\rho(x,y,z)$ at the point x_p , y_q , z_r . All points in three-dimensional space with values of $\rho(x_p, y_q, z_r)$ within certain narrow ranges are connected by contoured surfaces, or all points in sections through the fundamental unit cell with values of $\rho(x_p, y_q, z_r)$ within certain narrow ranges are connected by contour lines, and this procedure produces a map of electron density (Figure 4-12).⁸

The summations of Equation 4-2 or Equation 4-4 are theoretically infinite, but any finite number of structure factors will give an approximate solution. In any case, the data set can never contain reflections from beyond the diffraction limit. The effect of summing over only a **finite number of structure factors** in Equation 4-2 is to blur $\rho(x,y,z)$. The fewer the structure factors used, the more blurred $\rho(x,y,z)$ becomes. Usually 10,000–500,000 independent reflections are measured and indexed to calculate a map of electron density. The minimum Bragg spacing of this data set usually will be 0.1–0.3 nm, and the individual values of h , k , and l will lie between about –40 and 40.

The decision about which structure factors to include in the data set is based on the ability of the instruments to measure reflections with large angles of θ_{hkl} , the ability of the crystal to diffract from sets of faces with small Bragg spacings, and other technical limitations. Once the decision has been made, the data set is collected so that it includes the amplitudes of the structure factors from as many as possible of the reflections arising from sets of faces the Bragg spacings of which is greater than a minimum value. The universal choice of

Figure 4-12: Stereoview of the map of electron density (Bragg spacing ≥ 0.25 nm) calculated from crystals of deoxyribonuclease I from *Bos taurus*.⁸ The experimental phases were estimated by use of isomorphous derivatives obtained with solutions of TbCl_3 , K_2PtCl_6 , $\text{Pb}(\text{NO}_3)_2$, and the three binary combinations of these three salts. Portions of six contiguous sections (0.08 nm section⁻¹) through the fundamental unit cell (monoclinic; $a = 13.2$ nm, $b = 5.5$ nm, and $c = 3.8$ nm; $\beta = 91.4^\circ$) perpendicular to the b axis were stacked together. The contours represent three levels of electron density and were drawn through points on each section the electron densities of which were 10%, 20%, and 30%, respectively, of the maximum electron density observed. Reprinted with permission from ref 8. Copyright 1984 IRL Press.

“resolution” as the word used to report this **minimum magnitude of the Bragg spacings** between the faces, the reflections from which have been included in the data set, is unfortunate. This choice suggests that the property being noted is the same property as the resolution defined in optics, which it is not. The minimum magnitude of the Bragg spacings does place an upper limit on the quality of the final map of electron density, but it is not the only factor determining its quality. The difficulty is not collecting and indexing reflections, which ultimately determines the minimum Bragg spacing, but establishing accurate phases for each reflection.⁷

In practice, at a given minimum value for the Bragg spacing, it is the quality of the phases that defines the quality of the map of electron density.* It has been shown⁹ that if all of the correct amplitudes are used but all of the phases are set at the same arbitrary value, the map of electron density calculated is meaningless. If, however, all of the correct phases are used and all of the amplitudes are set at the same arbitrary value, a fairly accurate map of electron density can be calculated.† It is less misleading to refer to the data set as one “to Bragg spacings of” rather than as one “at a resolution of”.

The use of Equation 4-2 or 4-4 requires that the phase, α_{hkb} of each structure factor in a data set be estimated. One way such an estimate can be accomplished for crystals of protein is by **multiple isomorphous replacement**.¹⁰ Suppose there are two crystals of protein, alike in almost every way and hence isomorphous. The only difference between them is that, at one or a few specific locations on each of the molecules of protein in one of the crystals, an atom or several atoms that have a large number of electrons has been attached; the other crystal is of the unadorned protein. One of the requirements placed on the bound atoms is that they have high electron density, in other words, a large number of electrons in a small volume. For this reason, a **heavy atom** such as xenon, iodine, mercury, gold, or uranium is usually chosen. Another requirement is that these heavy atoms occupy specific points in the fundamental unit cell. This requirement is fulfilled if they are bound to particular amino acids or clusters of amino acids on the surface of each molecule of protein. For example, the PtCl_4^{2-} used to phase the structure factors from a crystal of phosphocarryer protein III^{glc} happened to be chelated by two histidines that by chance were adjacent to each other on the surface of the protein.¹¹ The reflections from the two crystals, the one containing the fixed heavy atoms and the one without them, will have the same values for all θ_{hkl} and hence the same geometric display of reflections,

* The quality of the phases is quantified by the **figure of merit**, which ranges from zero (completely unreliable) to 1.0 (perfect.)

† Even if, however, the phases were estimated perfectly but only amplitudes and phases for reflections to Bragg spacings of 0.5 nm were used in the calculation, the resulting map of electron density would not contain sufficient information to reveal the structure of a protein. A minimum Bragg spacing of 0.3–0.35 nm is required.

but the amplitudes of the reflections will differ (Figure 4–9)¹² as well as the phases.

The structure factor of a reflection from a set of faces with the index hkl can be represented as a vector \mathbf{F}_{hkl} . The length of the vector is the amplitude of the structure factor, F_{hkl} , and its direction is defined by the phase of the reflection, $2\pi\alpha_{hkl}$ radians. Because the computations are performed in complex space (Equation 4–2), complex coordinates are chosen to represent this vector:

$$\mathbf{F}_{hkl} = F_{hkl}(\cos 2\pi\alpha_{hkl} + i \sin 2\pi\alpha_{hkl}) = F_{hkl} \exp(2\pi i \alpha_{hkl}) \quad (4-5)$$

The real component of the vector \mathbf{F}_{hkl} is $F_{hkl} \cos 2\pi\alpha_{hkl}$, and the imaginary component is $F_{hkl} \sin 2\pi\alpha_{hkl}$. The amplitude of the vector is

$$F_{hkl} = F_{hkl}(\cos^2 2\pi\alpha_{hkl} + \sin^2 2\pi\alpha_{hkl}) \quad (4-6)$$

Equation 4–2 states that the electron density is the Fourier transform of the structure factors. It follows that the structure factors must be the Fourier transforms of the electron density. As a result, the amplitude and phase of a given structure factor from a crystal can be calculated if the distribution of atoms in a fundamental unit cell of that crystal is known

$$\mathbf{F}_{hkl} = \sum_j f_j \exp[2\pi i(hx_j + ky_j + lz_j)] \quad (4-7)$$

where f_j is the scattering factor for atom j and (x_j, y_j, z_j) is its position in the unit cell. The scattering factor is determined by the number of electrons in atom j and their distributions over their respective orbitals. Because the sizes of the orbitals are of the order of the wavelength of the X-radiation, the numerical value of the scattering factor for a given atom is a function of the angle θ_{hkl} of the reflection. As θ_{hkl} increases, the scattering produced by the electrons around an atom decreases as a result of interference. Values for scattering factors have been tabulated for all atoms and systematic values of θ .

It can be seen that, since Equation 4–7 is a summation

$$\mathbf{F}_{hkl, H+P} = \mathbf{F}_{hkl, H} + \mathbf{F}_{hkl, P} \quad (4-8)$$

where $\mathbf{F}_{hkl, H+P}$ is the structure factor from the crystal containing the heavy atom, $\mathbf{F}_{hkl, P}$ is the same structure factor from the unadorned crystal, and $\mathbf{F}_{hkl, H}$ would be the structure factor from a crystal in which only the heavy atoms were present at the same locations they occupy in the existing isomorph. This summation can be presented geometrically (Figure 4–13A).^{7,13} If one knows where the heavy atoms are located in the fundamental unit cell, the

vectors $\mathbf{F}_{hkl, H}$, both amplitudes and phases, can be calculated with Equation 4–7. Discovering the locations of the heavy atoms in a given isomorph is an art, the description of which is dramatic but not germane to this discussion. Their locations are eventually determined, and these locations are used to calculate each of the values of $\mathbf{F}_{hkl, H}$.

Unless the heavy atom chosen displays strong anomalous dispersion, at least two isomorphous crystals, each substituted with a heavy atom in a different way are required for a unique determination of the phases. The data that are available are $F_{hkl, P}$, $F_{hkl, (H+P)g}$, and $\mathbf{F}_{hkl, Hg}$, where the index g refers to each of the several isomorphous replacements from the crystals of which reflections have been measured. From Equations 4–5 and 4–8, these data provide a set of **simultaneous vector equations** equal in number to the number of isomorphous replacements for each structure factor. In theory, any two of these vector equations can be solved for the phase, $2\pi\alpha_{hkl, P}$, of structure factor $\mathbf{F}_{hkl, P}$; in practice, as many as are available are used.

There is a **geometric solution** to this set of simultaneous vector equations. The amplitude of the vector $\mathbf{F}_{hkl, P}$ is known from the data set, but not its phase, $2\pi\alpha_{hkl, P}$. Therefore, what is known about $\mathbf{F}_{hkl, P}$ defines a circle of radius $F_{hkl, P}$ with its center at point P (Figure 4–13B). Both the amplitude and the phase of a given $\mathbf{F}_{hkl, H}$ are known, and this vector can be placed so that its head is at point P. Its tail defines the position, point D, of the tail of vector $\mathbf{F}_{hkl, H+P}$ from the isomorphous derivative in the vector sum (Figure 4–13A). The phase of vector $\mathbf{F}_{hkl, H+P}$ is unknown but its amplitude, which is known, defines a second circle with its center at point D. Because the vector sum must balance (Equation 4–8), the two points where the two circles intersect must represent two possibilities for the one actual vector sum. In theory, the correct one of the two possibilities can be determined by going through the same steps with the data from a second isomorphous replacement because the phase of $\mathbf{F}_{hkl, P}$ must be the same in both, and only one of the two possibilities for $\mathbf{F}_{hkl, P}$, namely, the one defined by the actual vector sum, should be the same in both.

A particularly gratifying example of this way of choosing the correct point defining the head of vector $\mathbf{F}_{hkl, P}$ was the definition of the phase of structure factor $\mathbf{F}_{9,1,-2}$ for a crystal of hemoglobin by use of six different isomorphous replacements (Figure 4–13C). All seven circles intersect at approximately the same point and define the phase $\alpha_{9,1,-2}$. This is, of course, the best example from the thousands of structure factors for hemoglobin; and, in practice, the circles almost never intersect in the same spot or even near the same spot. The phase of each $\mathbf{F}_{hkl, P}$ must be estimated by taking a statistical average of all of the points of intersection.⁷ The uncertainty in this average value for each phase is then used to weight the contribution of the respective structure factor to the summations of Equation 4–2 or 4–4.

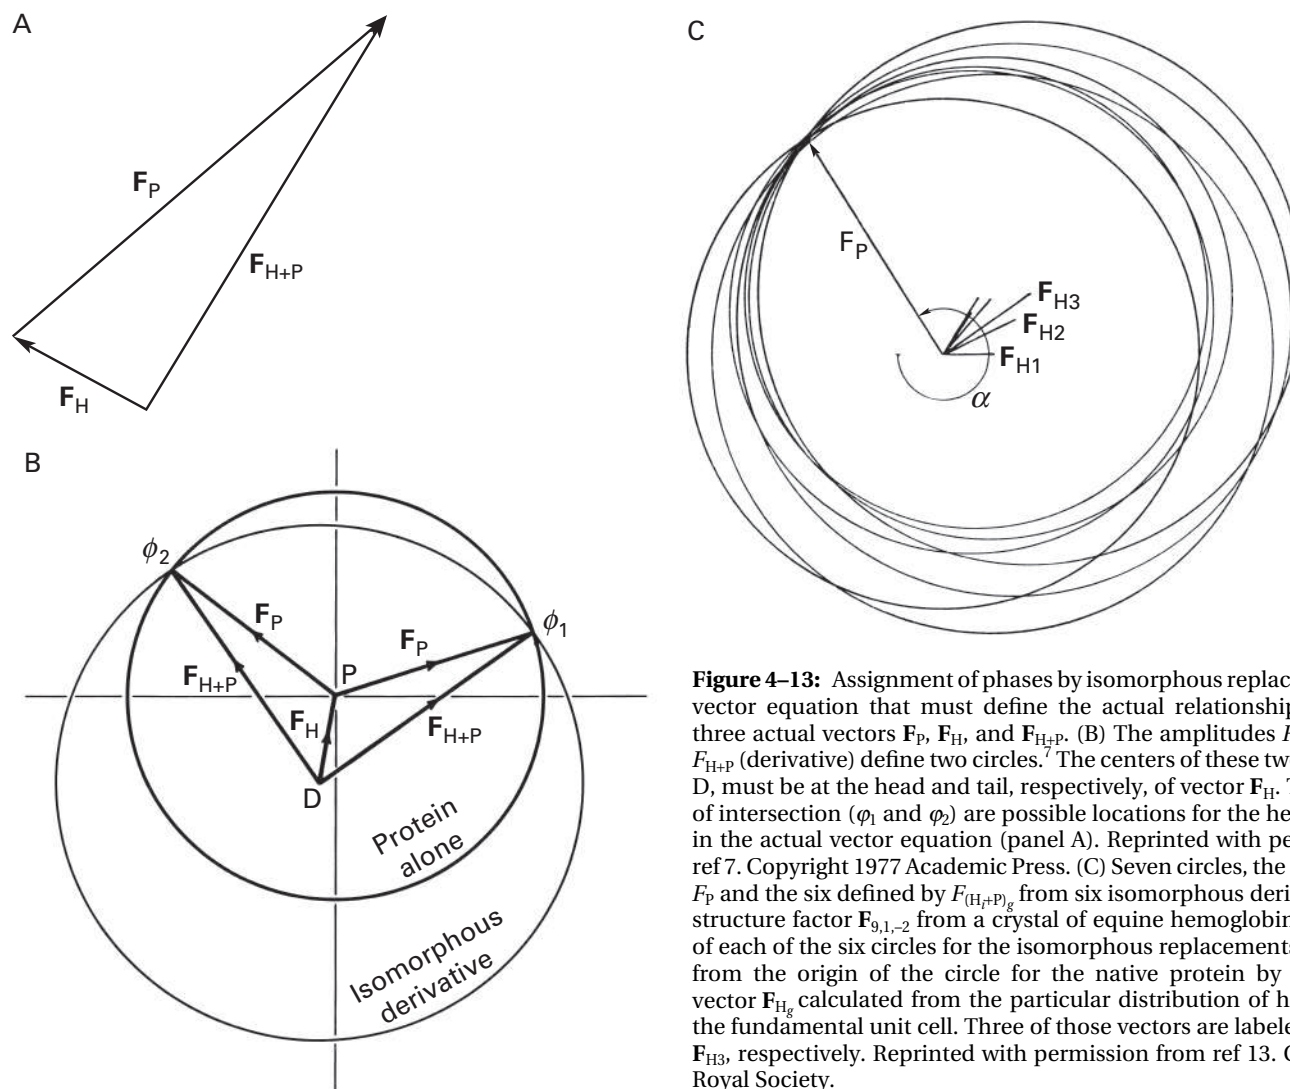

Figure 4-13: Assignment of phases by isomorphous replacement. (A) The vector equation that must define the actual relationship between the three actual vectors F_P , F_H , and F_{H+P} . (B) The amplitudes F_P (parent) and F_{H+P} (derivative) define two circles.⁷ The centers of these two circles, P and D, must be at the head and tail, respectively, of vector F_H . The two points of intersection (ϕ_1 and ϕ_2) are possible locations for the head of vector F_P in the actual vector equation (panel A). Reprinted with permission from ref 7. Copyright 1977 Academic Press. (C) Seven circles, the one defined by F_P and the six defined by $F_{(H+P)_g}$ from six isomorphous derivatives, for the structure factor $F_{9,1,-2}$ from a crystal of equine hemoglobin.¹³ The origins of each of the six circles for the isomorphous replacements are displaced from the origin of the circle for the native protein by the respective vector F_{H_g} calculated from the particular distribution of heavy metals in the fundamental unit cell. Three of those vectors are labeled F_{H1} , F_{H2} , and F_{H3} , respectively. Reprinted with permission from ref 13. Copyright 1961 Royal Society.

Some examples of isomorphous replacements that have been used in crystallographic investigations should make these considerations less abstract. Each isomorphous replacement is a different crystal, usually obtained by soaking a crystal of the unmodified protein in a solution of a compound containing the heavy atom. These compounds can be simple ions, such as Sm^{3+} , WO_4^{2-} , $\text{Pt}(\text{CN})_4^{2-}$, $\text{Au}(\text{CN})_2^-$, Hg^{2+} , or $\text{Pt}(\text{NH}_3)_2^{4+}$. Such ions are chelated at certain specific locations in the unit cells by functional groups on the surface of the protein in the crystal. Xenon gas at high pressure also produces isomorphous replacements¹⁴ by associating with hydrophobic pockets within the protein.¹⁵ Some organomercuric compounds, such as ethyl mercurithiosalicylate or diphenylmercury, are bound at specific locations on the protein while other organomercuric compounds, such as ethylmercury chloride, mersalyl, *o*-mercuriphenol, or *p*-mercuribenzoate, react covalently with the thiols of cysteines on the protein.¹⁶ As many as three mercuric ions, Hg^{2+} , can be noncovalently associated with the lone pairs of electrons of a cysteine.¹⁷ More complicated organomercury compounds such as 5-mercuride-oxyuridine

monophosphate,¹⁸ 3-acetoxymethyl-4-aminobenzene-sulfonamide,¹⁹ and ethylmercuriphosphate²⁰ have been designed as analogues of ligands specific to the protein. An oligonucleotide containing 5-iodouracil can be used to attach an iodine atom to a protein that normally binds the unsubstituted oligonucleotide.²¹

At least two and perhaps as many as six (Figure 4-13C) or seven isomorphous replacements are made. The isomorphous replacements used to obtain the phases for maltose binding protein were made by soaking crystals in K_2PtCl_4 , $\text{Pb}(\text{NO}_3)_2$, sodium mersalyl, dysprosium iodide, and glucosyl(α 1,4)-6-iodo-6-deoxyglucose.²² The last compound is a specific ligand for the binding protein. In the case of trimethylamine-*N*-oxide reductase (cytochrome *c*), six separate isomorphous replacements were prepared with $\text{Ta}_6\text{Br}_{14}$, $(\text{NH}_4)_2\text{OsCl}_6$, $(\text{NH}_4)\text{IrCl}_6$, K_2PtCl_6 , sodium ethylmercurithiosalicylate, and sodium bis(*N*-methylhydantoinato)gold, respectively.²³ In the case of chloramphenicol *O*-acetyltransferase, $\text{Sm}(\text{NO}_3)_3$, $\text{KAu}(\text{CN})_2$, K_2PtCl_4 , *p*-mercuribenzoate, and *p*-iodochloramphenicol, the last of which is a good substrate for the

enzyme, provided useful isomorphous replacements.²⁴ In the case of apoferritin, however, only two isomorphous replacements, made with *p*-mercuribenzoate and $K_2UO_2F_5$, were used to determine the phases to Bragg spacings of 0.28 nm.²⁵

Once the positions of two or more separate sets of heavy metal atoms are known within the fundamental unit cell, the reagents can be used in pairs to generate additional unique isomorphous replacements. The advantage is that because the positions in each of the original isomorphous replacements are already available, the positions in the combined isomorphous replacement can be readily established. Isomorphous replacements were made from crystals of alcohol dehydrogenase with $K_2Pt(CN)_4$ and $KAu(CN)_2$, and the positions of the platinum and gold, respectively, in the resulting fundamental unit cells were determined. In combination, these two anions produced a third isomorphous replacement.²⁶ From crystals of deoxyribonuclease I, it was possible to make three isomorphous replacements, one each with $TbCl_3$, K_2PtCl_4 , and $Pb(NO_3)_2$, which could then be used in the three possible combinations to generate three additional, unique isomorphous replacements.⁸

Today, however, phases are usually estimated by taking advantage of the **anomalous dispersion** of the heavy atoms in only one isomorphous derivative.^{27–29} The real and imaginary components of the scattering factors f_j (Equation 4–7) for atoms such as copper,²⁹ selenium,³⁰ holmium,³¹ terbium,³² tantalum,³³ uranium,³⁴ platinum,³⁵ and bromine³⁶ change with the wavelength of the X-radiation in the vicinity of their respective absorption edges. The changes are dramatic enough that if data sets are gathered at three or four different wavelengths properly chosen with respect to the absorption edge of the heavy atom, those data sets can be equivalent, in terms of the differences produced in the intensities of the reflections, to sets of reflections measured from three or four isomorphous replacements. The advantage of this procedure is that the same crystal containing the heavy atoms is used for all of the measurements, so that the errors associated with combining data from different crystals are avoided.

The appropriate heavy atoms are usually incorporated into the crystal by soaking. In the case of basic blue copper protein, however, only the copper ion already within the native protein was used as the heavy atom, and data sets gathered at four different wavelengths were sufficient to establish experimental phases to Bragg spacings of 0.25 nm with no isomorphous replacement at all.²⁹ It is also possible to take advantage of the anomalous dispersion of one isomorphous derivative in combination with the normal diffraction from several others to establish experimental phases.³⁷ A common way of introducing a heavy atom susceptible to anomalous dispersion³⁰ is to express the protein to be crystallized in a bacterium auxotrophic for methionine growing on a

medium containing selenomethionine rather than methionine. The selenium atoms end up at each position in the sequence of the protein normally occupied by methionine and are positioned at precise locations in the unit cell by the tertiary structure of the protein.

There is an additional component of a crystal of protein that is formally equivalent to a set of heavy atoms in an isomorphous derivative. This component is the featureless aqueous solvent that surrounds the protein. The fact that it should be featureless allows it to be used, much as an electron-rich atom is used, to improve the phases by **solvent flattening**.³⁸ A map of electron density is prepared with the available estimates of the phase for each structure factor gathered from isomorphous replacement and anomalous dispersion. If the map is clear enough that the boundary between protein and solvent can be defined (Figure 4–12), all of the region of the fundamental unit cell occupied by solvent is forced to have the same uniform electron density even though in this original map it was not uniform in density (notice the noise in the regions of the map occupied by solvent in Figure 4–12). From this geometric solid of uniform electron density, a set of structure factors equivalent to an additional $F_{hkl,H}$ for Equation 4–8 could be calculated with Equation 4–7 and used as an additional constraint on the phases (Figure 4–13), but solvent flattening is more successful if used iteratively.

The updated map of electron density with the vaguely defined features of the protein and the solvent that has been purposely flattened is used in its entirety to calculate a set of phases. These calculated phases are used in combination with the available estimates of the phase from isomorphous replacement to arrive at a set of improved phases. These improved phases and the observed amplitudes are used to calculate a new map of electron density. The regions of solvent in the new map are defined, the electron density in these regions is again forced to be uniform, and the process is repeated. As the iterations progress, the solvent in each new map becomes flatter and the protein more detailed. In theory³⁸ and in practice,³⁹ the method can provide adequate phases in the absence of measurements of anomalous dispersion when only one isomorphous heavy atom derivative is available. Usually, however, solvent flattening is used to improve the phases that have been gathered with multiple isomorphous replacements or by anomalous dispersion.

Because the quality of the final map of electron density (Figure 4–12) depends so heavily on the quality of the phases, the uninvolved observer can evaluate the results only if she is informed. It is important to learn how many isomorphous replacements were made, how many wavelengths were used for anomalous dispersion, and which data sets were used to calculate the phases. It is also essential to see at least a portion of the calculated, **unrefined map of electron density** (Figure 4–12) to get a feeling for its quality.⁴⁰ It must be emphasized that,

unless a map of electron density is already available for a closely related protein, the calculation of the initial map of electron density from the phases derived from isomorphous replacement is an unavoidable step in crystallography, and the quality of this map can affect significantly the remainder of the process. The work involved in obtaining this initial map is extensive, and many crystallographic experiments are designed specifically to avoid this work.

When the map of electron density within the fundamental unit cell or from several neighboring fundamental unit cells is examined, the electron density that corresponds to the intact molecule of protein can be discerned. Since a large fraction of the crystal is liquid water, which is featureless, the protein, which is fixed and highly featured, stands out (Figure 4-12). The compact globule of electron density eventually assigned to an individual molecule of protein usually has an overall size and shape consistent with its amino acid sequence, its frictional coefficient, and other molecular parameters. Within this globular solid, features can be seen in relatively sharp detail, but only seldom at atomic resolution.

Problem 4-1: Below there is a generic unit cell. Make several xerographic copies of it. Draw a right-handed set of axes labeled **a**, **b**, and **c** next to each of your copies of the unit cell. Draw a diagram of the (4,2,3) set of reflecting planes passing through the first unit cell as in Figure 4-6. Draw a diagram of the (4,-2,3) set of reflecting planes passing through the second unit cell. Draw a diagram of the (4,2,-3) set of reflecting planes passing through the third unit cell. Label each of your diagrams with the index number.

Problem 4-2: The amplitude of a particular structure factor from a crystal of protein, F_p , is 22.2. The amplitude of the structure factor with the same index from a crystal of the first isomorphous replacement, F_1 , is 24.2. The structure factor with the same index calculated from the established positions of the heavy metal ions in the unit cell of the first isomorphous replacement has an amplitude F_{H1} of 5.4 and a phase of 110° . The amplitude of the structure factor with the same index from a crystal of the second isomorphous replacement F_2 is 21.0. The structure factor with the same index calculated from the established positions of the heavy metal ions in the unit cell of the second isomorphous replacement has an amplitude F_{H2} of 8.9 and a phase of 65° . Estimate graphically the phase for the structure factor of this index from the crystal of protein alone.

Problem 4-3: Pig heart citrate (*si*) synthase crystallizes from solution at pH 7.4. The crystals are tetragonal. The dimensions of the fundamental unit cell are $a = b = 7.74$ nm and $c = 19.64$ nm.⁴¹ A crystal was submitted to diffraction with X-radiation generated from a rotating anode of copper. The $K\alpha$ emission of the copper ($\lambda = 0.154$ nm) was selected for the source of the X-radiation. On graph paper draw a view of the fundamental unit cell looking down the c axis with the set of (2,-4,0) faces intersecting it. At what angle θ to the incident beam of X-radiation will the reflection from the (2,-4,0) set of faces emerge from the crystal?

The Molecular Model

An **irregular tube of electron density** can be observed to meander through and account for the globule of featured electron density assigned to the intact molecule of protein in the map of electron density. Sections of one such continuous tube can be seen embedded in the flat slice

of electron density presented in Figure 4-12. This tube is the polypeptide of the protein (2-8) that has folded to assume the native structure of the molecule. It is into this tube that a molecular model of the known covalent structure of the polypeptide must be fit.

Once the covalent sequences of the polypeptides, the covalent sequences and points of attachment of any covalently bound oligosaccharides, and the identity and points of attachment of any other posttranslational modifications have been established and even before a map of electron density is available, it is possible to construct a **molecular model** of the fully modified and glycosylated polypeptide known to constitute a molecule of protein. Such a model would incorporate bond lengths and bond angles that have been measured with high precision during crystallographic studies of small molecules. These small molecules used as standards are molecules the covalent structures of which are identical to segments of polypeptide, the side chains of the amino acids, segments of oligosaccharide, or the monosaccharides in the oligosaccharide. As with any molecular model of such a size and complexity, the one of a polypeptide would be a flexible, protean object that assumes a new shape each time rotation around one of its acyclic single bonds occurs.

It is this long, flexible model that must be fit, amino acid by amino acid, into the map of electron density. Until recently, the process of fitting the model into the map was always performed visually by the crystallographer.^{40,42} It is now possible,⁴³ however, for a computer to fit the model into the map automatically. Nevertheless, the success of this automated process for a particular map of electron density still must be carefully evaluated by the crystallographer,⁴⁴ and the fit must be altered accordingly by manual adjustments. To determine whether or not the molecular model has been correctly fit into the map of electron density, there are no automated rules that are as reliable as the judgment and accumulated knowledge of the crystallographer. If careful human evaluation of each fit is not performed routinely, there is a risk that the frequency at which incorrect crystallographic molecular models are published will increase as more and more crystallographic molecular models are produced in an automated fashion.

One criterion that the molecular model of the polypeptide has been successfully fit into the map of electron density is the correspondence between the sequence in which amino acids of different sizes (Figure 4-14) are known to occur along the amino acid sequence of the polypeptide and the sequence in which protrusions of different size occur at regular intervals along the tube of electron density (Figure 4-15). The 20 different **amino acids** are, in order of increasing electron density (Figure 4-14), glycine, alanine, serine, proline, cysteine, valine, threonine, aspartate, asparagine, leucine, isoleucine, glutamate, glutamine, methionine, lysine, histidine, phenylalanine, arginine, tyrosine, and trypto-

phan. In terms of electron density, many of them are indistinguishable, for example, valine and threonine or aspartate, asparagine, leucine, and isoleucine, and only a few of them, for example, tryptophan, tyrosine, and phenylalanine, are of sufficient size and peculiar enough shape to be identified unambiguously with the protrusions jutting out from the continuous tube in the map of electron density (Figure 4-15).^{*} Together, however, the sequence in which the amino acids are arranged in a given protein and their relative sizes usually provide sufficient reassurance that the molecular model of the polypeptide has been fit into the map correctly.

An additional reassurance that the polypeptide has been properly fit into the map can be obtained from anomalous dispersion. If the protein has been expressed so that it contains selenomethionine instead of methionine, the electron density at the locations in the map that are occupied by the selenium atoms will vary in intensity when the wavelength of X-radiation used to produce the reflections is varied near the absorption edge of the selenium. These variations in intensity can be used to locate the positions at which the methionines must end up after the molecular model has been fit properly into the tube of electron density.⁴⁵ Although the anomalous dispersion from sulfur itself is weak, under appropriate circumstances the positions of both the cysteines and the methionines in the map of electron density of a molecule of protein expressed normally can be located by the anomalous dispersion of their sulfurs.⁴⁶

The reassurance provided by the agreement between the known amino acid sequence of the polypeptide and the sequence of the sizes of the protrusions along the continuous tube of electron density or the positions of atoms capable of anomalous dispersion is not inconsequential. It is rarely the case that the tube of electron density representing the polypeptide in the map of electron density is continuous over its entire length. Portions of the polypeptide that are so flexible that they vibrate too widely will not contribute to the diffraction and will produce no structured electron density. Often segments of the polypeptide can assume several different conformations while in the crystal. The movement among these conformations within a particular molecule of the protein can be rapid or a particular conformation can be statically occupied. Regardless of the rate at which the conformations interconvert, if at any given instant these segments from different molecules of the protein in the crystal assume different conformations, this disorder will prevent them from contributing to the diffraction and hence to the structured electron density. Occasionally

^{*} Although the side chain of cysteine has the same number of electrons as those of threonine and valine and the side chain of methionine the same number as those of glutamate, glutamine, and lysine (Figure 4-14), the sulfurs in cysteine and methionine, because they have 10 core electrons, produce strong localized features of electron density (Figure 4-15) that permit them to be distinguished from the others.

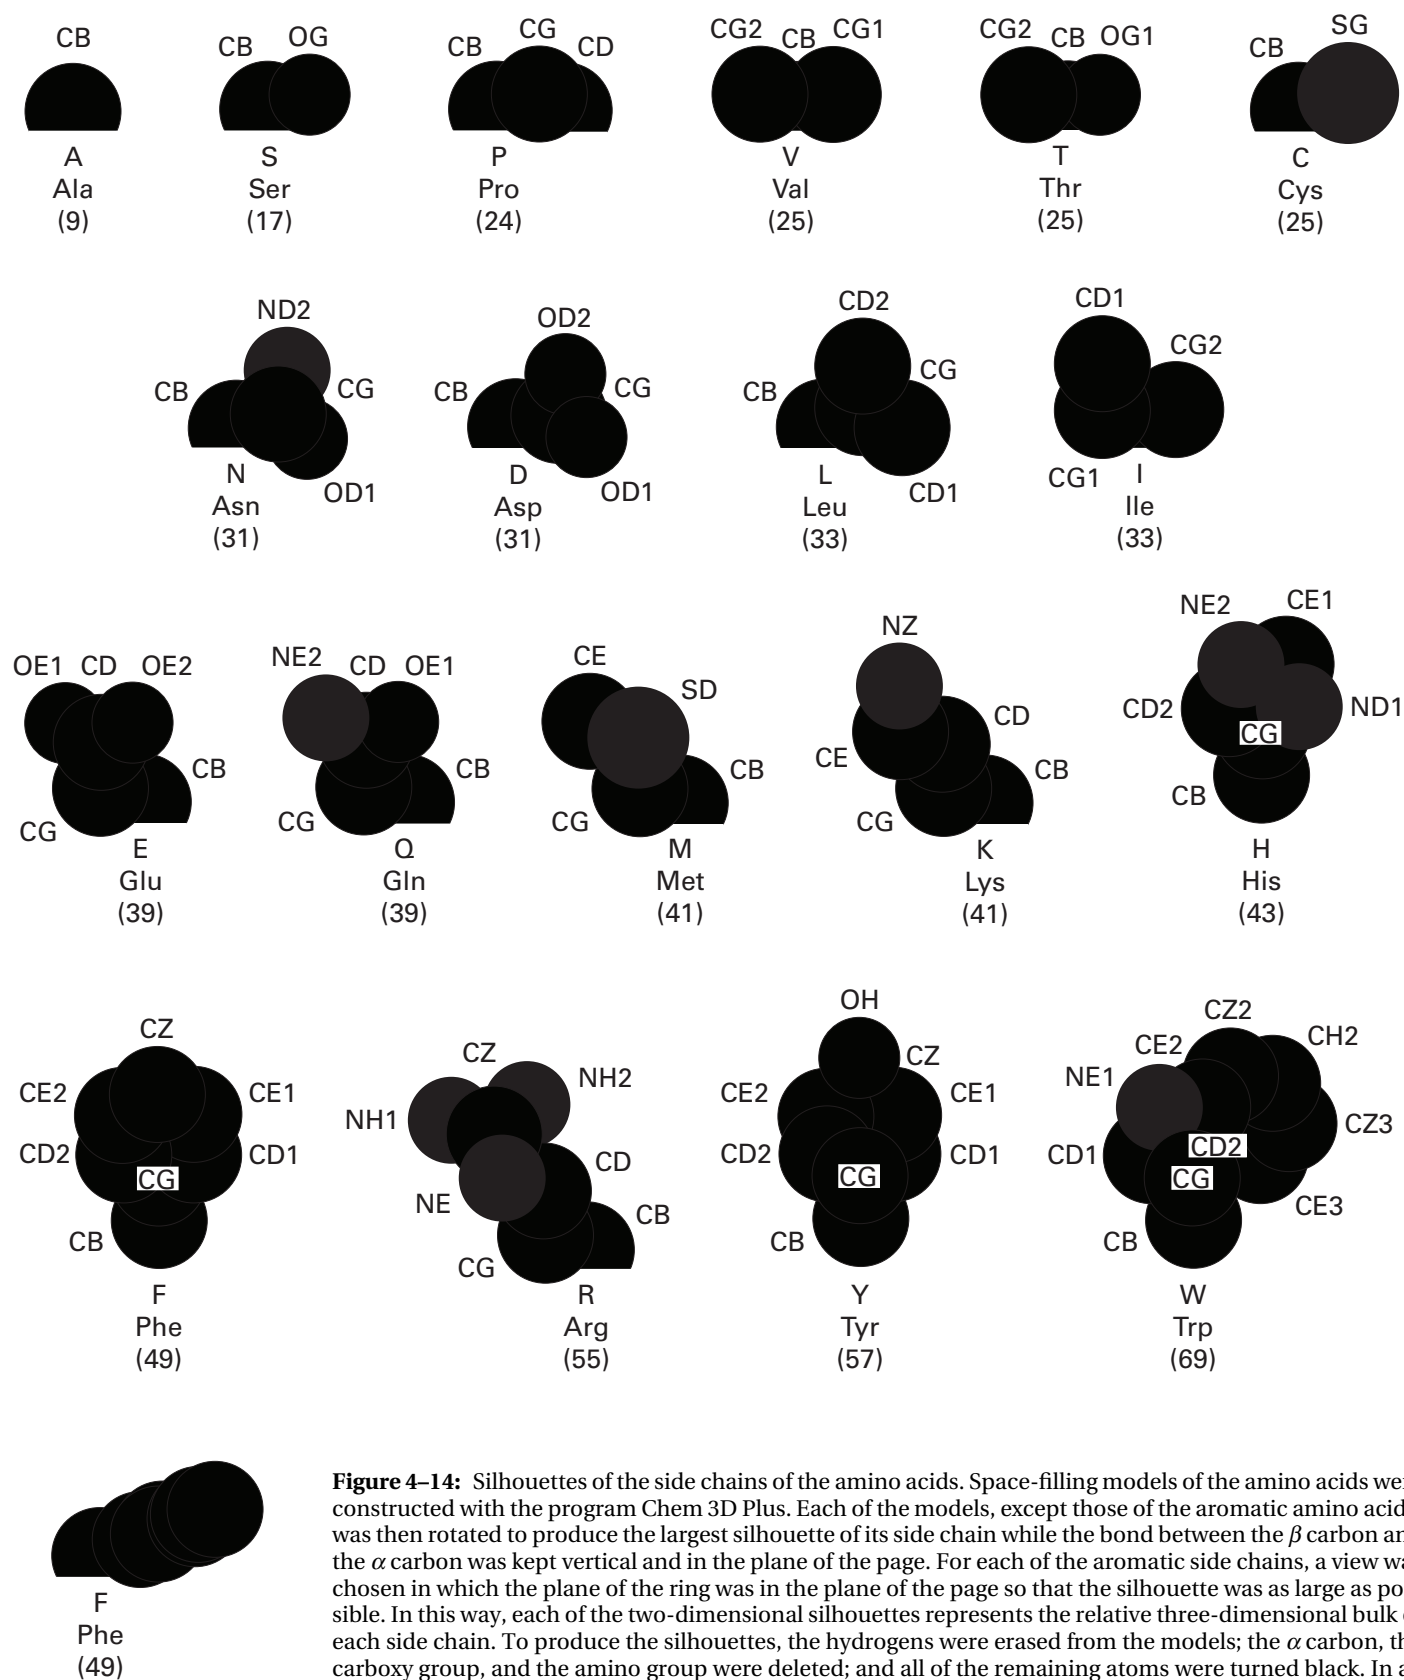

Figure 4-14: Silhouettes of the side chains of the amino acids. Space-filling models of the amino acids were constructed with the program Chem 3D Plus. Each of the models, except those of the aromatic amino acids, was then rotated to produce the largest silhouette of its side chain while the bond between the β carbon and the α carbon was kept vertical and in the plane of the page. For each of the aromatic side chains, a view was chosen in which the plane of the ring was in the plane of the page so that the silhouette was as large as possible. In this way, each of the two-dimensional silhouettes represents the relative three-dimensional bulk of each side chain. To produce the silhouettes, the hydrogens were erased from the models; the α carbon, the carboxy group, and the amino group were deleted; and all of the remaining atoms were turned black. In all of the silhouettes, except those of the aromatic side chains, the α carbon would occupy the position of the label. In each of the silhouettes of the side chains of the aromatic amino acids, the β carbon is directly above the label. The number of electrons in each side chain is indicated in parentheses. The standard crystallographic code for each atom in each side chain is indicated. A silhouette of phenylalanine viewed edge on is also included.

such unstructured electron density fills a large void in the map representing a significant portion (100–200 aa) of the molecule of protein.⁴⁷ Usually, however, it is short segments of the tube that are blurred or missing, breaking its continuity. Another source of ambiguity is when one segment of the polypeptide crosses another segment too closely to follow each tube confidently through the intersection. Missing segments of electron density and ambiguous crossings have led to serious errors in the fitting of polypeptides into maps of electron density,^{26,40,48,49} and these errors are often corrected by paying close attention to the patterns of the protrusions along the tube and correlating them with the sequence.⁵⁰

Such **errors** in tracing the polypeptide occur frequently enough that any crystallographic molecular model should be considered provisional until it has been shown to agree with other independent observations. This is an important point because crystallography has often assumed the mantle of infallibility. Even incorrect crystallographic molecular models look completely convincing. It should be pointed out, however, that they are convincing not because of the way the polypeptide is folded but because they are constructed with covalent bonds of the correct lengths and angles. These latter features are not indicative of the reliability of the crystallographic molecular model because they were incorporated into it automatically.

After the polypeptide has been fit into the map of electron density, certain regular patterns, collectively referred to as **secondary structure**, can be seen in the arrangement of the polyamide backbone. The regular patterns that are seen in the crystallographic molecular models of proteins are **α helices**, **β structures**, and **β turns**. α Helices and β structures were first observed in hypothetical models built by Pauling and his collaborators (Figure 4–16).^{51–53} After the models had been built, it was found that certain of their dimensions were consistent with molecular dimensions that had been observed in patterns of X-ray diffraction from oriented fibers of protein such as hair and silk,^{52,54} but it was not until much later that these structures were actually observed in maps of electron density of proteins. Several strands of β structure (Figure 4–15) are often joined together to form pleated sheets (Figure 4–16). Such sheets can be formed from strands all running parallel to each other or alternating in their orientation and thus each antiparallel to its neighbors or from a mixture of these two arrangements. β Turns (Figure 4–16D) were first noticed by Venkatachalam in the crystallographic molecular models of a cyclic hexapeptide, a short tetrapeptide, and the protein lysozyme.⁵⁵

Aside from the lengths of the covalent bonds of the polyamide backbone, the main structural element responsible for these secondary structures is the **hydrogen bond**, which is a noncovalent interaction that forms between the dipole of the nitrogen–hydrogen bond of one amide and one or two of the lone pairs of electrons

Figure 4–15: Fitting the molecular model of the polypeptide into the map of electron density (Bragg spacing ≥ 0.21 nm) for galactose oxidase.¹³⁷ The unrefined map of electron density shown was calculated with phases that were estimated by use of isomorphous derivatives obtained with K_2PtCl_4 , H_2IrCl_6 , and $Pb(NO_3)_2$ and then improved by iterative solvent flattening. The figure shows skeletal models of the segments –VLMW– and –TSSWDPSTGIVSDR– from the sequence of the protein fit into the three vertical tubes of electron density. These are three strands of an antiparallel β sheet. The large protrusions for the two tryptophans, the methionine, and the phenylalanine, which intrudes into the image from the left, are significant features along the course of the tube representing the polypeptide that confirm the fit. The isoleucine, valines, aspartate, and leucine are less dramatic protrusions. The contortion of the polypeptide at the proline is yet another indication that the sequence has been matched properly with the map of electron density.

Figure 4-16: Four types of secondary structure found in molecules of protein: (A) α helix,⁵¹ (B) parallel β sheet,⁵² (C) antiparallel β sheet,⁵² and (D) two types of β turn (type I and type II).⁵³ The polyamide backbone can be traced by the pattern $\dots N, C\alpha, CO, N, C\alpha, CO, N, C\alpha, CO \dots$ and the side chains are the groups protruding (marked R, O , or H , respectively). Side views of the β sheets are shown to the right of each overhead view to demonstrate the pleats. Reprinted with permission from refs 51–53. on the acyl oxygen of another amide of the backbone of the polypeptide. These hydrogen bonds are indicated in Figure 4-16 by dashed lines. A hydrogen bond connects the acyl oxygen contributed to the polyamide backbone by each amino acid in a sequence coiled into an α helix with the amido nitrogen-hydrogen contributed to the backbone by the amino acid four positions farther along (Figure 4-16A). In pleated sheets of parallel β structure (Figure 4-16B), the amido nitrogen-hydrogen and the acyl oxygen contributed by an amino acid in one of the polypeptides are connected by hydrogen bonds to the acyl oxygen and amido nitrogen-hydrogen, respectively, of amino acids two positions apart from each other in the sequence of a neighboring polypeptide to form a ring containing 12 atoms. In pleated sheets of antiparallel β structure (Figure 4-16C), hydrogen-bonded rings of 14 atoms and 10 atoms alternate along a ladderlike structure. The only structural element that defines the conformation of a β turn (Figure 4-16D) is a hydrogen bond between the acyl oxygen of the first amino acid in the turn and the amido nitrogen-hydrogen of the fourth and last amino acid in the turn.

Secondary structures enforce particular geometries on the conformation of the polypeptide. The β turn causes the polypeptide to double back on itself, often to form a hairpin the two tines of which are cross-connected in antiparallel β structure. An α helix has a right-handed pitch,* and the absolute stereochemistry of the L-amino acids causes each side chain, the R groups in Figure 4-16A, to cant toward its amino terminus. The side chains protrude from the helical core at intervals of about 100° . β Structure is pleated when viewed from the side (Figure 4-16B,C) owing to unavoidable steric requirements resulting from the angles of the covalent bonds along the polypeptide. In pleated sheets of β structure, the side chains of the amino acids in the sequence of each strand alternately protrude to one side and then the other of the surface in which the strands of polypeptide lie.

When the molecular model of the polypeptide has been fit into the tube of electron density, the final structure of its conformation represents, within the accuracy of the map of electron density, a skeleton of the actual molecule of protein. This **crystallographic molecular model** is the product of fitting atomically accurate molecular models of known covalent structures into a map of electron density.† The resulting arrangement of

the segments of secondary structure in three dimensions produces a representation of the tertiary structure of the folded polypeptide. The **tertiary structure** of a protein is the complete conformation into which its polypeptide is folded in its native form.

An example of a crystallographic molecular model is the one constructed for the protein penicillopepsin (Figure 4-17).⁵⁶ To obtain a full understanding of this molecular model, it must be viewed stereoscopically. The five panels of Figure 4-17 show drawings of the same view of the model. In Figure 4-17A, all of the atoms in the crystallographic molecular model are displayed in **skeletal representation**; in Figure 4-17B, the side chains of the amino acids have been removed to focus attention on only the polyamide **backbone** of the polypeptide and its hydrogen bonds, which are indicated by dashed lines; and in Figure 4-17C, only the α carbons of each amino acid are displayed, each connected to its two immediate neighbors in the amino acid sequence by line segments to create an **α -carbon diagram**. In all of the panels, the amino terminus is on the upper right at about 10 o'clock and the carboxy terminus is to the back at about 8 o'clock. You should follow the polypeptide [... N, C α , CO, N, C α , CO, N, C α , CO ...] through the whole drawing in Figure 4-17B. Note the α helices, β structures, and β turns. Compare what you see to the drawings presented by Pauling (Figure 4-16A-C). Note that α helices are rigid tubes while β structures are sinuous and flexible. Note the pleats in the β sheets. Distinguish between sheets of β structure formed from three or more strands and ribbons of β structure formed from only two strands. Now follow the polypeptide through the crystallographic molecular model in Figure 4-17A. Note the disposition of the side chains along secondary structures, and try to identify some of the amino acids.

The tertiary structure observed in a crystallographic molecular model is often presented diagrammatically (Figure 4-17D) in a **cartoon** where flat arrows are used to represent strands of polypeptide in β structure, with the head of the arrow at the carboxy terminus of the strand to provide the direction in which the chain is oriented, and cylinders are used to represent α helices. The tertiary structure of penicillopepsin, which you have explored in detail in Figure 4-17A, is represented, in the same orientation, by the diagram in Figure 4-17D. Follow the polypeptide through Figure 4-17, panels B and D, simultaneously.

The first three of the representations of the structure of a protein molecule that have been presented so far are skeletons of the crystallographic molecular model. The advantage of the skeletons is that the whole molecule can be examined simultaneously even in its interior. As with all molecules, flesh resides upon the bones in the form of the electron clouds that produced the map of electron density in the first place. It is possible to construct a model of a molecule of protein from space-filling units of the kind developed by Pauling and

* Put the four fingers of your right hand together, bent inward and horizontal, and put your thumb up. As you slide your fingers around a right-handed helix in the direction in which they are pointed, the helix rises in the direction in which your thumb is pointed. As you slide the fingers of your left hand around a left-handed helix, the helix rises in the direction of the thumb.

† To view a crystallographic molecular model on your own computer, find the file of the coordinates for the model in which you are interested at <http://betastaging.rcsb.org/pdb/Welcome.do> and download the file as text. Open the file with the program SwissPdbViewer, which can be obtained free of charge from us.expasy.org/spdbv/.

Figure 4-17: Crystallographic molecular model of penicillopepsin, from the mold *Penicillium anthinellum*.⁵⁶ In the first skeletal drawing (A), both the peptide backbone (heavy line segments) and the side chains (light line segments) of the amino acids are displayed, and no potential hydrogen bonds are indicated. This drawing was produced with MolScript.¹³⁹ In the second skeletal drawing (B), the side chains are left out and the crystallographer has assigned subjectively the locations of hydrogen bonds (dashed lines). Every tenth amino acid is identified and numbered to assist you in tracing the chain. Reprinted with permission from ref 56. Copyright 1983 Academic Press. In the α -carbon diagram (C), the positions of the α carbons of the amino acids in the crystallographic molecular model are designated by points and the points are joined by line segments. This α -carbon diagram often gives a clearer picture of the patterns of secondary and tertiary structure. This drawing was produced with MolScript.¹³⁹ In the cartoon (D), the skeletal drawing of panel B is represented diagrammatically. In a space-filling representation (E), each atom in the crystallographic molecular model is represented by a sphere with its van der Waals radius. This drawing was produced with MolScript.¹³⁹ As in the stereo image of Figure 3-9, black spheres are carbon atoms; gray, nitrogen; and white, oxygen.

Figure 4-18: Ball and stick drawing of the polyanide backbone of myoglobin. The positions of the atoms in the backbone are those of the atoms in the crystallographic molecular model (Bragg spacing ≥ 0.17 nm) of myoglobin from *Physiter catodon* built from a data set collected from a crystal at 40 K.⁵⁹ The color code of the atoms in this figure, as in Figures 3-9 and 4-17, and for most of the ball and stick drawings in the book is black for carbon, gray for nitrogen, and white for oxygen. The radii of the balls for the atoms are equal to the van der Waals radii of the respective atoms divided by 6.4, so the sizes of the balls differ with the type of atom. Consequently, had there been a sulfur in the model, it would have been indicated by a gray ball larger than the gray balls of the nitrogens. Hydrogen bonds are indicated by dashed lines. Only the hydrogen bonds within the eight α helices designated by the crystallographers are drawn. The heme within the protein is drawn in its entirety; the iron at its center is drawn as a gray sphere. The polyanide backbone begins with a nitrogen and ends with a carboxylate. This drawing was produced with MolScript.¹³⁹

Corey (CPK models) after the coordinates of the individual atoms in three dimensions have been gathered from the skeletal model. A three-dimensional photograph of such a model of the protein lysozyme can be seen in Volume 243 of the *Journal of Biological Chemistry*.⁵⁷ This photograph and a similar drawing found in Volume 32 of *Biochemistry*⁵⁸ produce a reliable mental image of the molecular structure of a properly folded polypeptide. A

stereoisomer of a **space-filling representation** of penicillopepsin is presented in Figure 4-17E in the same orientation as the other drawings of the crystallographic molecular model of the protein.

The space-filling representation in Figure 4-17E emphasizes the tight packing of the atoms of the protein in its tertiary structure. Penicillopepsin is an example of a **globular protein** is a protein in which the entire polypeptide is folded into a compact structure the three dimensions of which are of the same order of magnitude. There are also many proteins in which **globular units** are held together by flexible segments of polypeptide as well as **fibrous proteins** in which the folded polypeptide forms a structure severely elongated in one of its dimensions.

Penicillopepsin (Figure 4-17) contains mostly antiparallel β structure where adjoining strands are often connected at one end by β turns. Myoglobin (Figure 4-18)⁵⁹ is an example of a protein that is almost entirely α helical. Most proteins are mixtures of these two major types of secondary structure, β turns, and a certain amount of **random meander**.

If one assumes for the moment that a particular crystallographic molecular model has been constructed correctly and represents, to the level of precision of the initial map of electron density, the molecules of protein as they are packed in the crystal, what relationship does this structure have to the molecules of protein when they are in solution in the cytoplasm?

The existence of the diffracted reflections requires that every fundamental unit cell in the crystal contain the same distribution of structured matter. If the fundamental unit cell contains only one molecule of protein, then every molecule of protein in the crystal must have exactly the same structure. It has always been observed, however, that in fundamental unit cells containing several molecules of the same protein, the several maps of electron density for the several molecules are quite similar and differ from each other only at the surfaces of the molecules where **differences in crystal packing** have caused flexible side chains or short, flexible loops of backbone to assume somewhat different orientations. For example, most of the polypeptide in the four asymmetrically arrayed molecules of adenylosuccinate synthase in the fundamental unit cell coincides to within 0.03 nm when the four separate crystallographic molecular models are superposed. This coincidence is well within the limits of the accuracy of the model, but four **loops** of 5-9 amino acids on the surface of the protein deviate in their positions among the four different crystallographic molecular models by 0.15-0.5 nm because of differences in crystal packing.⁶⁰ From the fact that only differences such as these are usually observed, it follows that all of the structured regions of the molecules of protein within a given crystal usually have essentially the same conformation.

Over the inflexible portion of a globular protein or within each of the globular regions of a protein in which

globular structures are held together by flexible unstructured segments of polypeptide, there is little doubt that the one structure present in the crystal is the same as the unique structure, or is the same as one of a limited number of unique structures, assumed by the protein in free solution and therefore its **native structure**. First, unlike the usual anhydrous crystals of small molecules, a crystal of protein is 40–70% water.⁷ This water usually surrounds each molecule of protein almost entirely, and the contacts between molecules of protein in the crystal are adventitious and not extensive.⁶¹ Consequently, the molecule of protein is still dissolved in the same **aqueous solution** from which it crystallized. Second, there are many instances in which the same protein has been crystallized under two or more different conditions and was found to be incorporated into the two or more **different fundamental unit cells** with completely different orientations, yet the respective maps of electron density were almost indistinguishable from each other and could be superposed.⁷ For example, the polypeptides in the two crystallographic molecular models of subtilisin from *Bacillus alcalophilus* produced from the two nonisomorphous crystal types coincided to within less than 0.1 nm except at two short surface loops.⁶² T4 Lysozyme has been crystallized in 25 different nonisomorphous forms and crystallographic molecular models have been prepared from all of them. This molecule contains two independently folded globular portions connected by a flexible segment of polypeptide, and the angle between these two portions can vary by up to 45° over the different crystals, but within each of the two portions the conformation into which the polypeptide is folded is always the same.⁶³ Third, crystals of a protein usually retain its **enzymatic activity**,⁷ albeit sometimes at a lower rate, and this also indicates that the structure of the protein has not changed during its crystallization. In fact, when crystals of protein are suspended in an organic solvent that is sufficiently immiscible with water that the crystals retain all their water of crystallization and their interior remains a separate aqueous phase, the protein is unaffected and the crystals retain their enzymatic activity.⁶⁴ Fourth, Raman spectroscopy can be performed on solids as well as liquids, and when the **Raman spectrum** of ribonuclease in solution was compared to its Raman spectrum in the crystal, the two were virtually identical in the region of the amide III vibrations, a region that would be sensitive to any changes in the structure of the polypeptide chain that might have occurred during crystallization.⁶⁵ Finally, molecular models from a number of proteins in solution have been obtained by **nuclear magnetic resonance spectroscopy**, and at their level of accuracy, they are indistinguishable from the crystallographic molecular models of the same proteins.^{66,67}

There are proteins that have been shown to be able to assume two stable structures in rapid equilibrium with each other in solution, and in some cases, two different crystals can be made, each exclusively

incorporating one of these respective structures. The crystallization and elucidation of the structures of deoxyhemoglobin and oxyhemoglobin provide an example.⁶⁸ When such crystals are exposed to a ligand that binds to the protein they contain and coincidentally elicits the change in the structure of the protein, the crystals will often shatter⁶⁹ as the protein assumes the new structure, which is incompatible with the former crystal lattice. In addition to presenting another observation consistent with the conclusions that the molecules of protein in the crystal retain the potentialities that they assume in solution, this observation suggests why some crystals are not enzymatically active. If expression of enzymatic activity requires that the protein change its shape slightly and reversibly each time it catalyzes the reaction and that change in shape is sterically hindered by the lattice of the crystal, the protein would not be able to display activity.

Crystals of citrate (*si*) synthase provide an example of such a situation.⁴¹ This protein can be crystallized under different sets of conditions that yield two different types of crystals containing **two different conformations** of the protein. From a careful examination of the maps of electron density for these two conformations, it became clear that each time the enzyme in free solution converts acetyl-S-CoA and oxaloacetate into citrate and coenzyme A, it passes back and forth between these two conformations. Neither crystal is enzymatically active, but upon dissolving either, full activity is restored. The conclusion drawn was that the packing of the molecules of protein in the crystal sterically prevented the movement between the two conformations necessary for enzymatic activity, not that either crystallographic molecular model was unrepresentative of the enzyme.

The most compelling argument for the identity of the structure seen in the crystal and the structure assumed by the protein in solution is that the structure seen in the crystal makes sense. Over the more than three decades that crystallographic molecular models of high accuracy have been available for examination, what has been seen has consistently provided reasonable explanations for the behavior of the respective proteins in solution. These explanations have stimulated experiments to test those explanations that have usually yielded informative results. Often an experiment will rule out a hypothesis based on an examination of the structure, but the more informed reexamination of the structure that then occurs usually turns up the original error of judgment. The fact that a crystallographic molecular model makes sense is an unambiguous verification that it represents the actual structure of the molecule of protein even when it is in the crystal, let alone in solution.

Problem 4–4: The structure below was drawn from a crystallographic molecular model of a particular protein.⁷⁰ It depicts only a small portion of the entire molecule. Trace the polypeptide backbone through the structure.

- How many lengths of polymer enter the figure?
- Identify as many of the amino acids as you can along the polymer, and write out its sequence or sequences.
- Identify the symbols for the individual atoms. Which atoms are not depicted? Why?

Refinement

The result of fitting the molecular model of a protein into its map of electron density, either manually or automatically by computer, is an initial crystallographic molecular model. At this stage, the accuracy of the

crystallographic molecular model is sufficient to define the patterns in which secondary structures are arranged. Because individual atoms, however, usually do not appear in the initial map of electron density, the initial crystallographic molecular model usually does not have sufficient accuracy to establish atomic details. These are of importance in their own right as well as being essential to understanding most of the biological functions of proteins. If the data set has been gathered to narrow enough Bragg spacing (0.3–0.25 nm or less), the accuracy of a crystallographic molecular model can be improved significantly by the process of refinement. The **refinement** of a crystallographic molecular model is the systematic adjustment of the positions of its atoms and the uncertainties of those positions and the addition to the model of portions of its covalent structure unobserved initially as well as molecules of solutes and water so that the amplitudes of the set of structure factors calculated from the model reproduce the observed amplitudes of the data set as closely as possible.

Although the fold of the polypeptide chain and the general positions of the side chains of the individual amino acids usually do not change significantly upon refinement, the atomic details of both the polypeptide and the side chains almost always change dramatically. If it is the case that the dramatic changes occurring during refinement actually do bring the molecular model closer to reality, then the atomic details observed in initial, unrefined molecular models are best ignored until the refinement has validated their existence.

The first step in a refinement is to calculate the amplitudes of the structure factors that the initial molecular model itself would produce, so that these amplitudes can be compared to the observed amplitudes of the data set. Once the initial molecular model of the polypeptide has been fit into the map of electron density to the satisfaction of the crystallographer, the coordinates within the fundamental unit cell of each of its atoms other than the hydrogens can be determined by direct measurements of the model. Often, if the initial map of electron density is of high enough quality, some individual molecules of water and solutes can be observed and included in the initial model and their coordinates also measured. There are always large regions of bulk solution in which individual molecules of water and solutes are never delineated because these regions are fluid in the crystal and thus unstructured. These regions of bulk solvent are included in the initial model as geometric solids of the appropriate uniform electron density.

A set of theoretical structure factors can be calculated by Fourier transformation (Equation 4–7) from the coordinates of the atoms, the shape of the geometric solid occupied by the solvent, and the scattering functions for each atom and for the solvent. The amplitudes of this set of calculated structure factors are referred to as the **calculated amplitudes**, and the set of these ampli-

tudes is designated F_c . The set of simultaneously **calculated phases** of those structure factors is designated as α_c . The amplitudes of the original experimental data set or any subset thereof are referred to as the **observed amplitudes** and designated F_o . The set of phases estimated by isomorphous replacement are euphemistically referred to as the **observed phases**, and the set containing their values is designated as α_o . All of these designations, F_c , α_c , F_o , and α_o , refer to three-dimensional matrices, each containing 5000–100,000 elements, all individually indexed as either F_{hkl} or α_{hkl} .

The **only directly observed quantities** are the observed amplitudes F_o , and they are the only parameters against which the success of the construction of any molecular model can be judged. If the molecular model were an exact representation of the molecules of protein, small solutes, and water within the crystal and there were no systematic errors in the observed data set, the calculated amplitudes F_c would be identical to the observed amplitudes F_o . It is traditional to quantify the degree of this correspondence with a **crystallographic R -factor**:

$$R \equiv \frac{\sum_h \sum_k \sum_l |F_{o,hkl} - F_{c,hkl}|}{\sum_h \sum_k \sum_l F_{o,hkl}} \quad (4-9)$$

where $F_{o,hkl}$ and $F_{c,hkl}$ are the observed and calculated amplitudes, respectively, of the structure factor hkl . The summation is performed over all available pairs of corresponding observed and calculated amplitudes or some subset of the available pairs. Once the Bragg spacings included in the data set are less than about 0.5 nm, so that the electron density of the solvent can be properly reproduced, the differences between the initial molecular model and the real structure usually become more significant the smaller the Bragg spacing, and the value of the R -factor has a tendency to increase in magnitude as the data set is expanded to include the amplitudes of structure factors of smaller and smaller Bragg spacing.⁷¹ Therefore the minimum Bragg spacings of the reflections included in the data set must be known to assess the significance of the value of the R -factor.

The value of the R -factor is often presented as a measure of the **validity** of a particular crystallographic molecular model. Such claims should be ignored. An incorrect crystallographic molecular model can give a reasonable R -factor.⁴⁰ For example, an incorrect crystallographic molecular model (Bragg spacing ≥ 0.2 nm)⁴⁹ for the ferredoxin from *Azotobacter vinelandii* had an R -factor of 0.24, while the later, presumably correct, crystallographic molecular model (Bragg spacing ≥ 0.2 nm)⁷² had an R -factor of 0.21. An incorrect crystallographic molecular model (Bragg spacing ≥ 0.3 nm)⁴⁸ for the *ras* protein had an R -factor of 0.29, while the later, presumably correct, crystallographic molecular model (Bragg spacing ≥ 0.26 nm)⁷³ had an R -factor of 0.23. It is not the

value of the R -factor that should be used as a validation of the model but the agreement of the model with independent chemical observations. In the case of the ferredoxin from *A. vinelandii*, it was disagreements between the earlier crystallographic molecular model and several direct chemical observations of the protein that prompted a reevaluation.⁷² Both of these examples were situations in which the chains were incorrectly traced in the original maps of electron density, and this produced very large errors in the molecular model.⁴⁰ Smaller errors may often go undetected.

Usually, the initial molecular model yields an R -factor of 0.30–0.60. This means that the amplitudes calculated from the model differ on the average by 30–60% from the observed amplitudes. At first glance this seems alarming because a completely random acentric structure would give an R -factor of 0.59. It is not so disturbing, however, because it is obvious from direct observation (Figure 4–12) that a unique structure has been defined by the map of electron density. Nevertheless, such a large value of the R -factor indicates that the initial molecular model does not duplicate the structure of the actual molecule very accurately and suggests that there is **room for improvement**. The improvements made in the structure after the initial model has been constructed are the refinements. The goal of refinement is to produce a molecular model the calculated structure factors of which have amplitudes as close as possible to the respective observed amplitudes. To accomplish this goal, the positions of each of the atoms in the model are adjusted in such a way that the R -factor decreases in magnitude. Only when it is realized that models of molecules of protein have 500–10,000 atoms that are not hydrogen and that the movement of any one of these atoms in the model affects the amplitudes of all of the structure factors in the set F_c is the task of refinement placed in a proper perspective.

The most easily understood way to perform a refinement proceeds by calculating **difference maps of electron density**. When two sets of crystallographic amplitudes are available for the same structure or for two structures so similar that the same set of phases, α_{hkl} , can be used for both, a difference map of electron density, $\Delta\rho(x,y,z)$, can be calculated:

$$\Delta\rho(x,y,z) = \frac{1}{V} \sum_h \sum_k \sum_l (F_{hkl} - F'_{hkl}) \exp[-2\pi i(hx + ky + lz - \alpha_{hkl})] \quad (4-10)$$

where F_{hkl} and F'_{hkl} refer to the entries in the two available sets of amplitudes. Equation 4–10 produces a map that has positive electron density wherever $\rho(x,y,z)$ is greater than $\rho'(x,y,z)$ and negative electron density wherever $\rho(x,y,z)$ is less than $\rho'(x,y,z)$, where $\rho(x,y,z)$ and $\rho'(x,y,z)$ are the two maps of electron density that would be cal-

culated directly from the respective amplitudes and phases.

Difference maps of electron density have many more uses than in refinement; but, in this particular instance, F_{hkl} are the entries in the set F_o and F'_{hkl} are the entries in the set F_c , and α_{hkl} are almost always those in the set of calculated phases. The intention of such a difference map of electron density is to indicate where the molecular model differs from the actual molecule. Where there is positive electron density in the map, the actual molecules in the crystal have matter in that location that is not present in the molecular model. Where there is negative electron density, there is matter at a certain location in the crystallographic molecular model that is not present in the actual molecules in the crystal. Adjustments can then be made in the model at the locations where significant differences occur. For example, the phenyl ring of a phenylalanine in the molecular model, sitting in negative electron density, can be moved over to occupy positive electron density. Unfortunately, as adjustments are made at one point in the molecular model, unavoidable shifts occur elsewhere, and the new R -factor calculated with the adjusted model usually does not change dramatically and often increases. A new difference map must be calculated to locate the new problems and the process repeated. This approach is an example of **manual tuning**, and it is slow and ultimately unsatisfactory.

There are several approaches to refinement that are designed to discover the optimal shifts of all of the atoms simultaneously by computation rather than manual tuning. These techniques are all based on the **minimization of a particular multivariate function** by solving large sets of simultaneous differential equations through matrix methods. Suppose that there is a multivariate function θ where

$$\theta = f(x_1, x_2, x_3, \dots, x_n) \quad (4-11)$$

Suppose also that the values for the variables x_j have been assigned initial magnitudes and that one wishes to discover the individual shifts, Δx_j , in the magnitudes of the assigned values of each of the variables that will produce a minimum numerical value for θ . It can be shown⁷⁴ that

$$\mathbf{A}_{i,j} \times \mathbf{h}_j = \mathbf{k}_i \quad (4-12)$$

where $\mathbf{A}_{i,j}$ is the square matrix ($n \times n$) the elements of which are

$$a_{ij} = \frac{\partial^2 \theta}{\partial x_i \partial x_j} \quad (4-13)$$

\mathbf{h} is the vector the elements of which are the individual shifts, Δx_j , in each x_j required to minimize θ , and \mathbf{k} is the

vector the elements of which are $\partial \theta / \partial x_i$. Equation 4-12 is solved⁷⁵ for \mathbf{h} , and its solution defines the shifts, Δx_j , in each variable Δx_j , required to produce a minimum value for θ .

Suppose the variables x_j are the positions of the atoms j in the molecular model of a protein, and

$$\theta = \sum_h \sum_k \sum_l w_{hkl} (F_{o,hkl} - F_{c,hkl})^2 \quad (4-14)$$

where $F_{o,hkl}$ is the observed amplitude of a particular structure factor hkl , $F_{c,hkl}$ is the calculated amplitude of the same structure factor hkl , and w_{hkl} is a weight assigned to a given structure factor. The magnitude of w_{hkl} varies with the certainty of the value of each observed amplitude. The values of F_o are fixed quantities, but the values of F_c are direct functions of the positions of the atoms j of the molecular model in the fundamental unit cell. These positions are the variables x_j . The solution of Equation 4-12, the vector \mathbf{h} , would then be a list of the shifts in the positions of each atom j of the molecular model that would produce a minimum value of θ and, presumably, a minimum value of the R -factor. This differs from manual tuning in that the effects of all shifts are considered simultaneously.

This conceptually simple but computationally complex approach suffers from the drawback that the shifts of the atoms j are unconstrained. In other words, every atom j in the molecular model would be allowed to shift independently regardless of the shifts imposed upon its neighbors. Consequently, atoms j would drift away from the neighbors to which they are connected through covalent bonds to produce unrealistic structures. When the data set extends to small enough Bragg spacing, this is not a problem because each atom j is represented by a sphere of electron density in the map which confines it to the vicinity of its proper location. But because the data set usually does not extend to such small Bragg spacings, some other means must be used to confine the individual atoms j of the molecular model. As one is dealing with the covalent structure of a polypeptide rather than a distribution of unconnected atoms j , the bond lengths and bond angles of the covalent bonds connecting the atoms j can be used to correlate their motions. For example, when any one of the carbon atoms j in the phenyl ring of a phenylalanine is shifted, all the others must also be shifted accordingly because they are all covalently attached to each other. To accomplish this, **constraints** are added to the minimization to force the motions of the bonded atoms j to be correlated.⁷⁶ The definition of θ is changed so that

$$\theta = \sum_h \sum_k \sum_l w_{hkl} (F_{o,hkl} - F_{c,hkl})^2 + \sum_q w_q (d_{s,q}^2 - d_{c,q}^2)^2 \quad (4-15)$$

where $d_{s,q}$ is the ideal, standard distance between any two atoms j that are rigidly connected by the covalent structure, for example, one of the ortho carbons and the para carbon of a phenyl ring, $d_{c,q}$ is the distance between them in the final, refined molecular model, and w_q is a weight the magnitude of which is chosen on the basis of how constrained the particular distance must be. If the two atoms j the positions of which are x_i and x_j , respectively, are directly attached to each other, w_q is large. If there are three or four covalent bonds between them, w_q is small. By adding the second term in Equation 4–15, bond distances and any rigid bond angles, such as those in a phenyl ring, are retained during the minimization.

The choice of which bond angles and bond distances to constrain is a subjective one that has a significant effect on the final crystallographic molecular model. Phenyl, indolyl, or imidazolyl rings are obvious, but exocyclic bond angles less so. It is usually unwise to constrain these bond angles in any structure other than the routine polypeptide, for example, in a covalently bound enzymatic inhibitor.⁷⁷ When accurate values for bond angles and bond lengths for an Fe_2S_2 cluster were available from a model compound, these were used as constraints early in the refinement of the crystallographic molecular model of the ferredoxin from *Anabaena* but then were removed from the process later on to incorporate the actual differences between the structures of the cluster in the protein and in the model compound.⁷⁸ On the contrary, it was concluded that the orientations of the ligands from the protein to the two irons in the nuclear cluster in the crystallographic molecular model of ribonucleoside-diphosphate reductase from *Escherichia coli* were inconsistent with spectral studies when no constraints on those orientations were applied but that constraining its structure to a conformation consistent with the spectral observations produced as satisfactory a refinement.⁷⁹ A **compromise** must be made between including enough constraints to hold the atoms j together and in reasonable orientation and including so many constraints that ideality replaces reality.

Alternatively, it has been proposed⁸⁰ that θ can be written as

$$\theta = \sum_h \sum_k \sum_l w_{hkl} (F_{o,hkl} - F_{c,hkl})^2 + w_e E_p \quad (4-16)$$

where E_p is a theoretically calculated value of the **potential energy** for the molecular model and w_e is a weight given to this term. The weight w_e is arbitrarily adjusted to make it more or less important during the refinement. In this approach, covalent bonds between atoms j remain because their distortion would produce a major increase in E_p . This approach has an advantage over the consideration of only interatomic distances (Equation 4–15) because any shift in an atom j in the molecular model causing it to overlap another atom j automatically causes

E_p to increase dramatically. The disadvantage of using E_p is that once overlaps are eliminated and covalent bonds are retained, the refinement is influenced by a large number of noncovalent forces imposed by the theoretical function and these may or may not be realistic. These biases influence the shifts of the atoms j dictated by \mathbf{h} .

Even in a rigid, anhydrous crystal of a small molecule, the atoms j and functional groups retain rotational and vibrational motion, which displaces them continuously and rapidly from their mean positions. The **vibrational and rotational motion** of the atoms j of a macromolecule of protein in a hydrous crystal are much more dramatic. There are vibrational motions involving segments of the polypeptide as well as those of the individual atoms j , and the water surrounding the molecule of protein does not sterically hinder the rotational or vibrational motion of its functional groups so dramatically as the immediate neighbors hinder the rotational motions of functional groups in an anhydrous crystal. Often the vibrational and rotational motion that occurs within the molecule of protein in the crystal is sufficient to blur the electron density of a side chain or a segment of the polypeptide so extensively that it is never present even in the refined map of electron density. Every atom j for which electron density is observed, however, is subject to vibrational if not rotational motion, and the extent of the resulting displacements of each atom j differs depending on the rigidity of its bonding and the rigidity of its surroundings. During the refinement of the crystallographic molecular model, it is possible to estimate the magnitudes of the actual displacements from its mean position experienced by each atom j in the molecule within the crystal.

The scattering factors f_j inserted into Equation 4–7 are affected by the displacement of each atom j from its mean position. It was noted earlier that, because of interference, as θ_{hkl} increases, the scattering from a given atom j decreases. Vibrational motion and rotational motion, because they also increase interference, also cause the scattering produced by the electrons around an atom j to decrease. It has been shown¹ that for the scattering factor of atom j in a molecule within a crystal

$$f_j = f_{0,j} \exp[-8\pi^2 \bar{u}_j^2 (\sin^2 \theta_{hkl}) \lambda^{-2}] \quad (4-17)$$

where $f_{0,j}$ is the scattering factor for atom j at rest, obtained from the usual table listing scattering factors as a function of scattering angle, and \bar{u}_j^2 is the **mean square amplitude of the displacement** in all directions of atom j from its mean position, regardless of the reason for that displacement. This mean square amplitude of the displacement incorporates not only the vibrational and rotational motion experienced by the atom j but also static disorder that may occur within the crystal lattice and that consequently affects the position of the atom j when it is averaged over the whole crystal. It is customary to define a **B value** (temperature factor) for atom j

$$B_j \equiv 8\pi^2 \bar{u}_j^2 \quad (4-18)$$

to simplify Equation 4-17 and obscure \bar{u}_j^2 . The units of the B value are nanometers².

The procedure for refining the position of a given atom j in a crystallographic molecular model (Equation 4-15) is usually expanded to include a refinement of both its position and its B value.⁸¹ By use of Equation 4-17, the individual B_j are incorporated as variables into Equation 4-7 in addition to the variables of mean position x_j , y_j , and z_j . The distances constraining the atoms j in Equation 4-15 are replaced with variances of interatomic distances. In this way the B values quantifying the displacements of the atoms j can be explicitly estimated during the refinement as well as the mean positions of the atoms j . It is also possible to resolve \bar{u}_j^2 into its three components along the **a**, **b**, and **c** axes and refine these three **anisotropic thermal parameters** for each atom j .⁸¹ Every atom j in a molecule of protein in a crystal undergoes its own particular motion with which are associated displacements from its mean position. It is important to remember that B values or anisotropic thermal parameters obtained crystallographically are only estimates of the actual magnitudes of these displacements.

The B value for a particular atom j in the crystallographic molecular model of a protein, as an estimate of its mean displacement from its mean position, provides an indication of its confinement. Usually, the atoms j in the interior of the molecule are confined by the surrounding atoms j and have low B values while those on the exterior, exposed to the water, have high B values. The flexibility of a segment of polypeptide is indicated by the set of B values for the atoms j of which it is composed. The atoms j in the most flexible or statically disordered segments of polypeptide or side chains, however, do not have B values assigned to them because they do not contribute to the diffraction and hence do not display any structured electron density in the map.

It has been pointed out that if only a portion of the available amplitudes is used for refinement with Equation 4-15 or another like it, the R -factor calculated with the portion not used is a more unbiased measure of the validity of the final model than the R -factor calculated with all of the amplitudes.⁸² The observed amplitudes and calculated amplitudes are divided at random into a test set containing 10% of them and a working set containing 90% of them. The working sets are the amplitudes $F_{o,hkl}$ and $F_{c,hkl}$ used in Equation 4-15, while the test sets are the amplitudes $F_{o,t}$ and $F_{c,t}$ used at each cycle of refinement to calculate a **free R -factor** (R_{free}) with Equation 4-9. In this way, the set of calculated amplitudes, $F_{c,t}$, used to calculate R_{free} are not the same calculated amplitudes, $F_{c,hkl}$, guiding the refinement, and R_{free} becomes a more independent measurement of the success of the refinement than the complete R -factor.

The use of a free R -factor during refinement should

eliminate errors in fitting the molecular model into the map of electron density. A standard R -factor, by design (compare Equations 4-9 and 4-15), must always decrease as the refinement progresses. If, however, the molecular model has been fit into the map of electron density incorrectly, for example, if the polypeptide has been incorrectly traced, then the free R -factor should remain constant or increase as the refinement progresses and the standard R -factor automatically decreases. As a result, the free R -factor has become an important indicator of the validity of a crystallographic molecular model.

In the simplest, but most time-consuming, format for refining a crystallographic molecular model (Figure 4-19),⁸³ Equation 4-15 is used to calculate shifts in the atoms j that cause θ to assume a minimum value. These shifts are used to create a new set of atomic positions x_j and another cycle of refinement is performed with these new positions as initial values for the x_j . In each of the first few of these cycles the value of R , and ideally that of R_{free} , drops (Figure 4-19), but the decreases become more modest at each cycle until no further progress can be made. The reason for this is that the process of refinement has become trapped within a **local minimum** of the function θ because refinement performed in this way will only progress as long as θ is decreasing. Manual tuning, however, is a way to escape from the local minimum in which the process is trapped. At some point

Figure 4-19: Progress of a refinement of the crystallographic molecular model of deoxyribonuclease I.⁸³ An initial molecular model was constructed by fitting a molecular model of the polypeptide into the initial map of electron density. The R -factor of the initial map was 0.45. The R -factor is presented as a function of the number of cycles of least-squares refinement performed. At the cycles indicated by ΔF , difference maps were constructed from F_o and F_c by use of the calculated phases of the molecular model to that point. These difference maps were used to rebuild the model manually and establish a new trajectory for the refinement. At cycle 98, molecules of water were added to the molecular model at locations identified in the maps of difference electron density. The range of Bragg spacings included in the data sets at each cycle is indicated at the top of the figure. The final R -factor of the refined molecular model was 0.16. Reprinted with permission from ref 83. Copyright 1986 Academic Press.

(designated ΔF in Figure 4–19), the decision is made to calculate a difference map of electron density. Adjustments of the current molecular model are made by manual tuning, and this allows the minimization to enter realistically a new trajectory. After this trajectory reaches a new local minimum, more tuning is performed. This strategy, however, is never followed today.

The manual adjustments performed at various times during this simplified strategy for refinement require a significant amount of time. Whenever the refinement reaches a plateau and no further progress is evident (Figure 4–19), the molecular model must be examined in detail and manually adjusted with the assistance of difference maps of electron density before a new trajectory can be initiated. It has been found that one way to avoid such time-consuming manual adjustments during the refinement is to combine molecular dynamics and refinement.⁸⁴

In a **molecular dynamics** simulation, atoms j are positioned in space, for example, by the fitting of the molecular model into the initial map of electron density and perhaps an initial round of refinement. A global potential energy function E_p , incorporating the individual potential energy functions of the covalent bonds and the nonbonded interactions, is calculated. The atoms j are then given kinetic energies appropriate to a certain temperature and allowed to move for a short interval (less than 1 fs) within this global potential energy function according to classical laws of motion. The new positions in turn create a new global potential energy function and the atoms j are allowed to move again in response to the new component potential energy functions, and so forth.

When molecular dynamics is used in crystallographic refinement, the global potential energy function, $E_{p,i}$ for each step i in the usual molecular dynamics calculation is augmented by an effective potential energy

$$E_{p,f} = w_x \sum_h \sum_k \sum_l w_{hkl} (F_{o,hkl} - F_{c,hkl})^2 \quad (4-19)$$

where w_x is a weighting factor chosen so that $E_{p,f}$ has the same magnitude as E_p and F_c is the set of the amplitudes of the structure factors calculated for the instantaneous distribution of atoms j after each step in the molecular dynamics calculation. This effective potential energy, $E_{p,f}$, constrains the atoms j during the molecular dynamic trajectory to the vicinity they occupied in the original molecular model, but if a high enough kinetic energy is applied, the atoms j can move as much as 0.3 nm from their initial positions.^{85,86} This is what allows the structure to break out of local minima of the function θ .

The process proceeds in several steps referred to as **simulated annealing**.⁸⁷ Initially a high kinetic energy is applied to the atoms j (high temperature), and then the kinetic energy is decreased to finish within a minimum of

potential energy. It is while the kinetic energy is high that local minima of potential energy, and hence local minima of the function θ , can be passed through. It has been shown that in this way the R -factor can be minimized with much less need for manual adjustment of the molecular model.⁸⁸ Because rather high simulated temperatures are used, however, unexpectedly large movements of segments of the model can occur,⁸⁹ so the necessity to examine difference maps of electron density and perform manual adjustments remains. Nevertheless, with proper precautions, refinement by molecular dynamics converges on the same structure as refinement performed entirely by least-squares minimization and manual adjustment.^{85,86,88}

The use of simulated annealing by molecular dynamics for the purpose of pushing the refinement out of local minima includes coincidentally a large number of hidden constraints in the **potential functions** used for covalent bonds and nonbonding interactions that are necessary to cause the atoms j to move in each step. These potential functions were not constructed for solutes in aqueous solution, which is what a molecule of protein in a crystal is. As a result, they introduce **significant, uncontrolled biases** into the final molecular model.

These biases are most clearly manifested in the final positions of the charged side chains. The choice of a charge number for a side chain has a dramatic effect on its location in the final crystallographic molecular model in which simulated annealing is used for refinement.⁸⁹ This, however, should not be the case for charged groups in aqueous solution of moderate ionic strength. A compilation of the frequency of hydrogen bonds between oppositely charged donors and acceptors of hydrogen bonds in crystallographic molecular models found them to be no more frequent than hydrogen bonds between a neutral donor and a neutral acceptor or between a charged donor or acceptor and a neutral acceptor or donor, respectively.⁹⁰ This compilation was gathered from crystallographic molecular models refined by manual adjustments rather than by simulated annealing. Another compilation,⁹¹ gathered after refinement by simulated annealing had become widespread, found that hydrogen bonds between oppositely charged donors and acceptors were almost 5 times more frequent. Since the actual frequency cannot change, this latter result suggests that refinement by simulated annealing does consistently introduce artifacts into crystallographic molecular models. Because the potential functions for the attraction between these oppositely charged groups in simulations performed by simulated annealing are unrealistically strong, it would not be surprising if this procedure produced such interactions artifactually. Another indication of the unreliability of assignments of hydrogen bonds between oppositely charged donors and acceptors is that their identity usually changes significantly, and often dramatically, from an earlier version to

a later version of a crystallographic molecular model even though both versions were built from refined maps of electron density calculated from data sets gathered from the same crystal.

There are now at least five widely used procedures for refining crystallographic molecular models. It is reassuring that even though the final models prepared with each method differ detectably,⁹² when two of them are used to refine the same model with the same data set, the two refinements usually converge to a common structure.⁹³ Often two different refinement procedures are purposely used to reassure the investigators that a peculiar aspect of the molecular model is real.^{77,94}

As a refinement progresses, there is a noticeable improvement in the shape and continuity of the tube of refined electron density representing the polypeptide.^{35,95} Segments of the polypeptide in the initial molecular model often move during the refinement, sometimes as much as 1 nm, to assume their positions in the final molecular model,^{96,97} especially in regions where the initial map of electron density was vague. Elements of secondary structure missing in the initial map of electron density can appear and elements of secondary structure in the initial map can occasionally disappear upon refinement, and positions assigned to specific amino acids in the sequence of the protein within secondary structures can shift dramatically.⁹⁷

Locations where the published **amino acid sequence** is in error become obvious,⁹⁸ and it is sometimes possible visually to read the amino acid sequence of a segment of the protein as yet unsequenced.⁹⁹ If the map of initial electron density has been calculated from a data set gathered to narrow enough Bragg spacing (<0.16 nm), the electron density for individual amino acids in the initial map can be sharp enough that they can be tentatively identified and their side chains incorporated into the original molecular model even though the sequence of the protein is unavailable.¹⁰⁰ As the refinement progresses, mistakes in these initial assignments become obvious and can be corrected.

The electron density for the carbohydrate attached to a glycoprotein, if it is not disordered in the crystal, becomes progressively more detailed. The electron density for coenzymes, which are almost always held rigidly within the protein, also becomes easier to interpret. Posttranslational modifications, sometimes unexpected,¹⁰¹ as for example 3-(S-cysteinyl)tyrosine and β -hydroxytryptophan (Table 3-1), and sometimes hoped for, as for example the ester intermediate in the self-catalyzed pyruvylation of aspartate 1-decarboxylase (Equation 3-9),¹⁰² begin to appear in the difference maps of electron density. Previously unaccounted-for molecules of **water** (oxygen atoms j) and anions and cations from the crystallization solution that are bound at specific locations on the surface or in the interior of the molecules of protein begin to appear in the difference maps and they become sharp and repro-

ducible features. Any of these features not incorporated into the initial molecular model appear in a difference map of electron density because they are fixed at certain locations in the real fundamental unit cell by their specific covalent bonds and noncovalent interactions with the molecules of protein but are as yet missing in the model.

When the identity, location, and structure of each of these fixed molecules or portions of the covalent structure of the polypeptide that were not included in the initial molecular model, because they did not appear in the initial map of electron density, become sufficiently unambiguous, they are incorporated into the molecular model at that cycle of the refinement. Their inclusion causes a significant decrease in the *R*-factor because they are as real a feature of the actual crystallographic unit cell as the individual amino acids in the polypeptide, and they contribute accordingly to F_o . For example, in the refinement for deoxyribonuclease I (Figure 4-19), the inclusion of the water molecules observed in difference maps at cycle 98 caused the molecular model to be much more realistic and permitted the refinement to produce a significantly lower minimum of the *R*-factor than it had before they were included. This reasonable consequence suggests that the refinement is registering reality, but all of the changes taking place during the refinement are adequate evidence that a crystallographic molecular model is always provisional.

There are now more than 30 crystallographic molecular models of proteins that have been fit into maps of electron density calculated from data sets with minimum Bragg spacings so narrow (≤ 0.1 nm) that the individual atoms j , and in one instance even bonding electron density,¹⁰³ are clearly observed in the initial map.^{5,6,104-106} In these instances, few if any constraints were required during refinement. Nevertheless, almost all of even the most recently constructed crystallographic molecular models of proteins have not had the benefit of such accurate maps of electron density.⁴⁴ Consequently, regardless of how the refinement is performed, ideal bond lengths and bond angles are almost always enforced upon the crystallographic molecular model because if they were not, the refinement could not be performed at all. Therefore, if a refinement were performed entirely by the computer, the final molecular model would be confined by all of these implicit and often unsubstantiated constraints. To verify that the process of refinement has not biased the final structure, careful inspections of difference maps of electron density are always required to identify locations where the actual structure of the protein deviates from these simple expectations.

This inspection is routinely done by using **omit maps of difference electron density** (Figure 4-20). A segment of amino acids, a coenzyme, or a posttranslational modification in the final refined crystallographic molecular model is omitted, and the truncated model that

results is used to calculate $F_{c,omit}$ and $\alpha_{c,omit}$. The observed data set F_o and $F_{c,omit}$ and $\alpha_{c,omit}$ are used to calculate (Equation 4–10) a difference map of electron density. In this difference map the omitted segment appears as positive electron density. This positive electron density has the advantage that its details are defined only by the observed data set because nothing is present at this location in the truncated molecular model. The atoms j in the refined molecular model in this region are adjusted, if necessary, to fit within this difference electron density and added back to the molecular model. Then another segment of the updated molecular model is omitted and so forth over the whole structure. In this way, an attempt is made to incorporate into the final molecular model the ways in which the actual structure of the protein deviates from the ideal structure dictated by ideal bond lengths and bond angles and empirical functions of potential energy used during the refinement. It should be stressed at this point that the goal of all refinement is to produce a crystallographic molecular model that reproduces as accurately as possible the actual structure of the molecule of protein, including all of its perversities,¹⁰⁷ rather than some ideal structure consistent with a set of theoretical potential energy functions.

There is one interesting and enlightening aspect of the process of producing an omit map. After a segment of the molecular model has been omitted, it is necessary to perform additional cycles of refinement on the molecular model missing that segment before calculation of the $F_{c,omit}$ and $\alpha_{c,omit}$ used to produce the omit map of difference electron density.^{108–110} The reason for this requirement is that the positions of all of the atoms j in the initial refined model, not just the atoms j omitted themselves, contains information about the positions of the atoms j omitted. This information would be transmitted to the calculated amplitudes, $F_{c,omit}$, but even more critically to the calculated phases, $\alpha_{c,omit}$, that would be used to calculate the difference map of electron density were it not purged by repositioning the remaining atoms j in the truncated molecular model by additional cycles of refinement. These additional cycles must be performed on the model in which the omitted atoms j are missing and hence unable to bias the calculations performed during the cycles of refinement.

Now that the molecular model of the polypeptide is fit by computer into the map of electron density and the manual adjustments that were once performed manually by the crystallographer during refinement have been replaced by molecular dynamics, the intimate human involvement in these procedures that once occurred no longer occurs. There is no computational algorithm that approaches the acuity of an experienced human intellect. Consequently, at some point in the complete process the product must be examined carefully by the crystallographer if errors are to be avoided. It is the omit maps that present the most obvious opportunity for this **human intervention**.

The omit maps calculated for successive segments of the molecular model (Figure 4–20) must be examined carefully by the crystallographer to ensure that they do actually represent that segment of the model. If the polypeptide has been incorrectly traced and the wrong

Figure 4–20: Omit map of electron density.¹³⁸ The initial crystallographic molecular model for the amino-terminal domain of a variant glycoprotein from *Trypanosoma brucei* was built from a map of electron density calculated from observed amplitudes (Bragg spacing ≥ 0.29 nm) and phases from multiple isomorphous replacement. The molecular model was refined with the assistance of simulated annealing. From this refined molecular model, the first 31 amino acids of the polypeptide were omitted. The truncated molecular model was submitted to 40 additional cycles of refinement before phases, $\alpha_{c,omit}$, and amplitudes, $F_{c,omit}$, were calculated from it. These phases and amplitudes along with the observed amplitudes were used to calculate an omit map of difference electron density. The portion of that map including the segment of the polypeptide from Glutamine 12 to Glutamine 24 is presented. A molecular model of this segment of polypeptide in its final conformation is positioned within the omit map.

segment of the molecular model has been fit into a particular segment of electron density, that error will be obvious in an omit map of that segment of electron density.¹¹¹ The fit of the molecular model into the omit map of electron density must be adjusted manually by the crystallographer, not because a computer could not do so but because she must be convinced that the fit justifies the final conformation imposed upon the molecular model. Only in this way, with properly calculated omit maps and properly adjusted conformations, can the ideal structure resulting from the theoretical biases of the automated fitting and refinement be replaced by the real structure dictated by the observed amplitudes. For example, a hydrogen bond produced solely by the constraints of the refinement for which there is no evidence within the observed amplitudes will not appear in a properly calculated omit map and must be removed from the crystallographic molecular model. The conformation of a side chain produced by the constraints of the refinement may differ significantly from the conformation observed in an omit map and must be adjusted accordingly.

In addition to the polypeptide, the process of refinement adjusts the conformations of coenzymes and oligosaccharides in the crystallographic molecular model. **Coenzymes** can be either covalently bonded to the polypeptide as additional examples of posttranslational modifications (Table 3-1) or enclosed within it so tightly that they form an integral structural component. In either case, the coenzyme never leaves the protein and is incorporated with the protein into a crystal. At this point, these molecules will be considered to be merely small clouds of electrons that have interesting shapes. Usually the existence and covalent structure of these coenzymes is known before the protein is crystallized.

The electron density contributed by coenzymes known to be associated with a protein is always clearly featured because these molecules are enclosed within the protein and precisely aligned for functional purposes. The shapes of most coenzymes are unique, and they can usually be placed unambiguously into one of the envelopes of electron density unfilled by the polypeptide, but the decision as to when during the refinement they are included in the molecular model depends on the situation. If the initial, unrefined map is detailed enough and the coenzyme is large enough and of a shape peculiar enough, it can be inserted into its electron density at the same time the polypeptide is fit into its map of electron density. For example, the envelopes of electron density representing the four bacteriochlorophylls *b* in the initial map of electron density for the photosynthetic reaction center calculated from the phases estimated by isomorphous replacement were clear enough that molecular models of bacteriochlorophyll *b*, with its characteristic queue, could be inserted into several of them (Figure 4-21)¹¹² even before the polypeptide could be fit into its electron density. In fact,

the envelopes of electron density for the bacteriochlorophylls *b* could be distinguished from the envelopes for the almost identical bacteriopheophytins by the bulge of electron density due to the magnesium ions present in the former but missing from the latter. Usually, however, a coenzyme is added to the model at a step in the refinement when its electron density in the difference map becomes detailed enough to insert it unambiguously, but adjustments, often major ones,¹¹³ are made in its position and configuration as the map of electron density becomes more detailed during the cycles of refinement. The precise orientation of a coenzyme in the model is assigned in the end with an omit map (Figure 4-22).¹¹⁴

The crystallographic molecular model for myoglobin (Figure 4-18) displays the characteristic, intimate association between a coenzyme and the polypeptide that enfolds it. In this case, the heme is embraced by the α helices arranged to compose the entire structure, the purposes of which are to isolate the heme from the solution, to prevent two hemes from colliding, and to permit the heme to dissolve in water in addition to providing a fifth ligand to the iron.

Often **ligands** that are known to be specifically bound by the protein are included during the crystallization and are bound by the protein in the crystal. Significant changes can occur in the position and orientation of a ligand during refinement. For example, the molecular model of methotrexate inserted into the initial map of electron density of dihydrofolate reductase had to be adjusted significantly during refinement.¹¹⁵ The final position and orientation of the ligand are assigned in the final crystallographic molecular model by fitting them into features of electron density in omit maps.¹¹⁶

The positions in the amino acid sequence of a glycoprotein at which the **oligosaccharides** are attached are often known, so the locations of these serines, threonines, or asparagines in the map of electron density can be identified as soon as the polypeptide has been fit into it. Oligosaccharides are located on the outer surface of a protein and usually protrude into the aqueous phase surrounding it (Figure 4-23).⁸³ Under these circumstances, they are fully solvated, flexible, and structureless. This absence of a fixed structure is carried into the crystal, and the region within the fundamental unit cell occupied by the oligosaccharide is often featureless. Attempts to assign an atomic structure to such regions are probably irrelevant to an understanding of the behavior of an oligosaccharide in a biological situation where it will have no defined structure anyway. Sometimes, however, the carbohydrate is surrounded sufficiently by protein to assume a defined conformation and produce structured electron density. If the initial map of electron density is calculated from a data set gathered to narrow enough Bragg spacing and the oligosaccharide is sufficiently confined by the structure of the protein, a molecular model built from its previously determined sequence of monosaccharides can be unambiguously fit into that initial

Figure 4-21: Electron density assigned to a bacteriochlorophyll *b*,¹¹² one of the coenzymes in the reaction center from *Rhodospseudomonas viridis*. A skeletal model of the known atomic structure of the coenzyme has been placed within an envelope of electron density located in the initial, unrefined map. Note the bulge of electron density in the center of the coenzyme that results from the magnesium ion with its 10 core electrons. Reprinted with permission from ref 112. map.¹¹⁷ With initial maps of lower quality, the conformation of the oligosaccharide in the crystallographic molecular model is adjusted during the refinement (Figure 4-24).^{118,119}

As the refinement progresses, isolated spherical features of electron density larger than those that can be assigned to molecules of water appear and become more prominent in the map of electron density. These are negative **ions** such as chloride or bromide or positive ions such as Na^+ , K^+ , Mg^{2+} , Ca^{2+} , Fe^{2+} , Co^{2+} , Mn^{2+} , Zn^{2+} , or Cu^{2+} . Often these features, such as the chloride ions in human collagenase 3,¹²⁰ can be assigned by their scattering strength and the ionic character of the protein surrounding them. Such an assignment is strengthened by showing that if the designated ion is incorporated into the molecular model during the refinement, its refined *B* value ends up in the same range as the refined *B* values for the other atoms *j* in the model.¹²¹ If an incorrect assignment had been made, the refinement would have adjusted the *B* value to an unrealistic magnitude to compensate for the incorrect scattering factor incorporated into the calculations (Equation 4-17).

It is also possible to use their anomalous dispersion to identify ions.¹²² For example, when the wavelength of the X-radiation was decreased from 0.154 to 0.1377 nm, passing through the absorption edges for Ni (0.1488 nm) and Cu (0.1381 nm), the magnitude of the electron density for a metal ion in the map calculated from structure factors from a crystal of nitrite reductase (NO-forming) did not decrease significantly, but when it was further decreased to 0.104 nm, below the absorption edge of Zn (0.1284 nm), it decreased significantly.¹²³ This effect demonstrated that the sphere of electron density in the map at this location represented a Zn^{2+} ion. A difference map of electron density calculated from a data set gathered at a wavelength of 0.0870 nm and a data set gathered at 0.1488 nm, where iron has significant anomalous dispersion compared to other transition metal ions,

Figure 4-22: Omit map of electron density for one of the phycoerythrobilins in B-phycoerythrin from *Porphyridium sordidum*.¹¹⁴ A crystallographic molecular model constructed from an initial map of electron density (Bragg spacing ≥ 0.22 nm) was refined against the observed amplitudes with the assistance of simulated annealing. The phycoerythrobilin covalently bound by Cysteines 50 and 61 of the β subunit of the protein was then omitted from the molecular model, and an omit map of electron density was calculated. The final conformation chosen for the coenzyme is positioned within the electron density.

Figure 4-23: Skeletal drawing of the glycoprotein bovine deoxyribonuclease I. The skeletal drawing of the polyanide backbone (260 aa) is drawn with thin lines; and the oligosaccharide and the side chain of the asparagine (at the top of the structure), with thick lines. The positions of the atoms are from the crystallographic molecular model of the protein (Bragg spacing ≥ 0.20 nm).⁸³ Structured electron density could be observed in the vicinity of Asparagine 18 in the crystallographic model, but it was only large enough to contain the first two *N*-acetylglucosamines and one of the mannoses of the high-mannose oligosaccharide (GlcNAc₂Man₅; incomplete realization of the first entry in Table 3-3) known to be attached at this asparagine. The other four mannoses of the molecular model were arbitrarily positioned. The core of the structure is a laminate of two pleated β sheets. The laminate is flanked above and below by α helices and random meander. There was no electron density for the two amino acids preceding Cysteine 104 because they were either vibrating too widely or statically disordered in the crystal. The locations of convenient positions in the amino acid sequence of the protein are numbered to assist you in tracing the chain of the polypeptide. This drawing was produced with MolScript.¹³⁹

showed strong electron density at the eight positions occupied by the metal ions in the two tetranuclear clusters in hybrid-cluster protein from *Desulfovibrio vulgaris*, an observation demonstrating that all of those metal ions are irons.¹²⁴

Although they can be readily observed in maps of scattering density calculated from neutron diffraction,

atoms *j* of **hydrogen** are almost never observed in X-ray crystallographic studies of proteins because, unlike atoms *j* of carbon, nitrogen, oxygen, and sulfur, atoms *j* of hydrogen have no inner-shell electrons. Because they are in smaller orbitals, inner-shell electrons have the highest electron density and produce most of the features observed in the usual maps of electron density. In general, if hydrogens are present in a crystallographic molecular model, it is because the crystallographer knows they are there even though they were not observed. When, however, crystallographic molecular models obtained from data sets gathered to Bragg spacings of less than 0.1 nm are submitted to extensive refinement, spherical features of positive electron density appear in difference maps of electron density at positions that are occupied by hydrogens in the real molecule of protein.^{5,6,105,106} These features arise because the molecular model has no hydrogens but the molecule of protein does. Of particular interest are those features of difference electron density that can be assigned to the hydrogens in hydrogen bonds.^{125,126}

Another peculiar feature that becomes apparent as a refinement progresses is that a few of the amino acids display **alternative conformations** in the map of electron density. At the position of such an amino acid in an omit map of difference electron density, a feature having the shape of the superposition of two different rotational isomers of the amino acid is found (Figure 4-25).¹²⁷ This feature of electron density arises because in the crystal the actual amino acid spends part of its time in one conformation and part of its time in the other so the electron density in the map, which is averaged over the period in which the measurement was made, represents both conformations simultaneously. Maps of electron density calculated from data sets gathered to narrow Bragg spacing, because of their higher quality, reveal a greater frequency of alternative conformations and more subtle examples of alternative conformations, such as the *exo* and *endo* conformations of particular prolines¹²⁸ or the alternative conformations of a cystine,¹²⁹ and the features of electron density defining the alternative conformations are much sharper and less ambiguous.¹²⁶ In maps of electron density of low quality, however, most of the alternative conformations are never distinguished even upon refinement and their existence simply increases the *B* values for the functional groups that assume them.

Inherent in the process of refinement is the ability to produce a crystallographic molecular model by **molecular replacement**. Many proteins for which data sets have been gathered for the first time are closely related to other proteins for which a crystallographic molecular model is already available. Such a close relationship can be established by aligning the amino acid sequences of the two proteins. For example, the amino acid sequence of the aspartic endopeptidase from Rous sarcoma virus ($n_{aa} = 124$) can be aligned with the amino acid sequence of the aspartyl endopeptidase from

human immunodeficiency virus, type 1 ($n_{aa} = 99$), so that there are 30 identical positions and four gaps, all in the shorter protein.¹³⁰ It necessarily follows that the structures of these two proteins are superposable. The three long gaps in the shorter amino acid sequence (10, 5, and 6 amino acids, respectively) can be assumed to represent loops on the surface of the larger protein missing from the smaller. A crystallographic molecular model, produced by multiple isomorphous replacement, was available for the larger of the two proteins, that from Rous sarcoma virus.¹³¹ Crystals of the protein from the human immunodeficiency virus were produced, and a data set was collected from them. The side chains of the amino acids in the crystallographic molecular model of the protein from Rous sarcoma virus were replaced with the corresponding side chains in the aligned amino acid sequence of the protein from the human immunodeficiency virus. The loops corresponding to the gaps in the alignments were removed from the model to produce a preliminary molecular model for the protein from the human immunodeficiency virus.

This model was computationally aligned in the fundamental unit cell defined by the data set collected from crystals of the protein from human immunodeficiency virus. This preliminary model was then submitted to refinement to produce a final structure with an R -factor of 0.18.¹³² As this example illustrates, the purpose of using molecular replacement is to avoid the experimental difficulties of obtaining phases. Because there are so many proteins for which crystallographic molecular models are already available (<http://betastaging.rcsb.org/pdb/Welcome.do>), the likelihood that the protein in a new crystal is related closely enough to one for which a model has already been made is fairly high. Consequently, many of the newly reported maps of electron density have been calculated by molecular replacement.

How much more reliable is the refined crystallographic molecular model than the initial model built into the map of electron density produced by the phases determined experimentally? It is true that the R -factor is much smaller, but this is not surprising because the decrease occurred automatically. A significant decrease in the free R -factor is more reassuring. These decreases state that the refined molecular model, although it is usually not remarkably different from the original molecular model, has an electron density that produces structure factors the amplitudes of which are much closer to the observed amplitudes, which are the only directly observed quantities.

Often the success of the refinement is touted by showing that the map of electron density calculated from F_o and α_c of the final molecular model has features that very closely resemble phenyl rings or other equally characteristic side chains, but this is illusory. A map of electron density constructed from F_c and α_c would have to

have features precisely resembling these side chains because F_c and α_c are calculated from the molecular model itself, which always has ideal bond angles and bond lengths for the entire polypeptide, and the minimization has automatically caused F_c to be as close as

Figure 4-24: Fitting of an oligosaccharide into its assigned electron density.¹¹⁸ The oligosaccharide $\text{Man}(\alpha 1,3)\text{Man}(\alpha 1,6)[\text{Man}(\beta 1,4)\text{GlcNAc}(\beta 1,4)\text{GlcNAc}]$ was inserted into the final, refined map of electron density (Bragg spacing ≥ 0.22 nm) for the glucan 1,4- α -glucosidase from the fungus *Aspergillus awamori* to fill the electron density adjacent to Asparagine 395. The oligosaccharide was included in the refinement from the beginning. Asparagine 395 is at the bottom of the structure.

Figure 4-25: Alternate conformations of Valine 178 in ribonuclease T₁ from *Aspergillus oryzae*.¹²⁷ As the refinement of the map of electron density (Bragg spacing ≥ 0.15 nm) progressed, an unaccounted-for peak of electron density appeared that was continuous with the electron density for Valine 178 and was too close to it to have represented a molecule of water. All of the atoms of Valine 178 were then omitted from the molecular model, it was submitted to several cycles of refinement, and the omit map of electron density displayed in the figure was calculated. It contained electron density from two rotamers of Valine 178. Judging from the intensities of the two different features of electron density unique to each rotamer (those to the top and to the right), the two conformations are about equally populated. Skeletal models of the two alternative conformations of the valine are superposed within the envelope of difference electron density.

possible to F_0 . Furthermore, as has already been noted, the phases used in the calculation have more impact on the final map of electron density than the amplitudes. Therefore, it is not surprising that the details explicitly put into the model by the crystallographer should reappear when the map of electron density is reconstructed from F_0 and α_c or from any combinations of F_c , F_0 , and α_c .

A similar difficulty in evaluating the success with which a particular refinement has reproduced the real structure of the molecule of protein is the nature of the constraints applied. To progress efficiently, a refinement usually must be forced to retain bond lengths and bond angles or forced to be at the minimum of a function for potential energy; however, every constraint enforced upon the refinement is automatically incorporated into the final structure regardless of its reality. This fact is easily verified by examining crystallographic molecular models refined by different methods. The clear **imprint of the constraints** chosen for each method remains in each of the molecular models refined by that method.⁹² If one of the constraints in Equation 4-15 is that every peptide bond shall be planar, the planarity of the peptide bonds in the final structure cannot be cited as a measure of the success of the refinement. In fact, it is probably more an admission of its failure to detect the normal deviations from planarity.¹³³ If one of the constraints inadvertently introduced by Equation 4-16 is that the conformation along no carbon-carbon bond can eclipse vicinal methyls or methylenes, the absence of such eclipsed conformations cannot be cited as a measure of the success of the refinement.

These are not minor criticisms. The structure of a map of electron density usually improves so breathtakingly upon refinement that those changes that were enforced by the crystallographer must be clearly separated from those changes that arise only from the real molecular structure in the crystal. It is only these unconstrained and often unexpected features of the refined map of electron density which clearly state that it is an improvement.^{107,134}

The crystallographic molecular model, even after extensive refinement, should never be confused with the actual structure of the molecule itself. The crystallographic molecular model is no more than the coordinates of the centers of all of the atoms j in the model that was built by the computer from line segments, that was fit into the map of electron density, and that was then refined against the available amplitudes. It is only as accurate as the phases that were finally decided upon, which still incorporate some of the errors in the experimental phases, the arbitrary constraints imposed during refinement, and the inherent biases in the formula for calculating its structure factors, which assumes spherical atoms j and harmonic rectilinear atomic motions. The fact that most crystallographic molecular models change, often dramatically, as further refinement is performed or as additional data are collected from the same crystals to narrower Bragg spacing,¹³⁵ even though the real structure of the protein has not changed, is the most obvious demonstration that the model is not the structure of the protein but is a work of art representing the structure of the protein. It is unfortunate that the words "structure of the protein" are so widely used when referring to the crystallographic molecular model of the pro-

tein. This habit only adds to the misleading impression of infallibility associated with crystallography.

Suggested Reading

Oefner, C., & Suck, D. (1986) Crystallographic refinement and structure of DNase I at 2-Å resolution, *J. Mol. Biol.* 192, 605–632.

Problem 4–5: The figure to the right¹³⁶ is a stereo view of the crystallographic molecular model of a protein containing 71 amino acids. This drawing was produced with MolScript.¹³⁹ By examining the molecular model in stereo, you will be able to ascertain almost all of the amino acid sequence of the protein. You will not be able to distinguish threonine from valine, glutamate from glutamine, or asparagine from aspartate. Make an educated guess for threonine and valine, and just choose at random for asparagine and aspartate and glutamine and glutamate. If you can't make out an amino acid, put an X in its position in the sequence.

- (A) Write out the amino acid sequence of the protein in one-letter code. Number every tenth amino acid in your sequence to keep everything in register.
- (B) Which pairs of amino acids in the protein are cystines? Identify each pair by the sequence positions of the two cysteines that form the cystine.
- (C) What do the isolated atoms *j* scattered around in the crystallographic molecular model represent?
- (D) How did the crystallographer distinguish between threonine and valine, between glutamate and glutamine, and among aspartate, asparagine, and valine?

Chapter 5

Noncovalent Forces

Crystallographic studies have demonstrated that a molecule of protein, dissolved in aqueous solution, is composed of polypeptides, each of which is folded into a structure that is the same as or closely similar to the structure of all of the other polypeptides of the same amino acid sequence. A polypeptide, as it emerges from the ribosome, however, is a fluid polymer of undefined structure. Each newly synthesized polypeptide then folds spontaneously to assume its unique secondary and tertiary structure.

The folding of polypeptides to form the native structure of a protein, the association of folded polypeptides to form multimeric proteins, and the binding of substrates, coenzymes, or other molecules to proteins usually proceed without the formation of covalent bonds and are consequently controlled by noncovalent forces. It appears that four noncovalent forces are involved in these chemical reactions: ionic interactions, hydrogen bonds, the hydrophobic effect, and van der Waals forces. In the refined crystallographic molecular model of a folded protein, the consequences of these noncovalent forces are evident. The chemical and physical properties of these interactions, as they occur in aqueous solution, must be understood before those consequences can be appreciated. Therefore, a discussion of these interactions must precede a detailed description of the atomic details of refined crystallographic molecular models. None of the four categories of noncovalent forces—ionic interactions, hydrogen bonds, the hydrophobic effect, and van der Waals forces—can be completely separated from all of the others. Van der Waals forces must play a part in each of the other three phenomena, hydrogen bonds can be considered to be special cases of ionic interactions, almost all ionic interactions in biochemical situations involve hydrogen bonds, and the hydrophobic effect is to a large degree the reflection of hydrogen bonding in the solvent. It is informative, however, to discuss each of these categories separately to focus on their unique properties.

Each of these types of interactions can be considered to be a special case of a noncovalent association between two molecules, A and B, or between two segments, A and B, of the same molecule. For the situations under discussion, our attention will be directed to such a reaction as it would occur in aqueous solution. A general chemical equation for these associations is

The species $A(H_2O)_x$ and $B(H_2O)_y$ are the separated solutes dissolved in water and surrounded on all sides by water. Presumably, there are a certain number of water molecules, x and y , respectively, that are significantly affected by the presence of A or B. The effects of the solute on the surrounding molecules of water and the effects of the surrounding molecules of water on the solute are referred to as **solvation** or **hydration**. Around a particular molecule of solute at a particular instant, a particular number of water molecules are affected significantly by the presence of the solute. This number fluctuates with time, and the coefficients x , y , and z are intended to represent averages over a range of possible configurations for the hydration. When A and B associate to form the noncovalent complex, that complex will also be surrounded by water, and there will be a number of water molecules, z , that are significantly influenced by the complex. As A·B always has a smaller surface area than the sum of the surface areas of A and B, z should be less than $x + y$, and $(x + y - z)$ molecules of water will return to the bulk phase of the water when the complex is formed.

The change in standard free energy for the overall reaction can be expressed as

$$\Delta G^\circ = \Delta G^\circ_{A \cdot B} + \Delta G^\circ_{\text{hyd}(A \cdot B)} + \Delta G^\circ_{r H_2O} - \Delta G^\circ_{\text{hyd}(A)} - \Delta G^\circ_{\text{hyd}(B)} \quad (5-2)$$

where $\Delta G^\circ_{\text{hyd}(i)}$ refers to the standard free energy of hydration between each of the solutes and its surrounding waters of hydration, $\Delta G^\circ_{A \cdot B}$ refers to the direct standard free energy of interaction between A and B, and $\Delta G^\circ_{r H_2O}$ is the change in standard free energy experienced by the $x + y - z$ molecules of water as they leave shells of hydration and return to the bulk aqueous phase. It will become apparent that all of the terms on the right-hand side of Equation 5-2 except sometimes the first are remarkably influenced by the fact that this reaction occurs in water as a solvent. No noncovalent interaction has the same outcome in any other solvent. For example, hydrogen bonds and ionic interactions are stable in

almost any other solvent but are dissociated by water, while the hydrophobic effect is observed only when the solvent is water. To appreciate fully these influences of water on the outcome of noncovalent associations, the properties of liquid water itself must be understood.

Water

The properties of liquid water, when considered in their entirety, are unlike those of any other liquid. For example, the **surface tension** of water at 20 °C is 73 dyne cm⁻¹, while those of most other liquids are between 20 and 40 dyne cm⁻¹. The **relative permittivity**,* ϵ_r , of water at 20 °C is 80.2, while the relative permittivities of other liquids, with few exceptions, are less than 30. The high **melting point** and **boiling point** of water, for a molecule of its size and composition, are well-publicized anomalies. Not only are the numerical values of the physical constants anomalous, but the qualitative behaviors of the thermodynamic properties of the liquid, when it is exposed to variations of physical forces such as pressure, temperature, electric field, and electromagnetic energy, are unique. The details of these peculiarities provide an intuitive picture of the structure of liquid water that can serve as a basis for understanding the behavior of solutes such as polypeptides in this solvent. Unfortunately, there is no adequate molecular model for the structure of liquid water, and an informed intuitive picture is the closest approach to reality currently available.

A water molecule in the dilute, ideal **vapor** is an oxygen atom bonded covalently to two hydrogen atoms. Quantum mechanical calculations^{1,2} of the isolated molecule in the vacuum seem³ to support the conventional **orbital picture** of an oxygen hybridized sp^3 with two covalent bonds to two hydrogens and two σ lone pairs of electrons; these four substituents are oriented tetrahedrally around the oxygen. The HOH bond angle⁴ is 104.5°, distorted from 109.5° by the electron repulsion of the lone pairs or by a rehybridization, driven by energy of promotion, that gives the oxygen–hydrogen σ bonds more p character. The oxygen–hydrogen bond lengths are 0.096 nm.

In more concentrated vapor, **dimers of water** form (Figure 5-1).^{5,6} From results of molecular beam microwave spectroscopy, the mean structure of the dimer can be calculated.^{5,6} The two oxygens are separated by a distance of 0.298 nm. One of the four hydrogens lies on the line of centers between the two oxygens, and it is covalently bonded to one of them, which is referred to as the proton donor. The other oxygen, which is referred to as the proton acceptor, has two of the four hydrogens covalently bonded to it. The plane defined by

Figure 5-1: Selected dimensions of the dimer of two molecules of water in the gas phase. The distances and angles were obtained by microwave spectroscopy.^{5,6}

the two hydrogens and the oxygen of the proton acceptor is inclined at an angle of 60° to the line of centers between the two oxygen atoms. This means that the four substituents around the acceptor—the two hydrogens, the shared hydrogen, and the lone pair of electrons—are tetrahedrally arrayed in the dimer. This arrangement suggests that the oxygen–hydrogen bond on the donor points directly at one of the two σ lone pairs of electrons on the acceptor oxygen. The axis of the sp^3 orbital in which that σ lone pair resides should be congruent with the line of centers. The interaction between the hydrogen–oxygen σ bond on the donor molecule of water and the σ lone pair of electrons on the acceptor is an unhindered, intermolecular example of a **hydrogen bond**. The formation of dimers and higher oligomers in steam contributes significantly to its nonideal behavior at higher concentrations of water in the gas phase.

The **ice** that is in equilibrium with liquid water at atmospheric pressure and 0 °C is known as ice Ih. Ice Ih is a **tetrahedral diamond lattice** of oxygen atoms (Figure 5-2A),⁴ each 0.276 nm from its nearest neighbor.⁷ The oxygens are held in the lattice by hydrogen bonds to each of their four nearest neighbors. Between any oxygen atom and each of its four nearest neighbors in the lattice is one hydrogen atom. At any instant, each hydrogen is covalently bound to one of the two oxygens between which it is found, and every oxygen has only two hydrogens covalently bound to it. These two requirements create a situation in which only a predictable number of arrangements for these hydrogens can occur, and this number of arrangements can explain almost exactly the observed residual entropy of ice Ih at 0 K.⁴ There is a significant amount of **empty space** in ice Ih (Figure 5-2B), and this is one of the properties permitting it to be less dense than the liquid water with which it can be in equilibrium.

The structure and properties of ice Ih and water vapor have been exhaustively investigated and unambiguously established. At atmospheric pressure, **liquid water** lies between these two extremes on the phase diagram, and its properties can be compared with them. From the transitions between solid and liquid and between liquid and vapor, insight into the structure of the liquid can be gained.

When ice melts, the reaction involves a **standard enthalpy of fusion**, and when the liquid vaporizes, the reaction involves a **standard enthalpy of vaporization**. The enthalpy of water at atmospheric pressure can be

* The relative permittivity or **dielectric constant** of a substance is its permittivity relative to the permittivity of vacuum.

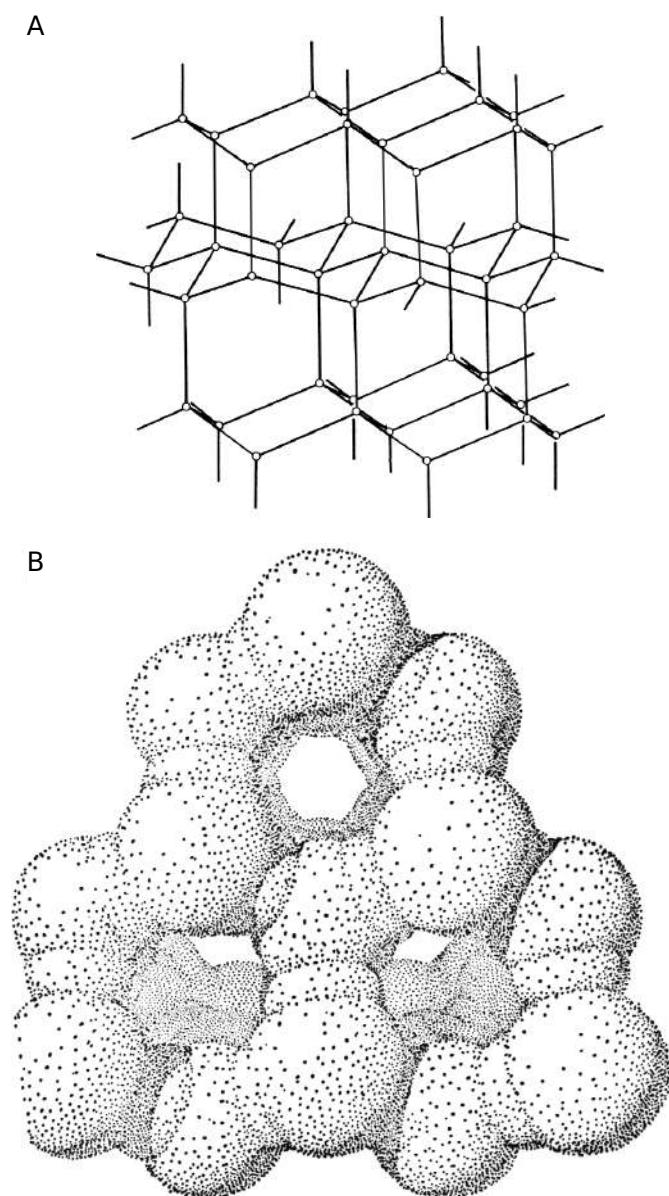

Figure 5-2: Structure of ice Ih. (A) Tetrahedral lattice.⁴ In a tetrahedral lattice, each atom or molecule occupies a position indicated by the small open circles. It forms equivalent connections with its four nearest neighbors, and because every connection is equivalent and every nearest neighbor is the same, the nearest neighbors are arrayed tetrahedrally and at equal distance. (B) Representation of space-filling models of molecules of water arrayed on the tetrahedral lattice of ice Ih. The spheres are atoms of oxygen, and the hydrogens, one for each connection of the lattice, are sandwiched between the oxygens. Reprinted with permission from ref 4. Copyright 1969 Clarendon Press.

plotted as a function of absolute temperature (Figure 5-3).⁴ On this plot, the discontinuities at the melting point and boiling point are the standard enthalpy of fusion and the standard enthalpy of vaporization, respectively. At 25 °C, the standard enthalpy of fusion is 8.0 kJ mol⁻¹, and the standard enthalpy of vaporization is 44 kJ mol⁻¹. This standard enthalpy of vaporization is more than twice that of a liquid such as chloromethane

Figure 5-3: Enthalpy ($H-H_0$), entropy ($S-S_0$), free energy ($G-H_0$), and isopiestic heat capacity (C_p) as a function of temperature for water at unit atmosphere (101.3 kPa) pressure.⁴ The quantities H_0 and S_0 are the absolute enthalpy and absolute entropy, respectively, at 0 K. Enthalpy and free energy are in units of kilojoules mole⁻¹, and heat capacity is in units of joule mole⁻¹ kelvin⁻¹. The values of entropy, also in joule mole⁻¹ kelvin⁻¹, are arbitrarily divided by 2 to put them on the same scale. Adapted with permission from ref 4. Copyright 1969 Clarendon Press.

($\Delta H_{\text{vap}} = 19 \text{ kJ mol}^{-1}$ at 25 °C), which is a polar solvent ($\epsilon_r = 13$) containing molecules incapable of forming hydrogen bonds but much larger than water (50.5 g mol⁻¹). This comparison illustrates the fact that the standard enthalpy of vaporization of water is anomalously large. In the sum of the two reactions, fusion and vaporization, all of the hydrogen bonds in ice Ih are lost. The fact that most of the standard enthalpy change occurs upon vaporization and the fact that the heat of vaporization is anomalously large suggest that liquid water retains most of the hydrogen bonds present in ice Ih.

The high isochoric **heat capacity**, C_V , of liquid water (Figure 5-3) also indicates that it is highly structured. Calculations of the isochoric heat capacities of both ice Ih and water vapor, from the known vibrational,

translational, and rotational energy levels of these two substances, agree quite closely with observed values.⁴ The observed values of the isochoric heat capacity of liquid water, however, are almost twice that calculated from its estimated vibrational, translational, and rotational energy levels (Figure 5-4).⁴ This excess or **configurational heat capacity** can be explained by postulating that much of the hydrogen-bonded structure of ice remains in the liquid and its gradual deterioration as the temperature is raised is responsible for the anomalous absorption of heat. The high and relatively constant value for the heat capacity throughout the range of temperature between 0 and 100 °C suggests that the hydrogen-bonded network in the liquid is gradually and constantly deteriorating as the temperature is rising.

Another indication of the extensive hydrogen-bonded structure in liquid water is its high static relative permittivity ($\epsilon_r = 88$ at 0 °C), which is almost equivalent to that of ice Ih ($\epsilon_r = 99$ at 0 °C). The large value for the relative permittivity of ice Ih is usually explained semiquantitatively⁴ as a result of the high correlation among the orientations of the individual dipole moments of the water molecules caused by their rigid arrangement in the hydrogen-bonded lattice. When an electric field is applied, the dipole moments reorient cooperatively, producing the large relative permittivity. The fact that the

Figure 5-4: Separation of the observed isochoric heat capacity C_V of water (solid line) into calculated (dashed line) and configurational (shaded difference) components.⁴ The heat capacity of ice Ih was calculated from the two vibrational absorption bands of lowest energy ($\nu = 840 \text{ cm}^{-1}$ and $\nu = 230 \text{ cm}^{-1}$); the heat capacity of water vapor was calculated from the vibrational, rotational, and translational energies of the water molecules; and the heat capacity of the liquid was calculated on the assumption that each molecule in the liquid has three hindered degrees of translation and three hindered librations. Adapted with permission from ref 4. Copyright 1969 Clarendon Press.

liquid has almost the same relative permittivity as the solid indicates that much of the lattice remains.

The **molar volume** of ice ($19.6 \text{ cm}^3 \text{ mol}^{-1}$) is somewhat greater than that of liquid water ($18.0 \text{ cm}^3 \text{ mol}^{-1}$) at 0 °C and much greater than the molar volume that would be expected if spheres the radius of molecules of water (0.14 nm) were randomly packed in an unstructured, disordered array ($10 \text{ cm}^3 \text{ mol}^{-1}$).⁴ The large molar volume of ice Ih is due to the vacant space created by the fact that oxygens are held in a tetrahedral array by the hydrogen-bonded network (Figure 5-2B). When ice melts, the molecules of water are allowed to occupy some of the vacant space in the hydrogen-bonded lattice and the density increases. A related fact is that the molar volume of liquid water increases as the temperature is decreased below 4 °C, presumably because the expansion caused by the strengthening of the hydrogen-bonded lattice is greater than the usual contraction experienced by most liquids resulting from the decrease in thermal energy. It is only above 4 °C that the latter effect becomes dominant. The contraction of water upon melting and the expansion of the liquid upon cooling below 4 °C are almost unprecedented. Diamond, silicon, and germanium are tetrahedral solids that also float upon their melts, as ice floats upon water. Aside from these peculiar features, the molar volumes of ice and liquid water at 0 °C are both large and not that different from each other. Consequently, much of the vacant space created by the hydrogen-bonded lattice in the solid remains in the liquid.

The fact that much of the vacant space remains in liquid water also explains the unique decrease in **isothermal compressibility** that occurs in liquid water as temperature is raised from 0 to 50 °C (Figure 5-5).⁴ The isothermal compressibility of a liquid, κ_T , is the fractional decrease in volume produced by the application of pressure at constant temperature:

$$\kappa_T = -\frac{1}{V} \left(\frac{\partial V}{\partial P} \right)_T \quad (5-3)$$

Figure 5-5: Isothermal compressibility κ_T (gigapascals⁻¹) for liquid water at unit atmosphere (101.3 kPa) pressure, presented as a function of temperature.⁴ Reprinted with permission from ref 4. Copyright 1969 Clarendon Press.

in units of reciprocal pressure (pascal^{-1}). In almost every other liquid, isothermal compressibility increases monotonically with temperature. In liquid water at low temperatures, most of the structured vacant space of ice Ih remains when the transition from solid to liquid occurs, and this structured vacant space is gradually replaced with randomly distributed, unstructured vacant space, similar to that in other liquids as the temperature is raised. The high compressibility at low temperatures results from the ability of the lattice to decrease its volume upon the application of pressure at the expense of the significant vacant space among the oxygen atoms.

The idea that liquid water at lower temperatures retains a structure similar to that of ice Ih is also supported by the small **cubic expansion coefficient** of liquid water. Upon heating at atmospheric pressure between temperatures of 20 and 30 °C, other liquids expand about 4 times more rapidly than does water (Figure 5–6).⁸ As pressure is applied, however, the cubic expansion coefficient for water increases while the coefficients of thermal expansion for other liquids decrease. At high pressures, both water and other liquids have about the same cubic expansion coefficient. If liquid water at atmospheric pressure is extensively hydrogen-bonded with an expanded structure similar to that of ice Ih (Figure 5–2B), then as the temperature is raised, the decrease in structured empty volume due to the deterioration of this hydrogen-bonded network could almost cancel the increase in unstructured volume due to increased thermal motion. As pressure is applied, however, it causes the hydrogen-bonded network to deteriorate or restructure and the liquid to have a more normal cubic expansion coefficient. In this view, the ability of pressure to

Figure 5–6: Cubic expansion coefficient for several liquids at 25 °C as a function of applied pressure.⁸ The liquids are (x) PCl_3 , (o) CH_3OH , (v) CS_2 , (•) $\text{C}_2\text{H}_5\text{Cl}$, (■) $\text{C}_2\text{H}_4\text{I}$, (Δ) $\text{C}_2\text{H}_5\text{OH}$, (▽) $\text{C}_3\text{H}_9\text{OH}$, (◆) isobutyl alcohol, and (□) $n\text{-C}_5\text{H}_{11}\text{OH}$. change the structure of the liquid is due to the fact that liquid water is in an extensively hydrogen-bonded form at normal pressures but not at higher pressures.

Such a transition between an ordered and a less ordered state caused by an increase in pressure would also explain why the application of pressure decreases the **viscosity** of liquid water rather than increasing it as it does the viscosities of other liquids.⁸ The viscosity of water is anomalously large in the first place ($\eta = 1.00 \text{ mPa s}$ at 20 °C) compared to the viscosity of liquids such as acetonitrile ($\eta = 0.36 \text{ mPa s}$ at 20 °C), pentane ($\eta = 0.24 \text{ mPa s}$ at 20 °C), and carbon disulfide ($\eta = 0.36 \text{ mPa s}$ at 20 °C).

Additional evidence for the retention of a significant fraction of the hydrogen-bonded lattice in liquid water is provided by **scattering of X-radiation**. When a beam of X-radiation is passed through a liquid, it is scattered by the electrons of the molecules in the liquid. The intensity of the scattered X-radiation varies as a function of the angle between the incident beam and the direction at which the scattered radiation emerges from the solution. This angular dependence of the intensity can be used to calculate a **radial molecular correlation function**, $G_M(r)$. This function is an approximation⁹ of the variation of electron density as a function of the radial distance from any one molecule in the liquid. The actual variation of electron density is distinguished from its approximation by designating it as $g(r)$. The function $G_M(r)$ registers any local variations in the electron density of the liquid, relative to the mean electron density of the liquid, that are maintained around any one of the molecules. Because it is a relative quantity, the value of $G_M(r)$ is unity when the electron density is equal to the mean electron density. Any variations in density that are observed are assumed to be permanent features of the structure of the liquid. As $G_M(r)$ or $g(r)$ is proportional to the electron density as a function of radial distance from a central molecule, they can be used to calculate the total number of molecules of solvent in a spherical shell between r_1 and r_2 by the integral⁹

$$n_s = \frac{p_0}{\gamma} \int_{r_1}^{r_2} 4\pi r^2 g(r) dr \quad (5-4)$$

where n_s is the number of molecules of solvent in that shell, p_0 is the bulk electron density of the liquid, and γ is the number of electrons in each molecule of solvent (10 in the case of water).

The radial molecular correlation function for liquid water has been determined over a range of temperatures from 4 to 200 °C (Figure 5–7).^{7,9,10} At fairly long distances from any one molecule of water ($>0.8 \text{ nm}$), the function becomes unity and does not vary noticeably. Therefore, beyond 0.8 nm from any given molecule the liquid is, on the average, homogeneous. A significant peak of density occurs, however, at 0.28 nm. Integration of this peak¹¹ for

Figure 5-7: Molecular correlation functions for liquid water^{7,9} and ice Ih.¹⁰ The molecular correlation functions for liquid water at several temperatures (solid lines) were calculated from the angular dependence of the intensity of the scattered X-rays from samples of pure water through which a collimated beam of X-rays was passed. A molecular correlation function for liquid molecules arranged on the lattice of ice Ih (dashed line) was calculated from the length of the hydrogen bonds in ice Ih (0.276 nm) and the fact that the oxygen atoms lie upon a tetrahedral diamond lattice. The calculation was performed with the assumption that the distributions of electron density around the maxima defined by the lattice could be approximated by error functions. The width of the first error function was made the same as the width of the first maximum in liquid water at 4 °C, and the widths of the two subsequent error functions were made proportional to the square of their distances from the origin.⁷ Adapted with permission from ref 7, originally from ref 9. Copyright 1971 American Institute of Physics.

the curve at 4 °C, upon the assumption that it is a Gaussian function, indicates that it is produced by about four nearest neighbors. In ice there are four nearest neighbors to each water molecule and they are held at a distance of 0.276 nm. It can be assumed that these are retained in the liquid. That the peak is centered at a distance so close to the hydrogen-bonded distance in ice has been interpreted to mean that each water molecule in the liquid has about four **hydrogen-bonded nearest neighbors**.

A radial molecular correlation function can be calculated¹¹ for liquid molecules of water confined to the tetrahedral lattice of ice Ih (Figure 5-7). In ice Ih, there are four nearest neighbors at 0.276 nm, 12 next neighbors at 0.45 nm, and 12 farther neighbors at 0.52 nm

(Figure 5-2). A distribution of liquid molecules of water confined to the diamond lattice of ice Ih would produce a radial molecular correlation function with a distinct minimum between the first four neighbors and the next group of 24 (Figure 5-7).¹⁰

When the radial molecular correlation functions of liquid water at 4 °C and liquid molecules of water confined to the lattice of ice Ih are compared, several differences are noted. Although still a prominent feature, the maximum in ice Ih centered at around 0.5 nm is considerably broadened in the liquid. This indicates that the hydrogen-bonded network has become considerably more elastic in water than in ice, permitting the second and third groups of neighbors to approach the molecule at the origin much more closely, rather than being held at a distance by a rigid lattice. There also seems to be too much electron density in the actual liquid between the first maximum and the second maximum.¹⁰ This has been interpreted to mean that molecules are able to break out of the lattice and become **interstitial molecules of water**, transiently occupying the vacant spaces (Figure 5-2B).¹²

So far the discussion has emphasized similarities between ice Ih at 0 °C and liquid water at low temperatures. There are, of course, remarkable differences. The most obvious is the fact that ice is a solid and water is a liquid. Even though ice Ih is a solid, however, it, like liquid water, is able to flow. In order for condensed matter to flow, layers of molecules in that matter must be able to slide past layers of other molecules above and below them. In the case of water or ice Ih the manifestation of this ability requires extensive and simultaneous disruption of continuous layers of hydrogen bonds in the liquid or solid as it flows. This capacity to flow is far more evident in water than in ice. It is quantified by values for the viscosity of the liquid and the solid. Liquid water at 0 °C has a viscosity of 1.8 mPa s, and ice Ih at 0 °C has a viscosity of about 10^{16} mPa s.^{13,14} The difference between liquid water and ice Ih is so large because, to flow, hydrogen bonds must be broken simultaneously over significant regions. There are, however, measurements that quantify the behavior of individual molecules of water.

When individual molecules in water change their relative positions, hydrogen bonds must be broken and re-formed elsewhere. The capacity to change positions is reflected in the process of self-diffusion, a measure of the rate at which the average molecule of water diffuses through a condensed phase of water molecules. The **self-diffusion coefficient** for ice Ih is about 10^{-10} cm² s⁻¹ at 0 °C, and for liquid water it is 1.4×10^{-5} cm² s⁻¹ at 5 °C.⁴ This difference of 10^5 demonstrates that water molecules can exchange their hydrogen-bonded neighbors far more rapidly in the liquid than in the solid. To the extent that this exchange involves breaking and making of hydrogen bonds, the hydrogen bonds in the liquid are weaker than those in the solid.

An even more easily understood measurement of the rate at which a molecule of water can detach itself from the hydrogen-bonded network in the liquid in order to reorient itself is the **dielectric relaxation** of liquid water. The relative permittivity of a chemical substance is a function of the frequency of the alternating electric field used to measure it. Tabulated relative permittivities are usually static relative permittivities that are measured with an alternating electric field with a frequency of alternation so low that the measured values may be confidently extrapolated to zero frequency. The low frequency of alternation allows the molecules in the substance more than ample time to align themselves, as far as they are able, with the electric field while the measurement is made. If the frequency of the applied field, however, is gradually increased, at some point the molecules in the substance are unable to invert their alignments at rates sufficient to keep up with the alternations of the applied field. Their inability to keep up results from intermolecular forces that hinder their rotation. The dielectric relaxation time is the time that an applied field must be in operation before $\exp(-1)$ of the increase in relative permittivity due to the rotation of the molecules aligning themselves with the field has occurred. The dielectric relaxation time of ice Ih at 0 °C is 2×10^{-5} s, that of liquid water at 0 °C is 2×10^{-11} s, and that of a water molecule in a dilute solution of water in benzene is 1×10^{-12} s.⁴ A similar value for the rotational correlation time of a water molecule in ice Ih (1.5×10^{-5} s at -6 °C)¹⁵ has been measured by nuclear magnetic resonance. Although a water molecule in liquid water is constrained so that it rotates 20 times more slowly than it does in a condensed phase lacking hydrogen bonds, it rotates 10^6 times faster in liquid water than in ice. This again demonstrates that the hydrogen bonds between water molecules in liquid water are weaker than those in ice.

This weakening of the hydrogen bonds in the liquid is also reflected in a shift that occurs in the frequency of the maximum **infrared absorption** of the oxygen-hydrogen stretching vibration of water when it melts.⁴ The frequency at which a covalent bond absorbs infrared electromagnetic energy is correlated with its bond energy. The greater the bond energy, the higher the frequency of the light required to excite its vibration. In the case of the stretching frequency of the oxygen-hydrogen bond in water, the stronger the hydrogen bond in which it participates, the weaker will be the covalent oxygen-hydrogen bond itself and the lower the frequency of its absorption. The **stretching frequency** of the oxygen-hydrogen bond in ice Ih is 3220 cm^{-1} , in liquid water it is 3490 cm^{-1} , and in the dilute vapor it is 3700 cm^{-1} . In the dilute vapor, no hydrogen bond weakens the oxygen-hydrogen bond. In ice Ih, a strong, fixed hydrogen bond weakens the oxygen-hydrogen bond significantly. In liquid water, less than half the decrease in frequency between the vapor and ice Ih occurs, presumably because the hydrogen bonds formed when the vapor is

converted into the liquid are weaker than the hydrogen bonds formed when the vapor is converted into the solid.

The weakening of the hydrogen bonds upon melting that is indicated by both the increases in self-diffusion and dielectric relaxation and the increase in the stretching frequency of the oxygen-hydrogen bond requires that the dissociation constant for the hydrogen bond in liquid water be significantly larger than that for ice Ih. This increase in dissociation constant upon melting may be large enough to produce a significant population of unbonded molecules of water in the liquid, presumably the interstitial water the existence of which is implied in the radial molecular correlation function.

There are infrared spectra of liquid water which suggest that there are two distinct species of oxygen-hydrogen bonds in the liquid,¹⁶ and these two species could represent intact and broken hydrogen bonds.¹⁷ It is possible to fit the temperature dependence of both these infrared spectra and the heat capacity of the liquid with a model of the liquid that assumes that there are only two types of oxygen-hydrogen bonds present, those participating in intact hydrogen bonds and those the hydrogen bonds of which are broken.¹⁷ From such a fit, the standard free energy of formation of a hydrogen bond in liquid water is estimated to be -2.0 kJ mol^{-1} at 25 °C; and the fraction of broken hydrogen bonds, 0.30 at 25 °C. From this fraction it would follow that at a given instant about 3–4% of the molecules of water would be either attached to the lattice by only one hydrogen bond or completely free of the lattice. There are, however, results suggesting both that these infrared spectra do not result from only two populations of oxygen-hydrogen bonds⁸ and that no simple two-state model can explain both the cubic expansion coefficient and the temperature coefficient of the isothermal compression of liquid water simultaneously.⁷ Consequently, the question of the molar concentration of intact hydrogen bonds in liquid water remains open.

The mental picture of liquid water that forms intuitively as its peculiarities are described is presently more adequate than any sophisticated physical model of its structure. The impression that is formed from a consideration of these properties is that liquid water retains most of the hydrogen bonds that are present in ice Ih but that these hydrogen bonds are more elastic, weaker, and break and re-form much more rapidly than those in ice Ih.

Problem 5-1: The isopiestic heat capacity of a substance, C_p , is defined as the amount of heat required to raise one mole of the substance one degree in temperature at constant pressure. The units of this quantity are joules degree⁻¹ mole⁻¹.

A substance has a certain intrinsic enthalpy at 0 K, and this intrinsic enthalpy increases as the temperature increases and the substance absorbs heat:

$$H_T - H_0 = \int_0^T C_p dT + \Delta H_{pc}$$

where H_T is the intrinsic enthalpy at $T = T$, H_0 is the intrinsic enthalpy at $T = 0$ K, and ΔH_{pc} is the sum of the enthalpy changes for all phase transitions between 0 K and T . The heat capacity of H_2O is the following function of temperature (Figure 5–3):

$$C_p = (0.172 \text{ J K}^{-2} \text{ mol}^{-1})T \quad [T = 0-60\text{K}]$$

$$C_p = 2.47 \text{ J K}^{-1} \text{ mol}^{-1} + (0.129 \text{ J K}^{-2} \text{ mol}^{-1})T \quad [T = 60-273\text{K}]$$

$$C_p = 77.5 \text{ J K}^{-1} \text{ mol}^{-1} \quad [T = 273-373\text{K}]$$

and

$$\Delta H_{\text{fus}} = 6.0 \text{ kJ mol}^{-1} \quad \text{at } 0^\circ \text{C}$$

$$\Delta H_{\text{vap}} = 40.7 \text{ kJ mol}^{-1} \quad \text{at } 100^\circ \text{C}$$

- (A) Use these experimental data to draw a graph of $H_T - H_0$ as a function of temperature from 0 to 375 K.

The intrinsic entropy of a substance is related to the heat capacity by the following equation:

$$S_T - S_0 = \int_0^T \frac{C_p}{T} dT + \Delta S_{pc}$$

where S_T is the intrinsic entropy at $T = T$, S_0 is the intrinsic entropy at $T = 0$, and ΔS_{pc} is the sum of the entropy changes for all phase transitions.

When phase transitions occur, $\Delta G^\circ = 0$ at the transition temperature. Use $\Delta H_{\text{fus}}^\circ$ and $\Delta H_{\text{vap}}^\circ$ to calculate $\Delta S_{\text{fus}}^\circ$ and $\Delta S_{\text{vap}}^\circ$.

- (B) Draw a graph of $S_T - S_0$ as a function of T .
- (C) If $G_T - G_0 = H_T - H_0 - S_T T + S_0 T$, are changes in G , as the temperature changes, greater than or less than changes in H in the case of H_2O ?

Standard States and Units of Concentration

Whenever standard entropy or its representative, standard free energy, are calculated from experimental

observations, a decision must be made on the **standard state** to be used. Unlike those of the standard enthalpy and those of the heat capacity, the numerical values of both standard entropy and standard free energy depend significantly on this choice of standard states.^{18,19} When dealing with reactants and products dissolved in solution, such as molecules of proteins and their ligands in water or alkanes in hexadecane, the choice of standard state, other than the obvious conventions of standard temperature and pressure, is a choice of the units in which the concentrations of the reactants and products are to be expressed. The desire in choosing the units for the concentrations is to eliminate any contributions to the entropy arising simply from the act of dispersing the solutes in the solvent and inescapably from the volumes of the solutes and the solvent. These contributions are the **entropy of mixing**. The reason for eliminating entropy of mixing is that the entropy that remains is the entropy of only the reaction itself and changes in the entropy of solvation that accompany the reaction.

It can be assumed, as seems reasonable, that the thermodynamic activity of benzene should be the same whether it is dissolved in octane, decane, dodecane, tetradecane, or hexadecane. It has been shown experimentally²⁰ that this assumption is valid only if the thermodynamic activity of benzene is expressed in units of **corrected volume fraction** as defined by the equation¹⁸

$$a_{A,j} = \gamma_{v,A,j} \phi_{A,j} \exp\left[1 - \left(V_{A,j}/V_j\right)\right] \quad (5-5)$$

where $a_{A,j}$ is the thermodynamic activity of solute A (benzene in the experiment) when it is dissolved in solvent j (octane, decane, dodecane, tetradecane, or hexadecane in the experiment), $\gamma_{v,A,j}$ is the activity coefficient necessary to convert real behavior into ideal behavior, $V_{A,j}$ is the volume of a mole of solute A when it is dissolved in a solution with solvent j , V_j is the volume of a mole of solvent j in the solution, and $\phi_{A,j}$ is the **volume fraction** of solute A in the solution with solvent j :

$$\phi_{A,j} = \frac{n_A V_{A,j}}{n_A V_{A,j} + n_j V_j} = [A] V_{A,j} \quad (5-6)$$

where n_A and n_j are the moles of solute A and solvent j , respectively, in the solution and $[A]$ is its molar concentration.* Most measurements of activity are performed in such a way that the activity coefficient $\gamma_{v,A,j}$ is insignificantly different from 1 or becomes 1 by extrapolation. That the thermodynamic activity of a solute should be

* One must remember that molarity is defined as moles liter⁻¹ and the volume of a mole of a substance is defined as centimeters³ mole⁻¹.

defined by Equation 5-5 was predicted theoretically^{21,22} before it was verified experimentally. Expressing activities of solutes by using Equation 5-5 can be thought of as correcting the concentration of the solute in units of mole fraction for the differences in the volumes of solute and solvent because when the volumes of a mole of solvent and a mole of solute are the same and $\gamma_{v,A,j}$ is 1, Equation 5-5 becomes

$$a_{A,j} = \frac{n_A}{n_A + n_j} = x_{A,j} \quad (5-7)$$

where $x_{A,j}$ is the mole fraction of solute A in solvent j . Equation 5-7 is **Raoult's law**.

The difficulty with the corrected volume fraction is deciding what volume to use for the volume of a mole of solute in the solution. When the solute is a liquid dissolved miscibly in a nonpolar liquid, the molar volume of the solute, V_m , which is the volume of a mole of the pure liquid solute, is a reasonable choice. If, however, the solute is a gas or a solid at the temperature of the measurement, its volume in the solution may be quite different from its volume at the temperature or pressure required to liquify it. In water, even a solute the pure phase of which is a liquid at the temperature of the measurement may have a volume in the solution that is significantly different from its molar volume. In the present discussion, the partial molar volume of the solute at infinite dilution has been chosen as an approximate estimate of the volume of a mole of the solute in the solution. Unlike the partial molar volume, however, which is only an estimate of the volume of a mole of the solute in the solution, the actual volume of a mole of the solute in the solution does not vary with the concentration of that solute.

The **partial molar volume** (centimeters³ mole⁻¹) of solute A or solvent j is defined as the increase in the volume of the solution, ∂V , that occurs when an infinitesimally small number of moles, ∂n , of solute A or solvent j is added to the solution

$$\bar{V} = \left(\frac{\partial V}{\partial n} \right)_{T,P} \quad (5-8)$$

at the concentrations of solute and solvent at which the measurement is made. If the solvent and solute are both hydrocarbons, it is usually assumed that the partial molar volumes of solvent and solute are

$$\bar{V} = \frac{M}{\rho} = V_m \quad (5-9)$$

where M is the molar mass (grams mole⁻¹) and ρ is the density (grams milliliter⁻¹) of the pure phase of the sol-

vent or the solute and V_m is the molar volume.²⁰ Equation 5-9 is also used to estimate the partial molar volumes of other solvents, including water, when solutions are dilute.

The partial molar volumes of most solutes when they are dissolved in water are significantly less than those defined by Equation 5-9.^{23,24} If the solute is a hydrocarbon, it occupies a significant portion of the empty space already present in the water (Figure 5-2). Direct measurement of partial molar volumes of hydrocarbons in water have rarely been performed, usually because such solutes are poorly soluble in water. In the absence of such measurements, the algorithms of Traube^{23,24} are used to estimate partial molar volumes of hydrocarbons in water and those of most other solutes as well.

Traube concluded from direct measurement that the partial molar volume of any neutral solute (centimeter³ mole⁻¹) when it is dissolved in water is the sum of the partial molar volumes of its atoms and functional groups plus the covolume, which is a universal correction. The partial molar volumes of the atoms and functional groups at 25 °C are for hydrogen, 3.1 cm³ mole⁻¹; carbon, 10.0 cm³ mole⁻¹; nitrogen, 1.5 cm³ mole⁻¹; the oxygen in an ether, 5.5 cm³ mole⁻¹; a hydroxyl group (-OH), 5.4 cm³ mole⁻¹; the oxygen in an amide, thioester, ketone, or aldehyde (=O) 5.5 cm³ mole⁻¹; an acyl group (-COO-), 15.9 cm³ mole⁻¹; phosphorus, 17.1 cm³ mole⁻¹; sulfur, 15.6 cm³ mole⁻¹; chlorine, 13.3 cm³ mole⁻¹; bromine, 17.8 cm³ mole⁻¹; and iodine, 21.6 cm³ mole⁻¹. From the sum of the partial molar volumes of its atoms and functional groups, 8.2 cm³ mole⁻¹ must be subtracted for each monocyclic ring, either saturated or unsaturated, and 26.6 cm³ mole⁻¹ for each bicyclic aromatic ring, such as a naphthyl group. To the final sum for the constituents of a particular molecule, a covolume of 12.5 cm³ mole⁻¹ must be added.

When ions are dissolved in water, their charge constricts the solvent in their vicinity. These electrostrictions vary between -10 and -30 cm³ mole⁻¹ for the addition of salts of monovalent ions or monovalent zwitterions.²⁴ How **electrostriction** is to be treated in estimating the volumes of ions to be used in calculating their corrected volume fractions is unclear. The volumes of their ionic solids, however, are also poor estimates of their volumes in solution.

When a reaction takes place in solution, its **equilibrium constant** can be defined by use of units of corrected volume fraction (Equation 5-5), which have the convenient advantage that they are dimensionless. For example, the equilibrium constant for the association

occurring in solvent j when activity coefficients can be ignored, would be

$$K_{\text{eq}} = \frac{a_{\text{C},j}}{a_{\text{A},j} a_{\text{B},j}} = \frac{[\text{C}]}{[\text{A}][\text{B}]} \left(\frac{\bar{V}_{\text{C},j}}{\bar{V}_{\text{A},j} \bar{V}_{\text{B},j}} \right) \exp \left(\frac{\bar{V}_{\text{A},j} + \bar{V}_{\text{B},j} - \bar{V}_{\text{C},j} - \bar{V}_j}{\bar{V}_j} \right) \quad (5-11)$$

If the reaction proceeds with no change in volume

$$\bar{V}_{\text{A},j} + \bar{V}_{\text{B},j} = \bar{V}_{\text{C},j} \quad (5-12)$$

and

$$K_{\text{eq}} = \frac{a_{\text{C},j}}{a_{\text{A},j} a_{\text{B},j}} = \frac{[\text{C}]}{[\text{A}][\text{B}]} \left(\frac{\bar{V}_{\text{A},j} + \bar{V}_{\text{B},j}}{\bar{V}_{\text{A},j} \bar{V}_{\text{B},j}} \right) \exp(-1) \quad (5-13)$$

Because the terms to the right of the quotient of the molar concentrations are not significant functions of the concentration of reactant and product, the quotient of the molar concentrations is a constant, namely, the equilibrium constant that is usually measured when units are molarity. But if entropy of mixing is to be eliminated, the equilibrium constant in units of corrected volume fraction (Equation 5-11) should be used for the calculation of the standard free energy of the reaction:

$$\Delta G^\circ = -RT \ln K_{\text{eq}} \quad (5-14)$$

If the two molecules that are associating are identical—for example, the association is the formation of a hydrogen bond between two molecules of phenol—the quotient of partial molar volumes in Equation 5-13 becomes $2\bar{V}_{\text{A}}^{-1}$, where A refers to one of the two identical molecules; if a small molecule, such as a ligand, associates with a macromolecule, such as a protein, the quotient of the partial molar volumes becomes \bar{V}_{A}^{-1} , where A refers to the ligand. These two situations, where both molecules are the same and where one is much larger than the other, respectively, are the limits on the quotient:

$$\frac{1}{\bar{V}_{\text{A},j}} < \frac{\bar{V}_{\text{A},j} + \bar{V}_{\text{B},j}}{\bar{V}_{\text{A},j} \bar{V}_{\text{B},j}} \leq \frac{2}{\bar{V}_{\text{A},j}} \quad (5-15)$$

where solute A is the smaller of the two molecules.

Another reaction in which the choice of standard state and units of concentration significantly affects the actual value of the standard free energy is the transfer of solute A from water to solvent *j*:

An aqueous phase and a phase of another solvent, for example hexadecane, are placed in contact with each other directly or indirectly. The solute of interest, for example benzene, is added to the system at low concentration, and its partition between the two phases is allowed to reach equilibrium.²⁰ The concentration of the solute in each phase is measured, and a partition coefficient, $K_{\text{p},\text{A}}$, is calculated. Although the concentration of solute A in each of the two phases is initially tabulated in units convenient to the method of measurement,²⁵ for example grams of solute (grams of solvent)⁻¹, units for the concentrations used to calculate the standard free energies of transfer, and hence the definition of standard state, has, as always, a significant effect on the magnitude of the standard free energy of transfer. If it is assumed that corrected volume fractions are the proper units and also that activity coefficients can be ignored, the **partition coefficient** for the transfer of solute A from water to solvent *j* is

$$K_{\text{p},\text{A}} = \frac{a_{\text{A},j}}{a_{\text{A},\text{H}_2\text{O}}} = \frac{\phi_{\text{A},j}}{\phi_{\text{A},\text{H}_2\text{O}}} \exp \left[\left(\frac{\bar{V}_{\text{A},\text{H}_2\text{O}}}{\bar{V}_{\text{H}_2\text{O}}} \right) - \left(\frac{\bar{V}_{\text{A},j}}{\bar{V}_j} \right) \right] \quad (5-17)$$

and the **standard free energy of transfer** is

$$\Delta G^\circ_{\text{A},\text{H}_2\text{O} \rightarrow j} = \lim_{a_{\text{A}} \rightarrow 0} -RT \ln \left(\frac{K_{\text{p},\text{A}} \bar{V}_{\text{A},\text{H}_2\text{O}}}{\bar{V}_{\text{A},j}} \right) = \lim_{a_{\text{A}} \rightarrow 0} -RT \ln \left[\frac{[\text{A}]_j}{[\text{A}]_{\text{H}_2\text{O}}} \exp \left(\frac{\bar{V}_{\text{A},\text{H}_2\text{O}}}{\bar{V}_{\text{H}_2\text{O}}} - \frac{\bar{V}_{\text{A},j}}{\bar{V}_j} \right) \right] \quad (5-18)$$

The limit defines the standard state as the solutions at infinite dilution, a condition at which both activity coefficients are 1 and can definitely be ignored.

The goal of the rather complex definitions of activities and hence standard states that has just been described is to arrive at a value for the standard free energy of transfer that is only the difference between the **standard free energy of solvation** for solute A by solvent *j* and the standard free energy of solvation for solute A by water.¹⁸ The use of Equation 5-5 for thermodynamic activities eliminates the contributions of the entropies of mixing to the standard free energy of transfer. The quotient $\bar{V}_{\text{A},\text{H}_2\text{O}}/\bar{V}_{\text{A},j}$ in Equation 5-18 corrects for the work performed when the volume of the system increases as solute is transferred from water to solvent *j*. In order to focus only on standard free energies of solvation, the conditions must be such that solute A is surrounded entirely by either molecules of water or molecules of solvent *j*, and no molecule of

either solute A or the molecules of water or solvent that surrounds it is affected in its behavior by the presence of another molecule of solute A. This is the reason for the limit in Equation 5-18, which defines the standard state of infinite dilution. In this way, the only contributions to the difference in standard free energy of solvation are the specific interactions between the molecule of solute A and the solvent j or the water.

The choice of units of concentration and standard state is also critical in calculating the transfer of a solute from the gas phase to a solution. The usual choice of standard state for the solution in such a reaction is the solute at infinite dilution in the solvent so that the solute is fully solvated and no interactions occur among the molecules of solute. The usual choice of standard state for the gas is the real gas extrapolated to zero pressure in order to eliminate the nonideal behavior of the real gas represented by its virial coefficients. Because of the proportionality between molarity and pressure, the practical units of concentration for a gas are usually pressure, but the thermodynamic activity of the gas should be defined as its molarity.¹⁸

To avoid both the standard entropy of mixing and changes in volume at constant pressure during the transfer of solute from the gas phase to a solution, the volume occupied by a mole of the solute in the gas phase would have to be equal to the volume occupied by a mole of the solvated solute in the solution.^{18,26} Consider a large volume of solution at standard state in contact with a large volume of the gaseous solute. Only when the pressure of the gas is such that 1 mol of gaseous solute has the same volume as the partial molar volume of the solute in the solution will the volume of the system not change when 1 mol of solute is transferred from the gas to the solution at constant pressure. Only under these circumstances is the transfer both isochoric and isobaric. As a result, the standard entropy of mixing is 0, no work is performed by the system, and the transfer occurs at constant pressure. To achieve this condition, the gas must be compressed mathematically to a volume equal to the partial molar volume of the solute in the solution. The standard free energy change for the compression of the gaseous solute to a volume equal to its partial molar volume in the solution is

$$\Delta G^\circ_{\text{compression}} = -RT \ln([A]_g \bar{V}_{A,j}) \quad (5-19)$$

where $[A]_g$ is its molar concentration in the gas phase

$$[A]_g = \frac{p_A}{2.479 \text{ kPa L mol}^{-1}} \quad (5-20)$$

where p_A is the partial pressure (pascals) of the gaseous solute A at 25 °C. When all of these considerations are combined with Equation 5-5,¹⁸ the equation for the stan-

dard free energy of transfer of solute A from the gas phase to a solution in solvent j , $\Delta G^\circ_{A,g \rightarrow j}$, becomes

$$\Delta G^\circ_{A,g \rightarrow j} = -RT \ln \left[\frac{\phi_{A,j}}{[A]_g \bar{V}_{A,j}} \exp \left(1 - \frac{\bar{V}_{A,j}}{\bar{V}_j} \right) \right] = -RT \ln \left[\frac{[A]_j}{[A]_g} \exp \left(1 - \frac{\bar{V}_{A,j}}{\bar{V}_j} \right) \right] \quad (5-21)$$

Again, the intention of Equation 5-21 is to apply the appropriate corrections so that the standard free energy of transfer is only the standard free energy of solvation for solute A by solvent j .

Ionic Interactions

The possibility that a positively charged cation might interact favorably with a negatively charged anion and bring two molecules or two segments of the same polypeptide together has a lasting appeal. Such an association seems plausible because, as everyone knows, unlike charges attract each other. When a positive ion in a solution encounters a negative ion and a complex between these two ions is formed, it is referred to as an **ion pair**. In terms of Equation 5-1, a hydrated ion pair forms whenever a hydrated anion associates with a hydrated cation. In this reaction, the various changes of standard free energy identified in Equation 5-2 can be separately considered by writing the following thermodynamic cycle:

It is easiest to consider the **changes of standard enthalpy** first because they constitute the main contribution to the changes in standard free energy and they have been measured least ambiguously. The standard enthalpy change when a positive ion and a negative ion associate in the gas phase, $\Delta H^\circ_{A^+,B^-}$, is governed by electrostatics. To the extent that the Born-Haber cycle is able to provide accurate estimations of crystal lattice energies

only from simple electrostatic theory,²⁷ the **standard enthalpy of formation of an ion pair in the gas phase** from the two separated ions, A^+ and B^- , if electron repulsion is ignored, should be

$$\Delta H^\circ_{A^+, B^-} = (z_{A^+})(z_{B^-})e_a^2 \left(\frac{1}{a_{A^+} + a_{B^-}} \right) N_A \quad (5-23)$$

where z_{A^+} and z_{B^-} are the charge numbers of the ions, e_a is the elementary charge (1.602×10^{-19} C), and a_{A^+} and a_{B^-} are the radii of the two ions. Values for the ionic radii in crystalline lattices, based on crystallographic studies of salts,²⁸ are usually used for a_{A^+} and a_{B^-} .^{7,29} The standard enthalpy of formation defined by Equation 5-23 can be presented for monovalent ions ($z_{A^+} = -z_{B^-} = 1$) as a function of the sum of the two ionic radii (Figure 5-8).

When an ion is transferred from the gas phase to water, there is a large release of heat.* This large negative change in standard enthalpy is referred to as the **standard enthalpy of hydration**, $H^\circ_{\text{hyd(l)}}$. Measurements of these standard enthalpies of hydration have been tabulated⁷ for a number of monovalent, divalent, and trivalent spherical ions. The values for the spherical monovalent cations and anions can be presented as a function of their ionic radii (Figure 5-8).

The large negative **standard enthalpies of hydration for ions** are commonly explained to be the result of the ability of the fixed charge on an ion to gather around itself a layer of tightly held molecules of water that are oriented either with the positive ends of their dipoles, their hydrogens, toward an anion or the negative ends of their dipoles, their lone pairs, directed toward a cation (Figure 5-9). This explanation is probably incorrect. From measurements of the standard enthalpy of formation for complexes between monovalent cations in the gas phase and 1-7 molecules of water, it has been concluded³⁰ that about four molecules of water are sufficient to hydrate a cation such as NH_4^+ , H_3O^+ , H_2COH^+ , Li^+ , or Na^+ . This result suggests that the innermost shell of the **layer of hydration** around an ion is not large. Furthermore, when the standard enthalpy changes for the formation of 1:1 complexes between a molecule of water and various cations and anions in polar nonaqueous solvents were determined, the values observed were quite small ($0 > \Delta H^\circ > -13$ kJ mol⁻¹).³¹ These two results suggest that the large standard enthalpies of hydration observed for ions arise far more from the influence exerted by the ion over a significant region of the water surrounding it than from the specific, intimate noncovalent contacts between the ion and its immediate neighbors.

In electrostatics the **self-charging energy** is the

* This large release of heat when any ion is transferred from the gas phase to water should not be confused with the small releases or absorptions of heat that occur when the ions in the solid crystals of a salt are dissolved in water.

Figure 5-8: Electrostatic enthalpies and standard enthalpies of hydration. The standard enthalpy change for bringing together a monovalent cation and a monovalent anion in a vacuum is presented as a function of the sum of the two respective ionic radii (solid dark line), as calculated from Equation 5-23. The standard enthalpies of hydration⁷ for monovalent cations (\square) are presented as a function of their ionic radii. The ions are, in order of increasing radius, Li^+ , Na^+ , K^+ , Rb^+ , and Cs^+ . The line connecting the points is drawn by hand. The standard enthalpies of hydration⁷ for monovalent anions (\circ) are presented as a function of their ionic radii. The ions are, in order of increasing ionic radius, F^- , Cl^- , Br^- , and I^- . The line connecting the points is drawn by hand. The standard enthalpy change for the hydration of a monovalent ion of either charge, based on the assumption that the standard enthalpy of hydration is due only to the difference in self-charging energies in the vacuum and in water (Equation 5-25), is presented as a function of ionic radius (dark dashed line). All enthalpies are presented in kilojoules mole⁻¹ for a standard temperature of 25 °C.

Figure 5-9: Schematic drawing of molecules of water with the negative ends of their dipoles directed toward a cation and the positive ends of their dipoles directed toward an anion.

energy required to charge a sphere of a given radius a in a medium of relative permittivity ϵ_r .³² The self-charging energy, E_{sc} , for placing the charge $z_j e_a$ on an ion j of radius a_j would be

$$E_{\text{sc}} = \frac{z_j^2 e_a^2}{2a_j \epsilon_r} N_A \quad (5-24)$$

The standard enthalpy change $\Delta H^\circ_{\text{sc}}$ associated with the electrostatic energy required to move an ion from the vacuum ($\epsilon_r = 1$) to water ($\epsilon_r = 78$) at 25 °C would be the difference in the two self-charging energies:

$$\Delta H^\circ_{\text{sc}} = \frac{z_j^2 e_a^2}{2a_j} \left(\frac{1}{\epsilon_{r,\text{H}_2\text{O}}} - 1 \right) N_A \quad (5-25)$$

This standard enthalpy change for a monovalent ion can be presented as a function of ionic radius (Figure 5–8). It can be seen that, for a sphere of unit elementary charge, the value of the difference in self-charging energy between the vacuum and a medium the relative permittivity of which is equal to that of water is close to the experimentally observed standard enthalpy of hydration for a spherical anion (○) of the same radius.

The observed standard enthalpies of hydration for the cations, however, are less than the values expected from differences in self-charging energies. The large differences between $\Delta H^\circ_{\text{sc}}$ and $\Delta H^\circ_{\text{hyd(A}^+)}$ have been explained as being due either to increases in the “effective radius”³³ of the cations or to decreases in the “effective dielectric constant around the ion.”³⁴ Which of these views is more realistic is unknown. Nevertheless, self-charging can explain the shapes and slopes of the curves connecting the experimental values for standard enthalpies of hydration and the majority if not all of the absolute value of each. Because Equation 5–25 accounts for the majority of the standard enthalpy of hydration for simple ions and because it is the large bulk relative permittivity of water that causes the result to be so large, it follows that it is the bulk dielectric of the water, rather than local interactions, that is responsible for the large standard enthalpies of hydration.

The **bulk relative permittivity** of any solvent is a measure of the macroscopic response of that solvent to a fixed electrostatic charge. Consequently, in the calculation of Equation 5–25, a solvent is treated as a uniform continuum and no account is taken of the properties of its individual molecules. The high relative permittivity of water, however, is actually a result of the cooperative behavior of the molecules of water in the liquid over a significant volume. Because the high relative permittivity of water arises from the correlation of the individual dipoles of the molecules of water, the necessity to rely on that relative permittivity to explain the large enthalpy of hydration means that an ion influences the structure of the water over a significant distance, not just in its immediate vicinity.

The **standard enthalpy of hydration for a monovalent ion pair**, $\Delta H^\circ_{\text{hyd(A}^+\text{B}^-)}$, can be estimated from electrostatic theory just as standard enthalpies of hydration were estimated. It should be equal to the difference between the sum of the standard enthalpies of charging

the two ions separately and the standard enthalpy of bringing them to within a certain distance of each other:

$$\Delta H^\circ_{\text{hyd(A}^+\text{B}^-)} = \frac{e_a^2}{2} \left(\frac{1}{a_{\text{A}^+}} + \frac{1}{a_{\text{B}^-}} - \frac{2}{d_{\text{A}^+\text{B}^-}} \right) \left(\frac{1}{\epsilon_{r,\text{H}_2\text{O}}} - 1 \right) N_A \quad (5-26)$$

where $d_{\text{A}^+\text{B}^-}$ is the distance between the monovalent ions in the ion pair; when the two ions are as close together as possible, $d_{\text{A}^+\text{B}^-}$ equals $a_{\text{A}^+} + a_{\text{B}^-}$. It can be shown that

$$\frac{0.828}{a_0} < \left(\frac{1}{a_{\text{A}^+}} + \frac{1}{a_{\text{B}^-}} - \frac{2}{a_{\text{A}^+} + a_{\text{B}^-}} \right) \leq \frac{1}{a_0} \quad (5-27)$$

where a_0 is the radius of the smaller of the two monovalent ions. It follows that the standard enthalpy of hydration for a monovalent ion pair is slightly less than the standard enthalpy of hydration for the smaller of the two ions alone.³²

The overall change in standard enthalpy for the formation of an ion pair in aqueous solution should be

$$\Delta H^\circ_{\text{IP}} = \Delta H^\circ_{\text{A}^+\text{B}^-} + \Delta H^\circ_{\text{hyd(A}^+\text{B}^-)} - \Delta H^\circ_{\text{hyd(A}^+)} - \Delta H^\circ_{\text{hyd(B}^-)} \quad (5-28)$$

From an examination of Figure 5–8, it becomes clear that for monovalent ions this change in standard enthalpy is a small difference between several large numbers, and its value could be either positive or negative. This conclusion, that the standard enthalpy change has a small value, is supported by estimating the electrostatic energy involved in bringing two monovalent ions of opposite charge together in a medium with a uniform relative permittivity equal to that of water:

$$\Delta H^\circ_{\text{IP}} \cong \frac{e_a^2}{\epsilon_{r,\text{H}_2\text{O}}} \left(\frac{1}{a_{\text{A}^+} + a_{\text{B}^-}} \right) N_A \quad (5-29)$$

For $a_{\text{A}^+} \geq 0.1 \text{ nm}$ and $a_{\text{B}^-} \geq 0.1 \text{ nm}$, $-9 \text{ kJ mol}^{-1} < \Delta H^\circ_{\text{IP}} < 0 \text{ kJ mol}^{-1}$.

These changes in standard enthalpy do demonstrate quite clearly why an ion pair sequestered in the middle of a folded polypeptide would be unstable relative to the separated hydrated ions in solution. The only reason an ion pair is almost stable in aqueous solution is that there is considerable standard enthalpy of hydration for the ion pair itself, $\Delta H^\circ_{\text{hyd(A}^+\text{B}^-)}$. In the center of a pro-

tein, this standard enthalpy of hydration would not be exerted and the ion pair would be much less stable. There will never be sufficient electrostatic energy in the ion pair alone to overcome the large negative standard enthalpies of hydration that are lost when the separated ions are removed from water during the folding of the protein. This fact can be verified by examining Figure 5–8. The total standard enthalpy of hydration lost is the sum of the two values for the individual enthalpies of hydration. The standard enthalpy of association gained is that for the sum of the two ionic radii. The former is always of a greater magnitude than the latter.

The **standard entropies of hydration**,³⁵ in marked contrast to the standard enthalpies of hydration, are small. Values of the entropies of hydration for a series of small monovalent ions of either charge lie between -67 and $+21 \text{ J K}^{-1} \text{ mol}^{-1}$ when the two standard states are chosen as the molten salt at one mole fraction in the ion and the ideal solution at one mole fraction in the ion.³⁵ At 298 K, these standard entropies of hydration would cause the standard free energies of hydration to differ from enthalpies of hydration by less than 4%, certainly less than the error in the estimation of enthalpies of hydration from experimental data.⁷

The small standard entropies of hydration seem at first glance to be inconsistent with the formation of a region of oriented water around an ion, which is the explanation given for the large standard enthalpies of hydration. The apparent inconsistency is usually explained by noting that the region of oriented molecules of water surrounding either an anion or a cation cannot merge flawlessly with the hydrogen-bonded lattice of the bulk water. Therefore, there must be an outer spherical shell of disorder between the inner sphere of order and the order of the lattice beyond the influence of the ion. The negative standard entropy change of forming the sphere of oriented water should be canceled by the positive standard entropy change of forming this outer shell of the disordered transition.⁷

Explanations of the large enthalpies of hydration and the small entropies of hydration both predict that an ion will affect the **structure of the water** well beyond the few molecules in its immediate vicinity. Direct evidence for such an extended region of oriented water comes from measurements of the repulsion of hydration.^{36,37} When two identical surfaces that have dense arrays of both negative and positive ions spread over them—both, however, in exactly equal concentration so that each of the two surfaces is electrostatically neutral—are brought together in water, a repulsive force between the surfaces is evident. This repulsive force becomes significant when the two surfaces come within about 2 nm of each other and increases in magnitude exponentially as the distance is decreased. It has been proposed that this repulsive force is the resistance of the layers of hydration around the ions on each surface to their interpenetration. That this **repulsion of the layers of hydration** extends out from each sur-

face by at least 1 nm indicates that each ion orders the waters around it over a significant distance.*

In the case of molecules of protein, the ion pairs that have received the most attention are those that would form between the carboxylate ion of an aspartate or a glutamate and the ammonium ion of a lysine or the guanidinium ion of an arginine. The association constant in water³⁸ for the ion pair between an acetate ion and an ammonium ion is around 0.5 M^{-1} , and that for the ion pair between an acetate ion and a guanidinium ion is somewhat less than 0.5 M^{-1} . Consequently, the concentration of either an ammonium or a guanidinium cation would have to be greater than 2 M for half of the acetate anion in the solution to be complexed with it. These weak interactions have free energies of formation of around -3 kJ mol^{-1} when the concentrations are expressed in units of corrected volume fraction. They are probably the result of hydrogen bonding between the anion and cation rather than ionic interactions, because the complex is stronger for ammonium than guanidinium and there is no evidence that small monovalent cations and anions that lack donors and acceptors of hydrogen bonds associate to form ion pairs in water.

Several additional observations demonstrate that ion pairs between an ammonium ion and a carboxylate ion are unstable relative to the separated ions. The dielectric increment is the change in the relative permittivity of a solution with the concentration of an added solute. The dielectric increments for a series of zwitterionic amino acids containing an ammonium and a carboxylate, namely, glycine, 3-aminopropionate, 4-aminobutyrate, 5-aminopentanoate, and 6-aminohexanoate, have been measured. The values display a monotonic increase with the number of methylenes between the positively charged ammonium ion and the negatively charged carboxylate ion. The values observed are in agreement with theoretical calculations of their magnitude from a simple model in which the distance between the elementary positive charge and the elementary negative charge is determined only by random, unbiased rotation around the carbon-carbon bonds connecting them.²⁴ Were the formation of an ion pair between an ammonium cation and a carboxylate anion a favorable interaction in aqueous solution, this regularity could not have occurred. In glycine, an intramolecular ion pair cannot form. In 3-aminopropionate and 4-aminobutanoate, excellent intramolecular ion pairs, forming rings five and six atoms in size, should form even more readily than a similar intermolecular ion pair. If these intramolecular ion pairs were able to form, how-

* The distance of this repulsive force (1 nm) is about the distance (0.7 nm) calculated for the decrease in the electrostatic field around a univalent ion in water to a potential energy equal to kT . If an ion significantly influences the water around it to a radius of about 1 nm, this region of its influence would contain about 100 molecules of water.

ever, the dielectric increments of these two amino acids should both be less than that of glycine, yet no anomaly is observed in their dielectric increments compared to the other compounds within the complete series. The behavior of the interaction volumes for the same series of amino acids also shows no evidence of peculiarities that would result from intramolecular ion pairing.³⁹

There is no steric hindrance to the formation of an ion pair between the ammonium ion of the lysine in the peptide *N*^α-acetyl-WLKLL and its carboxy terminus, and such an intermolecular ion pair forms readily when the peptide is dissolved in octanol. When the peptide is dissolved in water, however, no ion pair can be detected.⁴⁰

Although ion pairs do not have net favorable standard free energies of formation in aqueous solution and do not contribute to the stability of a folded polypeptide, the **electrostatic repulsion** of amino acids of like charge can destabilize a particular structure. This distinction is illustrated by the effect of ionic strength on the stability of coiled coils of α helices.⁴¹ A coiled coil of α helices is a stable structure that forms when two α helices coil around each other in a supercoil. This supercoil can stabilize the two α helices sufficiently that they can form in water. Few isolated α helices are stable in aqueous solution, but a coiled coil is one way to circumvent this problem. A series of peptides designed to form coiled coils were synthesized chemically. One of the peptides ($n_{aa} = 30$) had glutamates at the positions flanking its hydrophobic core; the other ($n_{aa} = 30$) had arginines flanking the core. The stability of the heterodimeric coiled coil formed from a positively charged peptide and a negatively charged peptide was not affected by changing the ionic strength, and this result indicated that electrostatic interactions such as ion pairing were not contributing to the standard free energy of formation of that coiled coil. The stabilities of homodimers formed from either two of the positively charged peptides or two of the negatively charged peptides, however, decreased significantly as the ionic strength of the solution was lowered, and this result demonstrates that these complexes were destabilized by charge repulsion. It is this destabilization of the two homodimers, not the formation of ion pairs, that accounts for the fact that the heterodimer forms preferentially.⁴¹

Proteins are generally dissolved in aqueous solutions the **ionic strengths** of which are between 0.1 and 0.3 M, and the effect of such ionic strengths on ionic interactions, although small, should be noted. The activity coefficients of electrolytes decline sharply from a value of 1 at low concentrations to minimum values, depending on the salt, of from 0.05 to 0.8 at concentrations of about 0.3 M.⁴² When activity coefficients of solutes are less than 1, it means that the solute is behaving with a chemical potential less than it would have if it were an ideal solute at the same concentration, and its tendency to leave the solution is less than it should be.

The fact that, at low concentrations, the activity coefficients of ions are near 1 means that as long as they are far enough apart their activities increase in proportion to their concentration as expected for any solute. As their concentrations become high enough that each ion begins to experience the presence of the others, the presence of the others decreases the tendency of that ion to leave the solution. This decreased tendency arises from the departure of all of the ions in the solution from a random distribution in such a way that a region enriched in counterions forms around each individual ion as expected of an ionic double layer (Equation 1-71).⁴² These enriched counterionic layers around each dissolved ion make each of them more stable in the aqueous solution than it would be if it were an ideal solute, and this is what causes the decrease in its activity coefficient.

This effect of ionic strength makes the formation of an ion pair even less likely than it would be in the absence of added salt, because its formation would involve the diminishment of a considerable fraction of the counterionic layer around each separated ion. The presence of these ionic layers also makes it more difficult to remove an ionic functional group from a solution of moderate ionic strength than it would be to remove it from pure water. The activity coefficients for most ionic solutes are between 0.2 and 0.8 at the ionic strengths encountered in biochemical situations, and these values should lead to decreases in the standard free energies of hydration between -4 and -0.4 kJ mol⁻¹, respectively.⁴²

Although ion pairs between simple monovalent cations and anions have positive standard free energies of formation, there are two situations in which ion pairs are favorable. Ion pairs involving **divalent metal ions** often have negative standard free energies of formation. For example, significant concentrations of the ion pairs $\text{Ca}^{2+} \cdot \text{SO}_4^{2-}$ and $\text{Mg}^{2+} \cdot \text{SO}_4^{2-}$ are present in aqueous solutions of the respective salts, and ion pairs between divalent cations such as Ba^{2+} , Ca^{2+} , and Mg^{2+} and hydroxide ion in aqueous solution show appreciable stabilities.²⁹ There are, however, no divalent side chains among the 20 natural amino acids. Phosphorylated amino acids, such as serine phosphate (**2-30**), are divalent at high pH and can readily form ion pairs with divalent cations such as Ca^{2+} .

The other situation in which ion pairs become favorable is encountered when **chelation** can occur. Chelation is the binding of an ion to a molecule, the chelating agent. The chelating agent contains two or more functional groups of opposite charge to the bound ion that can simultaneously associate with it, or it contains two or more dipoles that simultaneously can be favorably directed toward the bound ion, or it contains some combination of such charges and dipoles. The paradigm of chelating agents is *N,N,N',N'*-tetracarboxymethyl-1,2-diaminoethane:

which can wrap its nitrogens and carboxylates around a divalent or trivalent metal ion and form an ion pair of high stability. It has already been mentioned that the binding of monovalent cations and anions by proteins is thought to involve particular binding sites that have advantageous dispositions of functional groups, often with charge opposite to the charge on the bound ion. Chelation, however, assumes a preexisting arrangement of two or more charged groups or dipoles that create a pocket within which an ion can be held, and this arrangement does not exist in an unfolded polypeptide or with isolated anions and cations in solution. Chelation could be important in forming an interface between two already folded polypeptides or binding a charged substrate to an already folded enzyme.

Problem 5-2: Calculate the standard enthalpy changes for the transfer of a sodium ion ($a_{\text{Na}^+} = 0.097$ nm) and a chloride ion ($a_{\text{Cl}^-} = 0.181$ nm), respectively, from the gas phase ($\epsilon_r = 1$) to water at 25 °C ($\epsilon_{r,\text{H}_2\text{O}} = 78$ at 25 °C). Calculate the standard enthalpy changes for the formation of an ion pair between a sodium ion and a chloride ion in the gas phase and for the transfer of that ion pair from the gas phase to water. By difference, calculate the standard enthalpy of formation of an ion pair between a sodium ion and a chloride ion in water.

Problem 5-3: Consider the series of six compounds $\text{H}_3\text{N}^+(\text{CH}_2)_n\text{COO}^-$, where $n = 1-6$. Within each of these molecules there is a carboxy group and an amino group, which bear opposite charges at pH 7. The elementary negative charge on the carboxy group is located between the two oxygens.

- (A) For each compound, construct with molecular models the conformation of the molecule in which the positively charged nitrogen is positioned as close as possible to one of the negatively charged oxygens.
- (B) In which of the molecules is it possible to form an ion pair that juxtaposes NH_3^+ and O^- ?

The dipole moment (μ) of a particular molecular structure that contains fixed charges is equal to the product of

the magnitude of the charges $z_j e_a$ and the distance, r , that separates them: $\mu = z_j e_a r$. In each structure you have made, $z_j e_a$ is the same but r changes.

- (C) Examine the structures you have drawn and rank them in order of increasing dipole moment. Indicate ranking with the symbols $<$ and $=$.

The observed dipole moments for these molecules dissolved in water at pH 7.0 are⁴³

n	1	2	3	4	5	6
μ	12 D	15 D	18 D	20 D	22 D	24 D

- (D) Explain why the actual dipole moments for these molecules fail to agree with the theoretical predictions that you made in part C.

The Hydrogen Bond

A **hydrogen bond** is a noncovalent force that arises between an acid, known as the donor, A-H , and a base, known as the acceptor, :B . The atoms A and B in the case of proteins are the **heteroatoms** oxygen, nitrogen, and sulfur. A hydrogen bond is an intermediate on the trajectory of an acid–base reaction:^{44,45}

The two central complexes in Equation 5-30 are each held together by a hydrogen bond, but the overall reaction is the transfer of a proton between two lone pairs of electrons. An example of this relationship between a hydrogen bond and an acid–base reaction is the self-dissociation of water. In the liquid most of the water molecules participate in hydrogen bonds, and these hydrogen bonds are the intermediate steps in the production of a hydroxide anion and a hydronium cation. The anion and the cation are produced when the proton in a hydrogen bond between two molecules of water moves momentarily from donor to acceptor and the hydrogen bond between the new donor, the hydronium ion, and the new acceptor, the hydroxide ion, dissociates to yield the free species.

Manifestations of hydrogen bonding are the alterations it effects in the physical and chemical properties of liquids, gases, and solids. The nonideal behavior of certain gases can be explained by the existence of hydrogen-bonded oligomers of the molecules composing the

gas. The water dimer (Figure 5–1) is an example of such a situation; its existence lowers the pressure of water vapor. Abnormally positive values for the standard enthalpy of vaporization or abnormally negative values for the standard enthalpy of mixing can often be explained as the result of either the breaking of hydrogen bonds as the molecules depart the liquid or the formation of hydrogen bonds as a donor and acceptor are mixed, respectively. When an acceptor is added to a solution of a donor, the infrared spectrum of the resulting mixture often displays a new absorption band, at a lower frequency than the absorption of the A–H stretching vibration observed with the solution of the donor alone. This new absorption increases in magnitude in proportion to the amount of acceptor added, while the amplitude of the absorption of the unshifted stretching vibration of the A–H bond of the donor decreases in proportion. The new stretching vibration is assigned to that of the A–H covalent bond within a hydrogen bond between the donor and the added acceptor. A similar observation is made in nuclear magnetic resonance spectra of mixtures of donors and acceptors. In this case, two separate absorptions are not observed because the rates at which the hydrogen bonds are interchanging among the molecules in the solution are faster than the time resolution of the method, but the chemical shift of the proton participating in the A–H bond moves down-field until it reaches a maximum value, associated with the chemical shift of the proton within the hydrogen bond.

Taken together, these commonly encountered observations demonstrate three features of a hydrogen bond. First, a hydrogen bond causes two molecules to associate with each other and form a complex that prevents them from changing their relative positions as readily as they would otherwise; in other words, it correlates their movements. Second, there is a release of heat associated with the formation of this complex. Third, the proton in the A–H covalent bond of the donor experiences a change in its environment during the formation of this complex. The results of both infrared and nuclear magnetic resonance spectroscopy are consistent with a lengthening of the covalent bond between A and H concomitant with a movement of the proton away from the electrons of the σ bond.

The arrangement of the atoms in **crystallographic molecular models** of small molecules that display these physical manifestations of hydrogen bonding usually displays a pattern that can be assigned to the hydrogen bond itself. The positions in the unit cell of the atoms of the second and third periods of the periodic table, for example, carbon, nitrogen, oxygen, and sulfur, are determined by X-ray crystallography, and the positions of the protons, often as deuterons, are determined most reliably by neutron diffraction. Whereas a proton has little ability to scatter X-rays, inasmuch as it has no core electrons, a deuteron scatters neutrons as readily as a

carbon or an oxygen;⁴⁶ and deuterons are prominent features in maps of neutron scattering density, as opposed to hydrogens in maps of electron density. Furthermore, a proton has a negative scattering amplitude for neutrons while a deuteron has a positive scattering amplitude. This causes difference maps of neutron scattering density for deuterated against protonated molecules to display sharp maxima where the protons are located in the former.

In crystallographic molecular models of small molecules known to be hydrogen-bonded, the bond is recognized as an enforced orientation of the donor and acceptor (Figure 5–10).⁴⁷ Associated with this orientation are certain bond lengths and bond angles.⁴⁶ It is these bond lengths and bond angles that are the most important property of a hydrogen bond as far as the structures of proteins are concerned. The hydrogen bond provides no net standard free energy to the process of folding a polypeptide, but hydrogen bonds are responsible for aligning atoms and holding them at precise distances and constrained angles to each other in the folded structure. The A–H σ bond of the donor in a hydrogen bond is pointed at the heteroatom B of the acceptor. The distance, d , between A and B is always less than it would be if the proton on the donor atom and the atom acting as the acceptor were simply in van der Waals contact. For example, in a hydrogen bond of the type O–H \cdots N (Equation 5–30), the distance between oxygen and nitrogen is 0.28 ± 0.01 nm,⁴⁶ while the distance between carbon and nitrogen in a van der Waals contact of the type C–H \cdots N would be 0.35 nm. It is this shortened distance between donor and acceptor that reflects the bonding. The **bond lengths**, d , for most types of sterically unconstrained hydrogen bonds (Table 5–1) between neutral donors and neutral acceptors lie between 0.25 and 0.30 nm, but the bond angles are more variable.

In general, the angle α between the axis of the hydrogen bond and one of the σ covalent bonds to the heteroatom of the donor, A (Figure 5–10A), will reflect

Table 5–1: Length of Hydrogen Bonds^a

A–H \cdots B	compounds	average bond length ^b (nm)

^aThe values in this table are reproduced directly from tables in ref 46. With the exception of the hydrogen bonds involving ammonium cations, these are hydrogen bonds between a neutral donor and a neutral acceptor. ^bThese are the distances between the heteroatoms, nitrogens or oxygens. ^cThese standard deviations may be standard deviations of actual lengths or standard deviations of the measurement or both.

Figure 5-10: Relationships defining bond angles for hydrogen bonds.⁴⁷ (A) In a simple hydrogen bond between a donor AH and an acceptor $\odot B$, the line of center between heteroatoms A and B creates an axis, which is the axis of the hydrogen bond. The angle a is the angle between that axis and a σ covalent bond to the heteroatom A. The angle b is the angle between that axis and a σ covalent bond to the atom B. The distance d is the length of the hydrogen bond. (B, C) For a hydrogen bond between an amide nitrogen and a carbonyl oxygen or an acyl oxygen, the carbonyl or acyl group defines a plane. The bond angle b is the angle in the plane between the carbon–oxygen double bond and the projection of the axis of the hydrogen bond on the plane. In panel C, the lower dotted line shows the projection of the axis of the hydrogen bond on the plane. The bond angle c is the angle between this projection and the axis of the hydrogen bond. For a hydrogen bond between a nitrogen–hydrogen donor and the σ covalent bond of a carbonyl oxygen and acyl oxygen, the bond angle b can vary over a range bounded by the two lone pairs of electrons on the oxygen if the oxygen is otherwise unoccupied. (E) In several instances, the axis of the σ bond between the heteroatom of the donor and the proton lies between two lone pairs of electrons from two different heteroatoms, and one donor interacts with two acceptors in a bifurcated hydrogen bond.

the hybridization of that heteroatom, while the angle b between the axis of the bond and one of the σ covalent bonds to the heteroatom of the acceptor, B, although much more flexible than angle a , will tend to reflect the hybridization of the lone pair of electrons on atom B.

The type of hydrogen bond that accounts for the majority of those in biological macromolecules, both proteins and nucleic acids, is the hydrogen bond between the sp^2 lone pair on an acyl oxygen as an acceptor and the nitrogen–hydrogen bond of an acyl derivative such as an amide or an amidine as a donor (Figure 5-10B). From the crystallographic molecular models of 1500 intermolecular hydrogen bonds between either a carbonyl oxygen or an acyl oxygen and such a nitrogen–hydrogen bond, the bond lengths and **bond angles** were compiled.⁴⁷ For the collection of all such hydrogen bonds examined, the mean nitrogen–oxygen distance, d , was 0.297 nm. If it is assumed that the acyl or carbonyl carbon and its three σ bonds define a plane and that the line of centers between the nitrogen and oxygen of the hydrogen bond defines a line, two angles define the hydrogen bond: angle b , the angle in the plane between the projection upon the plane of the line and the carbon–oxygen double bond (Figure 5-10B); and angle c , the angle that the line of centers between the nitrogen and oxygen makes with the projection of that line of centers on the plane of the acyl group (Figure 5-10C). Angle c determines how far the nitrogen is above or below the plane, and $d \sin c$ is the actual distance the nitrogen is above or below the plane. In the hydrogen bonds examined, the nitrogen atom was usually within 0.1 nm ($\sin c = 0.33$) of the plane defined by the acceptor (Figure 5-11).⁴⁷ If the carbonyl oxygen or acyl oxygen participates as the acceptor in two hydrogen bonds, there is a strong tendency for angle b to be 120° (Figure 5-11B), the angle expected from an sp^2 hybridization of its two lone pairs.

If the carbonyl oxygen or acyl oxygen, however, participates as an acceptor in only one hydrogen bond, angle b will still show a slight preference for 120° but the angle can also assume other values between 120° and 180° with almost equal facility (Figure 5-11A). It is as though the nitrogen–hydrogen bond can **pivot** over the electron cloud formed by both lone pairs when the other one of them is not forming another hydrogen bond (Figure 5-10D), and the location it eventually assumes in the crystal is determined by forces other than the hydrogen bond itself. This apparent ability of a nitrogen donor to associate with two lone pairs on the same atom may be related to its ability to participate in a **bifurcated hydrogen bond**⁴⁸ in which it associates with two lone pairs from separate atoms (Figure 5-10E). The fact that the nitrogen is not confined strictly to the plane of the acyl group (Figure 5-11), although it has a strong preference for that plane, demonstrates that the nitrogen–hydrogen dipole can also pivot up or down out of the plane about a single lone pair (Figure 5-10C) or about two lone pairs (Figure 5-11A).

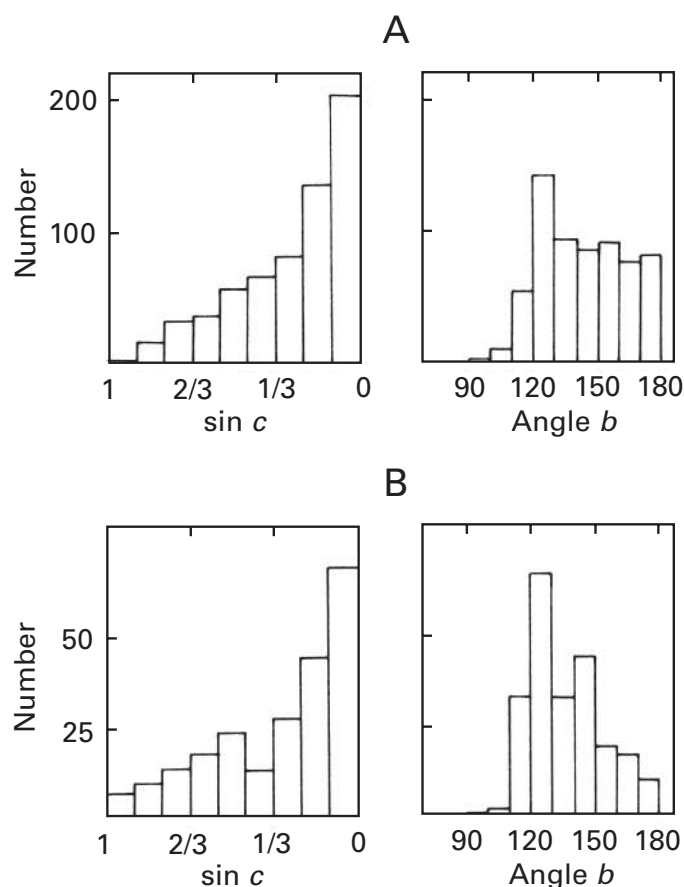

Figure 5-11: Distribution of values for the angle b (Figure 5-10B) and the sine of angle c (Figure 5-10C) over a population of hydrogen bonds between nitrogen-hydrogen donors and carbonyl oxygen acceptors or acyl oxygen acceptors observed in crystallographic molecular models of small molecules.⁴⁷ (A) Hydrogen bonds involving a carbonyl oxygen or acyl oxygen in which the oxygen atom accepts no other hydrogen bonds. (B) Hydrogen bonds involving a carbonyl oxygen or acyl oxygen in which the oxygen atom accepts one other hydrogen bond. In each of the four panels, the number of bonds falling within a range of values is plotted as the value of the ordinate. In the two left panels, the values on the abscissa defining the ranges are values of the sine of angle c ($\sin c$). In the two right panels, the values on the abscissa defining the ranges are values of the angle b in degrees. Adapted with permission from ref 47. Copyright 1983 American Chemical Society.

All of the observations presented in Figure 5-11 are for acyl oxygens that are not in carboxylates. In the case of the oxygens in **carboxylates**, such as those on the side chains of aspartate and glutamate, the tendency for the nitrogen to reside in the plane of the carboxylate is lessened and the tendency for angle b to assume 120° is increased.⁴⁷ Although it has been proposed that a *syn* pair of electrons on a carboxylate (Equation 2-12) should be more basic than an *anti* pair, no preference is shown for one over the other in forming hydrogen bonds in crystallographic molecular models of small molecules⁴⁹ or proteins.⁵⁰

The shift in frequency of the infrared absorption for an oxygen-hydrogen stretching vibration has been used to examine the effect of stereochemistry on the strength

of **intramolecular hydrogen bonds**.⁵¹ A series of pyridines substituted at the *o*-position by $-\text{CH}_2\text{OH}$, $-\text{CH}_2\text{CH}_2\text{OH}$, or $-\text{CH}_2\text{CH}_2\text{CH}_2\text{OH}$ were examined. These functional groups can form hydrogen-bonded rings with the pyridine nitrogen that are four, five, or six atoms in size, respectively, when the proton is not counted. All three compounds display an absorption that could be assigned to a shifted OH stretching vibration. The hydrogen bonds increase in strength, as indicated by the shift in wavelength of the OH stretching frequency ($\Delta\nu = 192$, 203, and 357 cm^{-1} , respectively), as the ring becomes larger. The ring with six atoms, the only one large enough to permit the hydrogen bond to be linear, display the largest frequency shift, an observation consistent with its being the strongest. This result suggests that, in a cyclic hydrogen-bonded structure, the hydrogen bond should be considered as a somewhat longer and more flexible covalent bond between the two heteroatoms, and the proton should not be counted as one of the atoms in the ring.

There has been some disagreement over the ability of **sulfur** to participate as an acceptor in a hydrogen bond because of the poor overlap between its atomic orbitals and those of nitrogen or oxygen. In a survey of crystallographic structures for a number of compounds in which nitrogen donors and sulfur acceptors both appear,⁵² juxtapositions were frequently observed and these were consistent with hydrogen bonds of the type $\text{NH}\cdots\text{S}$. The most telling observation in favor of the existence of such hydrogen bonds was the fact that the nitrogen-sulfur distances ($0.33\text{--}0.35\text{ nm}$) were shorter than the distance expected from purely van der Waals contact.

The pairs of electrons in π bonds in a simple olefin or a phenyl ring are less basic than the σ lone pairs on the acyl oxygen in a secondary amide ($\text{p}K_a = -0.5$)⁵³ or the oxygen of a molecule of water ($\text{p}K_a = -1.7$). The values of $\text{p}K_a$ for the conjugate acids of ethene and propene are -24.3 and -19.3 , respectively.⁵⁴ The values of $\text{p}K_a$ for the conjugate acids in which a carbon in the ring is protonated are -24.3 for benzene, -16.3 for benzofuran, -10 for 3-hydroxy-5-methyltoluene, -7.8 for 3-hydroxyphenol, -5.8 for 3,5-dihydroxytoluene, and -3.1 for 3,5-dihydroxyphenol.^{54,55} From these values, the values of $\text{p}K_a$ for the conjugate acids of a phenylalanyl side chain and a tyrosyl side chain, in which a carbon in the ring is protonated, should be around -20 and -13 . The phenyl ring of a tryptophanyl side chain should have a $\text{p}K_a$ somewhat greater than that of a tyrosyl side chain. The differences between the values of $\text{p}K_a$ for donor and acceptor in the hydrogen bonds between two water molecules or between two molecules of *N*-methylacetamide, however, are already large, around $17\text{--}18$ units, so it would not be surprising if the differences in $\text{p}K_a$ required to use one of these aromatic side chains as an acceptor, although even larger, would still permit the formation of a hydrogen bond.

There are indications that hydrogen bonds can

form between the π clouds of **aromatic rings as acceptors** and biologically relevant donors.⁵⁶ In the complex between water and benzene in the gas phase, the water sits upon the π cloud with the positive end of its dipole oriented towards the ring and its two hydrogens lie 0.1 nm closer to the plane of the ring than van der Waals contact should allow.⁵⁷ All of these features suggest that a hydrogen bond has been formed. There are crystallographic studies of other complexes that also suggest that hydrogen bonds between a hydroxyl group and the π electrons of an aromatic ring do form,^{58,59} and theoretical calculations suggest that a hydrogen bond between an amido nitrogen–hydrogen and a phenyl ring could be as much as half as strong as a normal hydrogen bond between an amido nitrogen–hydrogen and a σ lone pair of electrons.⁶⁰

Associated with any hydrogen bond are two **wells of potential energy** (Figure 5–12), the well of potential energy for a proton within the lone pair of the donor and the well of potential energy for a proton within the lone pair of the acceptor. As there is only one proton between the donor and the acceptor, only one of the two wells is occupied at any given instant. When the proton is located in a particular well, it is participating in a covalent bond with the heteroatom to which the well belongs. When in that covalent bond the proton cannot have an energy less than that of the lowest or first vibrational energy level, and it is usually occupying that level. Because energy is quantized, the energy of the first vibrational level is above the bottom of the well of potential energy. The energy of the first vibrational level is the **zero-point energy** of the bond to which the well applies.

Figure 5–12: Overlap of wells of potential energy for the covalent bonds between the proton and the heteroatom of the donor (left panel) and between the proton and the heteroatom of the acceptor (right panel) in a hydrogen bond. In a case where the values of pK_a for donor and acceptor are matched, the zero-point energies (thin horizontal lines) are the same. (Left panel) If the distance between donor and acceptor is long, the intersection of the two wells of potential energy is above the zero-point energy and there is a barrier to transfer of the proton between the wells (arrow pointing to the left). The proton divides its time between the wells and the two mean positions it assumes are separated by d_{HH} , the distance between the bottoms of the two wells. (Right panel) If the distance between donor and acceptor is short, the intersection between the two wells is below the zero-point energy and the barrier to transfer between the wells (arrow pointing to the left) is no longer effective. The proton (H) is found halfway between donor and acceptor.

In the separated donor and acceptor, these two wells of potential energy are also present and are the wells of potential energy associated with protonating the acceptor or protonating the conjugate base of the donor. As the donor and acceptor approach each other, these wells of potential energy overlap. The point of their intersection (Figure 5–12) is the height of the barrier of potential energy that must be crossed if the proton is to be transferred from donor to acceptor (Equation 5–30). The more closely the heteroatom of the donor and the heteroatom of the acceptor approach each other, the lower will be this barrier.

The difference in the zero-point energies between the well for the donor and the well for an oxygen–hydrogen bond in the hydronium ion is the standard enthalpy change associated with the pK_a of the donor; the difference between the zero-point energies of the well for the conjugate acid of the acceptor and the well for the hydronium ion is the standard enthalpy change associated with the pK_a of the acceptor; and the difference in zero-point energies of the well for the donor and the well for the acceptor is the standard enthalpy change associated with the difference in pK_a (ΔpK_a) between them. If the difference in pK_a between donor and acceptor is small, the two wells of potential energy will have about the same minimum; or better yet, if the acceptor is the conjugate base of the donor, the two wells of potential energy will be mirror images of each other. In such situations, as the heteroatoms are brought closer together, the barrier between them decreases rapidly until it is equal to or less than the zero-point energy (Figure 5–12). When this occurs, the two wells become continuous, as far as the proton is concerned, even though there are still two minima of potential energy. Hydrogen bonds in which the distance between the heteroatoms of donor and acceptor approaches but does not necessarily reach this point at which the barrier vanishes are **low-barrier hydrogen bonds**.

In a hydrogen bond in which the distance between donor and acceptor has become short enough that the barrier has vanished, the two wells have become one and the proton necessarily occupies a position midway between the two heteroatoms.⁶¹ A number of such hydrogen bonds have been observed by neutron diffraction in the crystalline state. When the same hydrogen bond in which the proton is found to be centered in the crystalline state is formed in solution, however, the proton is usually not centered^{62,63} because **solvation** of the bond is more favorable for the situation in which the proton is closer to one of the heteroatoms than to the other.⁶⁴ It is as if solvation has recreated the barrier, probably by biasing the relative energies of the occupied and unoccupied wells at a given instant even if they are identical when unoccupied. When the proton is transferred to the other heteroatom, the change in solvation causes the levels of the wells to switch. Because water strongly solvates dipoles, a barrierless hydrogen bond in

which the proton is centered between the heteroatoms and in which the distinction between donor and acceptor has disappeared rarely if ever exists in water.⁶³

The **length of the covalent bond A–H** between the proton and the heteroatom of the donor is longer when it is in a hydrogen bond than when it is not. In a series of hydrogen bonds of the same type (Figure 5–13),⁶⁵ regardless of whether they are intermolecular or intramolecular examples of the class,⁶⁵ as the distance d_{AB} between the two heteroatoms in a hydrogen bond decreases, the length of the bond between the proton and the heteroatom of the donor increases^{66,67} from its length when it is not hydrogen-bonded (horizontal dashed lines) until the bond becomes so short that the proton sits halfway between donor and acceptor (Figure 5–12). There are several physical measurements that register this increase in the length of the bond between the proton and the heteroatom of the donor as the bond shortens.

The movement of the proton away from the heteroatom of the donor that occurs as the hydrogen bond is formed decreases the electron density of the covalent bond surrounding that proton, and this **deshielding** shifts its peak of absorption downfield in a **nuclear magnetic resonance** spectrum. In a series of hydrogen bonds

Figure 5–13: Length of the bond between the proton and the oxygen atom of a donor [$d(\text{O}–\text{H})$] in a hydrogen bond between two oxygens as a function of the distance between the oxygen atom of the acceptor and the proton [$d(\text{H}\cdots\text{O})$].⁶⁵ Crystallographic molecular models of complexes containing either intermolecular or intramolecular hydrogen bonds between two oxygens were retrieved from the Cambridge Crystallographic Database. The types of complexes collected were carboxylic acid–carboxylates (○), metal oximes (□), inorganic acid salts (×), hydronium hydroxyls (+), β -diketone enols (■), carboxylic–carboxylics (▲), alcohols (◇), and ice Ih (△). The dashed diagonal line in the upper left-hand corner is drawn for $d(\text{O}–\text{H}) = d(\text{H}\cdots\text{O})$. In the shortest hydrogen bonds, $d(\text{O}–\text{H})$ does equal $d(\text{H}\cdots\text{O})$, the proton sits halfway between donor and acceptor, and donor and acceptor are indistinguishable. As the hydrogen bond increases beyond a length of about 0.24 nm, the proton is closer to the more basic oxygen, and donor and acceptor become distinguishable. The horizontal dashed lines indicate the range of the values for the length of an oxygen–hydrogen bond in an isolated, non-hydrogen-bonded molecule in the gas phase.

of the same type, as the hydrogen bond becomes shorter and the proton moves farther away from the heteroatom of the donor and becomes even more deshielded, its chemical shift becomes even larger.⁶⁸ An absorbance in nuclear magnetic resonance spectroscopy between 16 and 24 ppm for a proton demonstrates that it is in a low-barrier hydrogen bond. For example, chemical shifts of 20.5 ppm for the proton between the two oxygens in hydrogen maleate monoanion (5–2),

of 16.1 ppm for the proton between the two oxygens of the enol of 2,4-dioxopentane (5–3), and 18.5 ppm for the proton between the two nitrogens in hydrogen 1,8-diamino-*N,N,N',N'*-tetramethylnaphthalene monocation (5–4), each measured in organic solvents,⁶⁹ indicate that these are low-barrier hydrogen bonds, as do their lengths (0.241, 0.243–0.251, and 0.258 nm, respectively).^{70–75}

When the donor enters into a hydrogen bond and its A–H bond becomes longer, the force constant for its stretching vibration becomes smaller and the frequency at which it absorbs infrared light becomes lower than when it is not in a hydrogen bond. Consequently, the peak of absorption for the A–H bond of the donor when it is in a hydrogen bond appears in the **infrared spectrum** at a lower frequency than the peak of absorption for the free A–H bond of the donor. The existence of these two distinct peaks of absorption allows the concentrations of bonded and unbonded donor to be quantified (Problem 5–7). In a series of hydrogen bonds of the same type, as the hydrogen bond becomes shorter and the A–H bond becomes longer, the **stretching frequency** of the A–H bond decreases.

The **fractionation factor** ϕ is the equilibrium constant defined by

$$\phi = \frac{[\text{AD}\cdots\text{B}][\text{L}_2\text{O}\cdots\text{HOL}]}{[\text{AH}\cdots\text{B}][\text{L}_2\text{O}\cdots\text{DOL}]} \quad (5-31)$$

where H is protium, D is deuterium, and L is either protium or deuterium. AD \cdots B is the hydrogen bond between the deuterated donor and the acceptor, L₂O \cdots HOL is a hydrogen bond between two molecules of water in which a proton is within the hydrogen bond, AH \cdots B is the hydrogen bond between undeuterated donor and acceptor, and L₂O \cdots DOL is a hydrogen bond between two mol-

ecules of water in which a deuteron is within the hydrogen bond. A fractionation factor of less than 1 indicates that a proton has a greater preference than a deuteron for sitting in the hydrogen bond being examined, relative to the preferences of proton and deuteron for sitting in a hydrogen bond between two molecules of water. The fractionation factor scales the relative preferences of proton and deuteron for any hydrogen bond to their relative preferences for the reference hydrogen bond between two water molecules, much as the acid dissociation constant scales the basicity of any lone pair of electrons to the basicity of a lone pair of electrons on a molecule of water. The fractionation factor is measured by following the concentration of the protonated form of the hydrogen bond of interest as the mole fraction of H₂O is varied in mixtures of H₂O and D₂O.⁷⁶

In a series of hydrogen bonds of the same type, as the distance between the heteroatoms of donor and acceptor decreases, so does the fractionation factor.⁷⁷ This decrease states that as the hydrogen bond becomes shorter, the proton has a greater and greater preference for its occupation relative to that of a deuteron. A value of less than 1 indicates that the hydrogen bond is a short, low-barrier hydrogen bond. The fractionation factors for the hydrogen bonds in hydrogen maleate monoanion (5-2) and hydrogen 1,8-diamino-*N,N,N',N'*-tetramethylnaphthalene monocation (5-4) are 0.84 and 0.90 in water.^{78,79} The fractionation factor for aqueous FHF⁻, which contains one of the shortest hydrogen bonds, is 0.60.⁸⁰ Fractionation factors for hydrogen bonds in organic solvents, however, can be as small as 0.4.⁸¹

The chemical shift, the stretching frequency, and the fractionation factor all monitor the length of the hydrogen bond. They do not, however, provide any indication of its strength.

The strength of a hydrogen bond is expressed in thermodynamic parameters. The **standard enthalpy of formation**, or the heat released when the bond forms, is a measure of the electronic strength of the bond. It is usually the property that is referred to when the **strength of the bond** is discussed indiscriminately. The standard free energy of formation determines the degree to which the hydrogen bond will be favored over the unbonded reactants. Its magnitude is complicated by the fact that it is a function of both the standard enthalpy of formation, the electronic term, and the standard entropy of formation, the quantitative measure of the total change in disorder occurring during the reaction. The standard entropy of formation is usually a negative term because order increases when hydrogen bonds are formed. It is also affected significantly by changes in solvation. In addition, the standard entropy of formation depends on the choice of units for concentration because of the entropy of mixing. The association equilibrium constant, which is usually the quantity that is directly measured, is connected directly to the standard free energy of formation, not to the standard enthalpy of formation.

Ordinarily, the values of these thermodynamic properties are obtained systematically.⁴⁶ A method of measurement, such as infrared spectroscopy, is used to provide values for the molar concentration of free donor, [HA], the molar concentration of free acceptor, [B⊙], and the molar concentration of hydrogen bonds, [B⊙HA], in a solution. The total concentrations of donor and acceptor are systematically varied at a given temperature, and the experimental association equilibrium constants are measured for each set of concentrations:

$$K_{\text{AHB}} = \frac{[\text{B}\odot\text{HA}]}{[\text{B}\odot][\text{HA}]} \quad (5-32)$$

From the **association equilibrium constant** at a particular temperature converted into the proper units (Equation 5-13), the standard free energy of formation of the hydrogen bond can be calculated (Equation 5-14). The variation of the equilibrium constant with temperature is determined experimentally, and from these observations, the standard enthalpy of formation of the hydrogen bond can be calculated:

$$\left(\frac{\partial \ln K}{\partial T^{-1}} \right)_P = - \frac{\Delta H^\circ_{\text{AHB}}}{R} \quad (5-33)$$

Finally, the **standard entropy of formation** is calculated from the experimental results by the relationship

$$\Delta S^\circ = \frac{\Delta H^\circ - \Delta G^\circ}{T} \quad (5-34)$$

The standard enthalpies of formation for hydrogen bonds between uncharged donors and acceptors of biological interest (Table 5-2) lie between -12 and -23 kJ (mol of bond)⁻¹ when the donor and acceptor are dissolved in organic solvents such as CCl₄ or benzene. In spite of these favorable standard enthalpies of formation, the equilibrium constants for the formation of the complexes in a similar set of hydrogen bonds, disregarding those that involve two hydrogen bonds, are quite small when expressed in units of molarity⁻¹ (Table 5-3). When expressed in units of corrected volume fraction (Equations 5-5 and 5-13) to eliminate entropy of mixing, the values are somewhat larger. The small magnitude of these values results from the fact that the negative standard enthalpy of formation is canceled to a considerable degree by a negative standard entropy of formation because even though the correction for volume fraction takes care of the entropy change involved in their finding each other, the two molecules still must reach the proper relative orientations so that the bond can form. Even in the best of circumstances, a hydrogen bond is a weak interaction.

The standard enthalpy of formation of a hydrogen bond is a function of the **difference in pK_a** between the

donor and the acceptor.²⁹ For example, a reference donor, *p*-fluorophenol, was chosen, and a series of acceptors were used to form hydrogen bonds with this donor in CCl₄ at 25 °C.^{82,83}

The correlation between standard enthalpy of formation and $\text{p}K_{\text{a}}$ for these hydrogen bonds was⁸³

$$\Delta H^\circ_{\text{AHB}} = (-1.3 \text{ kJ mol}^{-1})\text{p}K_{\text{a}} + b_j \quad (5-36)$$

where b_j (kilojoules mole⁻¹) assumes different values for each category of base examined; for example, b_j has different values for carbonyl oxygens, pyridines, and primary amines. Within a particular category, however, the standard enthalpies of formation are linearly related by Equation 5-36.* This correlation states that as the acceptor becomes a stronger base (as the $\text{p}K_{\text{a}}$ of its conjugate acid becomes larger), the hydrogen bond becomes stronger (the standard enthalpy of formation becomes more negative).

A closely related correlation also exists between the standard free energy of formation and the $\text{p}K_{\text{a}}$ for hydrogen bonds between *p*-fluorophenol and various bases of different $\text{p}K_{\text{a}}$.⁸²

$$\Delta G^\circ_{\text{AHB}} = (-1.3 \text{ kJ mol}^{-1})\text{p}K_{\text{a}} + c_j \quad (5-37)$$

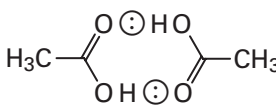

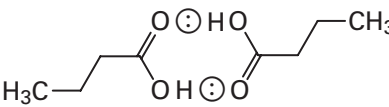

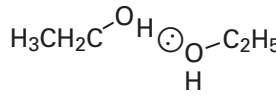

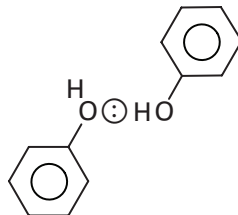

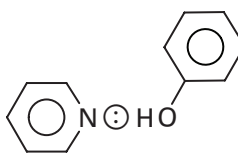

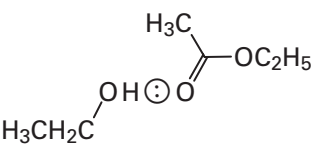

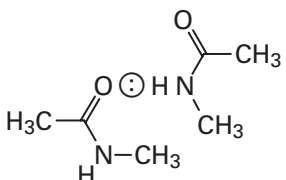

where c_j (kilojoules mole⁻¹) again assumes a different value for each category of bases. The standard enthalpy of formation⁸³⁻⁸⁵ and the standard free energy of formation⁸⁶ of a hydrogen bond are also linearly related to the $\text{p}K_{\text{a}}$ of the donor in similar experiments in which a common acceptor and a systematic series of donors were used (Figure 5-14).⁸⁷

It has been observed that when the infrared stretching frequencies of the A-H bond in a particular donor are examined as a function of the values of $\text{p}K_{\text{a}}$ for the conjugate acids of a set of acceptors, the stretching frequencies of the donor, which monitor the strength of the A-H bond, decrease linearly as the acceptor becomes a stronger base.^{88,89} This observation is consistent with the fact that as an unconstrained, intermolecular hydrogen bond becomes stronger, it also becomes shorter.

If one considers the situation of a hydrogen bond in which the acceptor remains the same and a series of donors of increasing acidity is examined, the standard enthalpy of formation of the hydrogen bond will decrease linearly as the $\text{p}K_{\text{a}}$ of the donor decreases until

* This correlation is an example of the common practice of relating thermodynamic properties to the acid dissociation constant. When the correlation is between the respective values of $\text{p}K_{\text{a}}$ the logarithms of a set of equilibrium and constants (Figure 5-14), the slope is a dimensionless number referred to as the **Brønsted coefficient**. When the correlation is between the values of $\text{p}K_{\text{a}}$ and enthalpies or free energies, the slope of the correlation is the Brønsted coefficient multiplied by $2.303RT$ (kilojoules mole⁻¹). When the correlation is between the values of $\text{p}K_{\text{a}}$ and entropies, the slope of the correlation is the Brønsted coefficient multiplied by $2.303R$ (kilojoules mole⁻¹ kelvin⁻¹). The units on the slope should be consistent with the comparison being made.

Table 5-3: Association Constants of Hydrogen Bonds

hydrogen bond	solvent	temperature (°C)	$K_{\text{AHB}} (\text{M}^{-1})^a$	$K_{\text{AHB}} (\text{cvf})^b$
	benzene	30	130	1680
	benzene	30	430	3420
	CCl ₄	25	0.64	8.1
	CCl ₄	21	2.3	19
	CCl ₄	20	55	480
	CCl ₄	25	1.7	17
	benzene	25	6.2	60

^aValues are copied directly from tables in ref 46. ^bValues for the the association constant given in the dimensionless units of corrected volume fraction (Equation 5-13).

the $\text{p}K_{\text{a}}$ of the donor is equivalent to the $\text{p}K_{\text{a}}$ of the conjugate acid of the acceptor. If the acidity of the donor is increased further, the proton will be transferred between donor and acceptor, the conjugate acid of the former acceptor becomes the new donor, and the conjugate base of the former donor becomes the new acceptor. If the $\text{p}K_{\text{a}}$ of the former donor is decreased below the $\text{p}K_{\text{a}}$ of the conjugate acid of the former acceptor, the standard enthalpy of formation for the hydrogen bond, because donor and acceptor have switched roles, will begin to increase. A corresponding argument could be made for the situation in which the donor remains the same and a series of acceptors, the conjugate acids of which increase in $\text{p}K_{\text{a}}$, is examined. From these considerations and the

fact that $\Delta G_{\text{AHB}}^{\circ}$ tracks $\Delta H_{\text{AHB}}^{\circ}$, it follows that the strength of the hydrogen bond, as measured by its association equilibrium constant K_{AHB} , is determined by the difference in $\text{p}K_{\text{a}}$ between the donor and the conjugate acid of the acceptor (Figure 5-14); the smaller the difference, the stronger the bond. If this is the case, it must follow that the **strongest possible hydrogen bond** in a given series is the one in which the $\text{p}K_{\text{a}}$ of the donor is equal to the $\text{p}K_{\text{a}}$ of the conjugate acid of the acceptor. The most obvious examples of such a hydrogen bond are those between a donor and its conjugate base.

It is important to note, however, that such a **symmetric hydrogen bond**, even one between a donor and its conjugate base, is no stronger than would be pre-

Figure 5-14: Association constants K_{AHB} in tetrahydrofuran for the hydrogen bonds between either 3,4-dinitrophenolate ion (\circ) or 4-nitrophenolate ion (\square) (5-5) and a series of phenols acting as donors as a function of the difference in the values of $\text{p}K_{\text{a}}$ ($\Delta\text{p}K_{\text{a,H}_2\text{O}}$) for the donor and the conjugate acid of the acceptor.⁸⁷ In tetrahydrofuran, the absorptions of both the 3,4-dinitrophenolate ion and the 4-nitrophenolate ion shift from 420 to 388 nm upon formation of a hydrogen bond. As donor is added to the solution, the absorbance at 420 nm decreases and that at 388 nm increases with a clear isosbestic point. The molar concentrations of free donor ($[\text{HA}]$), free acceptor ($[\text{B}\ominus]$), and hydrogen bond ($[\text{B}\ominus\text{HA}]$) were calculated from the ratio of the two absorbances (see Problem 5-7). The logarithms of the association constants (K_{AHB}) in units of molarity^{-1} calculated in this way are plotted as a function of the difference between the respective values of the $\text{p}K_{\text{a}}$ ($\Delta\text{p}K_{\text{a,H}_2\text{O}}$) as measured in water. These values of $\Delta\text{p}K_{\text{a,H}_2\text{O}}$ are expected to be proportional to those in tetrahydrofuran.

dicted by the relationship between the difference in $\text{p}K_{\text{a}}$ and the association constant K_{AHB} (as indicated by the points on the ordinate in Figure 5-14). A similar continuous increase in the strengths of hydrogen bonds has been observed in the gas phase as the difference in the proton affinities of the donors and acceptors decreases again, however, with no evidence for a discontinuity when they are matched.⁸⁰ It has also been observed that the downfield shift of the proton in the hydrogen bonds between 1-methylimidazole and a series of carboxylic acids passes through a maximum with no obvious discontinuity as a function of the $\text{p}K_{\text{a}}$ of the carboxylic acids.⁹⁰

There are at least two ways that the distance between a donor and acceptor in a particular type of hydrogen bond can be shortened. If the hydrogen bond is an intermolecular one, anything that increases its strength will cause it to shorten. If the hydrogen bond is an intramolecular one, the structure of the molecular

scaffold supporting that hydrogen bond can physically compress it. The consequences of these two effects are quite different and should not be confounded.

In a simple, unconstrained, intermolecular hydrogen bond, such as the one between 4-nitrophenolate ion and 4-nitrophenol (5-5 and Figure 5-14)

the distance between donor and acceptor is established by two opposing forces. The short-range, unfavorable potential energies of repulsion between the electrons of the structure and between the three nuclei in the hydrogen bond push donor and acceptor apart. The longer-range, favorable potential energy of attraction between the monopole and dipole and the overlap energies of any covalent bonding pull donor and acceptor together. As with any ionic or covalent bond, it is this tradeoff between longer-range attraction and shorter-range repulsion that defines the **minimum in potential energy** that sets the length of the bond (Figure 5-15).⁹¹ These potential energies are unrelated to the wells of potential energy confining the proton.

Strong intermolecular hydrogen bonds such as the ones in FHF^- ($d_{\text{FF}} = 0.226 \text{ nm}$) and $\text{H}_2\text{OHOH}_2^+$ ($d_{\text{OO}} = 0.236 \text{ nm}$)⁹² are short hydrogen bonds because the monopoles and dipoles are large and the repulsive energies become dominant only at shorter distances. Such

Figure 5-15: An estimate of the energy of formation of a hydrogen bond as a function of the distance between the heteroatom of the donor and the heteroatom of the acceptor.⁹¹ The calculations were for the energy of formation of a hydrogen bond between two molecules of water in the gas phase (Figure 5-1). The variation of that estimate of the energy as a function of the distance between the two oxygens is presented.

hydrogen bonds are special cases that are irrelevant to hydrogen bonds in a molecule of protein at neutral pH. Other hydrogen bonds between acids and their conjugate bases, however, are more relevant to the acids and bases found in a protein (Table 5–4). The hydrogen bond between an acid of a type found in proteins and its conjugate base is about 0.02–0.03 nm shorter than the hydrogen bond between the neutral acid and itself or an equivalent functional group on a different molecule (Table 5–1) because it is a stronger hydrogen bond (Figure 5–14). It seems reasonable that such **strong, short hydrogen bonds**—for example, that between the imidazole of histidine and the imidazolium of another histidine or between the carboxylate of a glutamate and the carboxylic acid of another glutamic acid—should be found in crystallographic molecular models of proteins, but they are rarely observed, probably because the neutralization of the cationic acid or the anionic base required to produce the acceptor or the donor, respectively, requires more free energy at neutral pH than would be gained by forming the stronger hydrogen bond.

It is also possible to shorten a hydrogen bond by physically compressing it within a covalent framework. A number of intramolecular hydrogen bonds are short because of such compression. For example, the hydrogen bond in hydrogen maleate monoanion* (0.241 nm)^{70–72} is shorter than the unconstrained hydrogen bond between two hydrogen fumarate monoanions* (0.247 nm),^{102–105} and that in hydrogen 1,8-diamino-*N,N,N',N'*-tetramethylnaphthalene cation (0.258 nm) is

Table 5–4: Lengths of Hydrogen Bonds between Acids and Their Conjugate Bases^a

acid or conjugate base	bond length (nm)
<i>p</i> -nitrophenol ⁹³	0.246
8-hydroxyquinoline ⁹⁴	0.243
pentachlorophenol ⁹⁵	0.244
	0.248 ^b
1-(<i>p</i> -hydroxyphenyl)thianium ⁹⁶	0.247
cyclohexylamine ⁹⁷	0.280
1,10-diaminodecane ⁹⁸	0.280 ^c
<i>N,N,N</i> -tris(2-aminoethyl)amine ⁹⁹	0.280 ^c
	0.285
<i>N</i> -methylimidazole ¹⁰⁰	0.265
hydrogen succinate ¹⁰¹	0.244 ^d

^aValues presented in this table were gathered during a search of the Cambridge Structural Database by Dr Hens Borkent at the Catholic University of Nijmegen.

^bTwo different hydrogen bonds in the same unit cell. ^cHydrogen bond between two monocations of the diamine or triamine, respectively. ^dHydrogen bond between two hydrogen succinates.

* The crystallographic molecular models on which these measurements are based were gathered from the Cambridge Structural Database by Dr Hens Borkent at the Catholic University of Nijmegen.

shorter than the unconstrained hydrogen bond between a dimethylalkylamine and its dimethylalkylammonium cation* (0.264 nm).¹⁰⁶ Both of these **short intramolecular hydrogen bonds** display downfield chemical shifts (20.5 and 18.5 ppm) and fractionation factors less than 1 (0.84 and 0.90). In a comparison between intramolecular and intermolecular hydrogen bonds between carboxylate anions and the corresponding carboxylic acid or between enols of β -diketones and the corresponding carbonyl oxygen,⁶⁵ the ranges of lengths of intramolecular hydrogen bonds (0.239–0.242 and 0.243–0.255 nm, respectively) were about 0.006 nm shorter than those of the intermolecular hydrogen bonds (0.244–0.249 and 0.246–0.265 nm, respectively).

In such intramolecular situations where a hydrogen bond is constrained by the framework of the molecule to be shorter, this **compressed hydrogen bond** must have a less negative standard enthalpy of formation relative to an equivalent, intermolecular, uncompressed one. This conclusion follows from the fact that repulsive potential energy has to be overcome to compress the bond (Figure 5–15). The energy necessary to compress the bond is provided by the covalent framework of the molecule. It follows that an intramolecular hydrogen bond that is shorter than an equivalent intermolecular hydrogen bond must be weaker than that intermolecular hydrogen bond even though it has a lower barrier to proton transfer (Figure 5–12).

The measurements available for the **free energies of formation for such intramolecularly shortened hydrogen bonds** confirm this expectation. The hydrogen bond in hydrogen maleate anion in dimethyl sulfoxide is only -18 kJ mol^{-1} more stable than that in neutral maleic acid,¹⁰⁷ about what one would expect for the difference in standard enthalpy of formation for two hydrogen bonds the acceptors of which differ in $\text{p}K_a$ by 10 units. In water, the difference is only -2 kJ mol^{-1} . The hydrogen bond between the carboxylic acid and the carboxylate anion in **5–6**

shows a chemical shift (18.0 ppm) in its nuclear magnetic resonance spectrum that is characteristic of a low-barrier hydrogen bond. Yet the standard free energy of its for-

mation differs from the standard free energy of formation for the hydrogen bond in the homologous acid amide, in which an NH_2 replaces the OH , by only -10 kJ mol^{-1} in benzene ($\epsilon_r = 2.3$) and -6 kJ mol^{-1} in dichloromethane ($\epsilon_r = 8.9$).¹⁰⁸ These differences, if anything, are less than expected for the differences in free energies of formation in these two solvents for two hydrogen bonds the donors of which differ by so much in $\text{p}K_a$. The proton in the hydrogen bond in zwitterionic *cis*-urocanic acid

has a downfield shift (18.5 ppm) in nuclear magnetic resonance characteristic of a low-barrier hydrogen bond, yet the standard free energy of formation of this hydrogen bond is only 5 kJ mol^{-1} less than the standard free energy of formation of the hydrogen bond in its conjugate base, *cis*-urocanic acid monoanion,¹⁰⁹ even though the difference in $\text{p}K_a$ between donor and acceptor in the latter hydrogen bond is 13. Consequently, the strength of hydrogen bond 5-7, in which the values of $\text{p}K_a$ for the donor and the conjugate acid of the acceptor are closely matched, cannot be unusually high even though it has the signature of a low-barrier hydrogen bond. The chemical shift and fractionation factor for the proton in the hydrogen bond in the enol of 2,4-dioxopentane (5-3) are those expected of a low-barrier hydrogen bond, but the values of the $\text{p}K_a$ for its donor and the conjugate acid of its acceptor differ so widely ($\Delta\text{p}K_a = 22$) that this cannot be a strong hydrogen bond.

The common practice of equating the unusually high values for $\text{p}K_a$ of the donor in an intramolecular hydrogen bond to its strength is mistaken. The unusually high $\text{p}K_a$ of such an intramolecular hydrogen bond is because of the **repulsion between the lone pairs** of the acceptor and the unprotonated donor that are forced by the framework of the molecule to reside immediately adjacent to each other in the conjugate base

and not because of the strength of the hydrogen bond. The interposition of the proton between the two lone pairs of electrons that are forced into juxtaposition

relieves the repulsion. It comes as no surprise that the activation energy for the exchange of the proton in such a confined location is much higher than that for a proton in an unconstrained, intermolecular hydrogen bond.¹¹⁰

Whether an intermolecular hydrogen bond is shortened by its strength or an intramolecular hydrogen bond is shortened by the compression exerted by the molecular framework to which it is covalently attached, the same increase in the overlap of the wells of potential energy for the proton associated with the heteroatoms of donor and acceptor (Figure 5-12) and the same lowering of the barrier occur. Both strong intermolecular hydrogen bonds and compressed intramolecular bonds can be low-barrier hydrogen bonds because the height of the barrier depends on the length of the bond, not its strength. It follows from these considerations that comparisons of the physical properties of intermolecular hydrogen bonds with those of intramolecular hydrogen bonds are misleading and should be considered guilty until proven innocent. This becomes an even greater offense whenever entropy is involved, as will become more apparent in the next section.

A hydrogen bond is mainly an **electrostatic attraction** between donor and acceptor. The A-H bond of the donor is a dipole, electronegative on the heteroatom, A, and electropositive on the proton. The σ orbital of the acceptor, $\odot\text{B}$, is electronegative on the lone pair and electropositive on the heteroatom, B. These two dipoles attract each other electrostatically when oriented in the same direction. If the donor is positively charged or the acceptor is negatively charged or if both are so charged, the electrostatic attraction is increased.

The hydrogen bond may also have a covalent component and thereby may involve both the overlap of atomic orbitals to form molecular orbitals and the delocalization of valence electrons over the three participating atoms, A, H, and B. Its **covalency** would result from the mixing of the sp^2 or sp^3 orbital on the heteroatom, A, of the donor, the $1s$ orbital of the proton, and the sp^2 or sp^3 orbital of the lone pair of electrons of the acceptor, B, to form a molecular orbital system with three molecular orbitals (Figure 5-16). The covalent component, however, is significantly less important than the electrostatic attraction of the dipoles. It has been proposed that as much as 10% of the hydrogen bonding in ice Ih could be covalent,^{111,112} but this conclusion has been challenged by alternative evaluations of the data suggesting that there is no covalency.¹¹³ The hydrogen bond between two molecules of water, however, is one of the weaker ones, and stronger, shorter hydrogen bonds may have more covalent character.^{65,80}

To the extent that a hydrogen bond is the electrostatic attraction between the dipole of the donor and the dipole of the acceptor, the **relative permittivity of the solvent** should affect its strength just as it affects the strength of an ion pair. The more effectively these dipoles are solvated when they are separated from each other,

Figure 5-16: Molecular orbitals for a covalent hydrogen bond. The molecular orbitals are for a symmetric hydrogen bond in which the donor and the conjugate acid of the acceptor are equivalent. The covalent molecular orbital system is formed from two sp^2 or sp^3 orbitals, one from atom A and one from atom B, and the s orbital on hydrogen. These three atomic orbitals combine to form the three molecular orbitals—bonding, nonbonding, and antibonding—shown in the middle of the diagram. The final molecular orbital system is constructed formally in steps by first mixing the atomic orbitals of atom A and the hydrogen to form the two molecular orbitals—bonding and antibonding—of the A-H covalent bond and then mixing the A-H molecular orbital system with the atomic orbital on atom B containing the lone pair of electrons.

the less advantage will there be in their combination to form the hydrogen bond. The higher the relative permittivity of the solvent, the weaker will be the bond. One way to quantify this effect⁸⁰ is to compare the slopes of correlations between the free energies of formation of a set of hydrogen bonds and either the values for pK_a of the donor (Figure 5-14) or the values for pK_a of the conjugate base of the acceptor (Equation 5-37). In water ($\epsilon_r = 78$ at 25 °C), the slope for such a correlation for hydrogen bonds between phenolate ion and a set of ammonium ions (Figure 5-17)¹¹⁴ is $0.6 \text{ kJ mol}^{-1} (\text{unit of } pK_a)^{-1}$ and that for a correlation¹¹⁴ of hydrogen bonds between ethylenediammonium dication and a series of phenolate ions is $-0.9 \text{ kJ mol}^{-1} (\text{unit of } pK_a)^{-1}$. The magnitudes of these slopes are less than the $3.1 \text{ kJ mol}^{-1} (\text{unit of } pK_a)^{-1}$ for the correlation of hydrogen bonds between 4-nitrophenolate or 3,4-dinitrophenolate ion (Figure 5-14) and a series of phenols in tetrahydrofuran ($\epsilon_r = 7.5$) or the $-1.3 \text{ kJ mol}^{-1} (\text{unit of } pK_a)^{-1}$ for the correlation (Equation 5-37) of hydrogen bonds between fluorophenol and a diverse set of bases in CCl_4 ($\epsilon_r = 2.2$).

To this point, most of the hydrogen bonds that have been discussed are those formed in aprotic organic sol-

Figure 5-17: The apparent association equilibrium constants ($K_{app,AHB}$) for a series of hydrogen bonds between the phenolate ion and a series of aliphatic ammonium ions in aqueous solution as a function of the acid dissociation constants $K_{a,AH}$ for those ammonium ions.¹¹⁴ The associations between the phenolate ion and the ammonium ions were followed spectrophotometrically by changes in absorbance at 300 nm as ammonium ion was added to an aqueous solution of phenolate ion at 2 M ionic strength and 25 °C. The values of the apparent association equilibrium constants were divided by the number of protons (p) on the respective ammonium ion to convert the molar concentration of the free cation to the molar concentration of donors. The acid dissociation constants were also statistically corrected by multiplying the observed acid dissociation constants by the number of lone pairs on the conjugate base (q) and dividing by the number of protons on the conjugate acid (p), so that the corrected values are for the molar concentration of protons on the respective conjugate acid and the molar concentration of the lone pairs of electrons on the respective conjugate base. The logarithms of the apparent association equilibrium constants (in units of molarity^{-1}) are linearly correlated with the logarithms of the corrected acid dissociation constants (in units of molarity^{-1}) by a line with Brønsted coefficient of 0.15. As the same corrections would be made to both the association constant and the acid dissociation constant in converting to units of corrected volume fraction, the slope of the line would be unaffected. The value of $\log(K_{app,AHB} p^{-1})$ calculated by Equation 5-51 for an acid with a pK_a equal to that of water is indicated by a filled square. The ammonium ions used were (1) hydroxylammonium ion, (2) piperazine dication, (3) *sym*-tetramethylethylenediammonium dication, (4) *N,N,N*-trimethylethylenediammonium dication, (5) ethylenediammonium dication, (6) 2-hydroxy-1,3-diaminopropane dication, (7) 1,3-diaminopropane dication, and (8) (2-hydroxyethyl)ammonium ion. vents such as carbon tetrachloride or benzene. The situation changes dramatically when the donor and acceptor are dissolved in **water** because of the competition of the donors and acceptors of the water molecules themselves. Pauling and Pressman¹¹⁵ noted that the standard free energy of formation of a hydrogen bond in water must be the difference between its own standard free energy of formation and the free energies of formation of the hydrogen bonds of its donor and acceptor with water.

The fact that the concentrations of donors and acceptors in water are both 110 M is a sufficient observation in itself to lead to the conclusion that the hydrogen bond between a solute A-H and a solute \ominus B would be unlikely to form.

The intermolecular hydrogen bond between the nitrogen-hydrogen bond of an **amide** and the lone pair of electrons on the acyl oxygen of another amide can be used again as an example of the majority of the hydrogen bonds in biological macromolecules. When *N*-methylacetamide is dissolved in carbon tetrachloride or dioxane, an absorption appears in the infrared spectra of the two solutions that can be assigned¹¹⁶ to the stretching vibration of the hydrogen-nitrogen bond in a hydrogen bond of the structure

Hydrogen bond 5-8 is the one supposedly holding α helices and β structure together in a molecule of protein and the base pairs together in DNA. From calorimetric measurements, it can be calculated that the standard free energy of formation of this hydrogen bond¹¹⁷ at 25 °C in CCl_4 is -16 kJ mol^{-1} , when an infinitely dilute solution of *N*-methylacetamide is defined as the standard state and the association equilibrium constant is expressed in units of corrected volume fraction (Equation 5-13). When *N*-methylacetamide is dissolved in water, however, the infrared absorption arising from hydrogen bond 5-8 can barely be detected even at a concentration of 12.5 M. From the small absorption that was observed, the standard free energy of formation of the hydrogen bond in aqueous solution was judged¹¹⁶ to be about $+7 \text{ kJ mol}^{-1}$ at 25 °C, again in units of corrected volume fraction.

A more complete picture of the situation is gained by estimating the **standard free energy of transfer** of an amido group from water to CCl_4 at 25 °C.^{118,119} The standard free energy of transfer of *N*-methylacetamide from water to CCl_4 at 25 °C is $+9 \text{ kJ mol}^{-1}$ at infinite dilution in both phases when units are corrected volume fraction (Equation 5-18). If this value is corrected for the hydrophobic effect expressed during the transfer of the three hydrogen-carbon bonds on the methyl group in the acetyl group and the three hydrogen-carbon bonds of the *N*-methyl group from water to CCl_4 ,^{119,120} the standard free energy of transfer for just the unassociated amido group ($-\text{CONH}-$) should be about $+25 \text{ kJ mol}^{-1}$. One amido group contains one donor and an acceptor and by itself represents the two participants in the final hydrogen bond, so its free energy of transfer from water to CCl_4 should be equal to that for the transfer of one

amido nitrogen-hydrogen and one acyl carbon-oxygen (indicated in Figure 5-18 by N-H and $\text{C}=\text{O}\ominus$). The complete standard free energy diagram for the hydrogen bond (Figure 5-18)¹¹⁷⁻¹¹⁹ suggests that the standard free energy of transfer of a hydrogen-bonded amido nitrogen-hydrogen and acyl carbon-oxygen from water to CCl_4 at 25 °C is around $+2 \text{ kJ mol}^{-1}$, a value that registers the polarity of the hydrogen bond. The most significant difference between CCl_4 and H_2O , however, is the high stability of the separated donors and acceptors in the H_2O . The large unfavorable standard free energy of transfer for the amido group from water to CCl_4 reflects the necessity to break hydrogen bonds between it and the water before the transfer can occur.

If this is the case, the **formation of the hydrogen bond in water** must be written, in analogy to Equation 5-1, as

Figure 5-18: Diagram of standard free energy for a hydrogen bond between the amido nitrogen (NH) and acyl oxygen ($\text{C}=\text{O}\ominus$) of *N*-methylacetamide.¹¹⁷⁻¹¹⁹ The standard free energies of association for the hydrogen bond in water ($+7 \text{ kJ mol}^{-1}$) and carbon tetrachloride (-16 kJ mol^{-1}) are positioned in relation to each other on the diagram by an estimate of the standard free energy of transfer ($+25 \text{ kJ mol}^{-1}$) of an unbonded amido group between the two solvents. The standard free energy of transfer for the amido group alone was calculated from the distribution coefficient of *N*-methylacetamide between water and carbon tetrachloride, extrapolated to infinite dilution, with the concentrations of solute in each solvent expressed in units of corrected volume fraction, and an estimate of the standard free energy of transfer of its two methyl groups^{119,120}

where the association constant for any of the complexes, $K_{\text{ass},XY}$, is

$$K_{\text{ass},XY} = \frac{[X\odot Y]}{[X][Y]} \quad (5-41)$$

It is entirely possible⁴⁴ that the concentrations of unbonded donors and unbonded acceptors in aqueous solutions are negligible and that only the upper part of Equation 5-40 is thermodynamically relevant.

The equilibrium constant for the upper part of Equation 5-40, K_{AHWBW} , is defined by

$$K_{\text{AHWBW}} = \frac{[\text{B}\odot\text{HA}][\text{H}_2\text{O}\odot\text{H}_2\text{O}]}{[\text{B}\odot\text{H}_2\text{O}][\text{H}_2\text{O}\odot\text{HA}]} \quad (5-42)$$

where, in the particular case of *N*-methylacetamide, AH is the amido nitrogen–hydrogen bond and $\text{B}\odot$ is a lone pair of electrons on the acyl oxygen. The equilibrium constant actually observed, $K_{\text{app,AHB}}$, is

$$K_{\text{app,AHB}} = \frac{[\text{B}\odot\text{HA}]}{([\text{B}\odot\text{H}_2\text{O}] + [\text{B}\odot])([\text{H}_2\text{O}\odot\text{HA}] + [\text{HA}])} \quad (5-43)$$

from which it follows that

$$K_{\text{app,AHB}} = K_{\text{ass,AHB}} \left[\frac{1}{1 + \frac{K_{\text{ass,AHW}}}{(K_{\text{ass,WW}})^{1/2}} [\text{H}_2\text{O}\odot\text{H}_2\text{O}]^{1/2}} \right] \times \left[\frac{1}{1 + \frac{K_{\text{ass,WB}}}{(K_{\text{ass,WW}})^{1/2}} [\text{H}_2\text{O}\odot\text{H}_2\text{O}]^{1/2}} \right] \quad (5-44)$$

If, as is reasonable, $K_{\text{ass,AHW}} > (K_{\text{ass,WW}})^{1/2}$, $K_{\text{ass,WB}} > (K_{\text{ass,WW}})^{1/2}$, and $[\text{H}_2\text{O}\odot\text{H}_2\text{O}] > 1 \text{ M}$, it follows that

$$K_{\text{app,AHB}} \cong \frac{K_{\text{AHWBW}}}{[\text{H}_2\text{O}\odot\text{H}_2\text{O}]} \quad (5-45)$$

where $[\text{H}_2\text{O}\odot\text{H}_2\text{O}]$ is the molar concentration of hydrogen bonds in the water.

The difference in $\text{p}K_{\text{a}}$ between the nitrogen–hydrogen bond in *N*-methylacetamide as a donor ($\text{p}K_{\text{a}} = 16$) and the oxygen–hydrogen bond in water as a donor ($\text{p}K_{\text{a}} = 15.7$) should be negligible, as should be the differ-

ence between the lone pair of electrons on the acyl oxygen of *N*-methylacetamide ($\text{p}K_{\text{a}} = -0.6$) and the lone pair of electrons on water ($\text{p}K_{\text{a}} = -1.7$) as acceptors. Therefore, the standard enthalpy of formation for the following four hydrogen bonds should be similar

5-9

5-10

5-11

5-12

and the standard enthalpy change for the upper part of Equation 5-40 should be near zero. If the upper part of Equation 5-40 were isoentropic as well as isoenthalpic, so that $K_{\text{AHWBW}} \cong 1$ (Equation 5-42), then $K_{\text{app,AHB}}$ would be equal to $[\text{H}_2\text{O}\odot\text{H}_2\text{O}]^{-1}$. The observed apparent association constant for the formation of hydrogen bond 5-8 in aqueous solution when expressed in units of reciprocal molarity¹¹⁶ is about $(190 \text{ M})^{-1}$, which is in the range expected for the reciprocal of the concentration of hydrogen bonds in pure water, $[\text{H}_2\text{O}\odot\text{H}_2\text{O}] \leq 110 \text{ M}$. The conclusion to be drawn from these considerations is that a hydrogen bond in aqueous solution will always have a **small apparent association constant** and a large apparent standard free energy of formation because the concentration of hydrogen bonds between water molecules in the solution is a hidden and significant term in that apparent association constant (Equation 5-45).

The hydrogen bond represented by that of *N*-methylacetamide accounts for the majority of those found in proteins and nucleic acids, and yet its standard free energy of formation is positive by a considerable degree. From this it follows that each hydrogen bond of this type in a protein or a nucleic acid is an energetic liability rather than an asset. It is possible, however, that some other combination of donor and acceptor might produce a hydrogen bond strong enough to overcome the competition of the water and provide a negative standard free energy of formation. In assessing this possibility, it would be useful to have an equation that could be used to **estimate the apparent**

equilibrium constant, $K_{\text{app,AHB}}$, for the formation of any hydrogen bond in aqueous solution. Such an equation has been derived⁴⁴ and has been demonstrated to be reliable.¹¹⁴

Consider the hydrogen bond

and focus in turn on the portions within the brackets and the portions without the brackets. The portion within the brackets is the same for all hydrogen bonds. The structures without the brackets on either side affect the intrinsic enthalpy of the hydrogen bond by donating or withdrawing electrons from this central structure.¹²¹ The net result of their action is an intrinsic enthalpy, $H_{\text{int,AHB}}$, that is proportional to the product of the two respective σ constants:¹²¹

$$H_{\text{int,AHB}} = v_{\ominus\text{H}} \sigma_{\text{A}} \sigma_{\text{B}} \quad (5-46)$$

where $v_{\ominus\text{H}}$ is a constant of proportionality. These σ constants are the same terms used in physical organic chemistry to provide a quantitative assessment of the ability of any group to withdraw or donate electrons and cause changes in standard enthalpy in any similar situation.

For the upper part of Equation 5-40, when the specific example of *N*-methylacetamide is replaced by the general reaction between A-H and $\ominus\text{B}$, the standard enthalpy change for the reaction should be

$$\Delta H_{\text{AHWBW}}^{\circ} = H_{\text{int,AHB}} + H_{\text{int,WW}} - H_{\text{int,AHW}} - H_{\text{int,BW}} \quad (5-47)$$

or

$$\Delta H_{\text{AHWBW}}^{\circ} = v_{\ominus\text{H}} (\sigma_{\text{A}} - \sigma_{\text{OH}}) (\sigma_{\text{B}} - \sigma_{\text{H}_2\text{O}}) \quad (5-48)$$

where σ_{OH} is the σ constant for OH taking the place of A in 5-13 and $\sigma_{\text{H}_2\text{O}}$ is the σ constant for H_2O taking the place of B in 5-13. As the values of the σ constants are proportional to the values of $\text{p}K_{\text{a}}$ for the appropriate acids

$$\Delta H_{\text{AHWBW}}^{\circ} = 2.303 RT \tau (\text{p}K_{\text{aHA}} - \text{p}K_{\text{aHOH}}) (\text{p}K_{\text{aHB}} - \text{p}K_{\text{aH}_3\text{O}^+}) \quad (5-49)$$

where τ incorporates the constants of proportionality. If it is assumed for the moment that the standard entropy change for the upper part of Equation 5-40 is negligible and that differences in standard enthalpy are the only significant determinants of the relative strengths of the hydrogen bonds being considered, then

$$-\log K_{\text{ass,AHWW}} = \tau (\text{p}K_{\text{aHA}} - \text{p}K_{\text{aHOH}}) (\text{p}K_{\text{aHB}} - \text{p}K_{\text{aH}_3\text{O}^+}) \quad (5-50)$$

and⁴⁴

$$\log K_{\text{app,AHB}} = \tau (\text{p}K_{\text{aHA}} - \text{p}K_{\text{aHOH}}) (\text{p}K_{\text{aH}_3\text{O}^+} - \text{p}K_{\text{aHB}}) - \log [\text{H}_2\text{O} \odot \text{H}_2\text{O}] \quad (5-51)$$

where the values of the measured $\text{p}K_{\text{a}}$ have been corrected statistically for the number of protons, p , on the conjugate acid and the number of lone pairs, q , on the conjugate base:

$$K_{\text{a,corr}} = \frac{q}{p} K_{\text{a,meas}} \quad (5-52)$$

As the units of concentration for the acid dissociation constants are in units of molarity, the units for the association constant and the concentration of hydrogen bonds in the water must also be expressed in units of molarity. Equation 5-51 can be used to estimate the association equilibrium constant in units of molarity^{-1} , and hence the standard free energy of formation (Equations 5-13 and 5-14), of any hydrogen bond in aqueous solution.

This relationship was validated¹¹⁴ by an examination of the formation of hydrogen bonds between a series of phenolate anions as acceptors and ammonium cations as donors at 25 °C

5-14

where the substituents X and R were various electron-donating and electron-withdrawing groups chosen to vary the values of $\text{p}K_{\text{a}}$ for the donor and acceptor. The logarithms of the association equilibrium constants for the formation of these hydrogen bonds varied with the $\text{p}K_{\text{a}}$ of either the donor (Figure 5-17) or the acceptor as predicted by Equation 5-51. Extrapolating the relationships to either $\text{p}K_{\text{a,HA}} = \text{p}K_{\text{a,HOH}}$ or $\text{p}K_{\text{a,HB}} = \text{p}K_{\text{a,H}_3\text{O}^+}$ gave the same value, 2.0, for $\log [\text{H}_2\text{O} \odot \text{H}_2\text{O}]$. This numerical value is a reasonable estimate for the logarithm of the concentration of hydrogen bonds in liquid water, where $[\text{H}_2\text{O} \odot \text{H}_2\text{O}] \leq 110 \text{ M}$, and it is in reasonable agreement with the results gathered independently with *N*-methylacetamide.

The value of τ (Equations 5-49 and 5-51) at 25 °C and 2 M ionic strength was found to be 0.013, from which it follows that even the strongest possible hydrogen

Because the large **relative permittivity of water weakens** the overwhelming electrostatic component of the hydrogen bond and because the **donors and acceptors of the water molecules themselves compete** for occupation of any other donors and acceptors in solution, any comparisons of hydrogen bonds in organic solvents with hydrogen bonds in water are misleading and should be avoided. It is incumbent on the author to state clearly the solvent in which the property of each hydrogen bond being discussed was measured.

The interaction coefficient τ in Equation 5-49 is a small number because it is the product of the slope of the line relating $\Delta H^\circ_{\text{AHB}}$ to the difference in the values of $\text{p}K_{\text{a}}$ between the donor and water (Figure 5-17) and the slope of the line relating $\Delta H^\circ_{\text{AHB}}$ to the difference in the values of $\text{p}K_{\text{a}}$ between the conjugate acid of the acceptor and conjugate acid of water. Both of these slopes are small because, as a result of its high relative permittivity, water solvates the separated donors and acceptors so strongly. Because both slopes are small, their product is even smaller. Because τ is such a small number (0.013), the standard enthalpy of formation for any hydrogen bond formed in water will be negligible. It follows that a hydrogen bond in aqueous solution cannot be strengthened significantly by any alteration of the acid dissociation constants of donor and acceptor.

Consequently, it is the standard entropy of formation that determines the standard free energy of formation.¹²³ It is the entropic effect of the high molar concentration of the hydrogen bonds between molecules of water ($[\text{H}_2\text{O} \cdots \text{H}_2\text{O}]$ in Equation 5-51) that is usually the overriding contributor to this standard entropy of formation. Equation 5-51 states that the standard free energy of formation of a hydrogen bond in an aqueous solution, when standard state has the units of molarity for concentration, will be increased by about $+11 \text{ kJ mol}^{-1}$ because of the high molar concentration of the hydrogen bonds between molecules of water. There is a way, how-

Problem 5–4: Draw structures that represent all of the possible hydrogen bonds that can form between the following pairs of molecules when they are dissolved in a nonpolar solvent. Draw the structures with proper geometry and include all lone pairs of electrons.

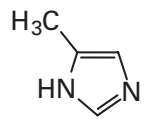

- (A) two molecules of *N*-methylacetamide
(B) *N*-methylacetamide and ethanol
(C) ethanol and water
(D) *N*-methylacetamide and water
(E) urea and *N*-methylacetamide
(F) acetic acid and *N*-methylacetamide
(G) 4-methylimidazole and *N*-methylacetamide
(H) 4-methylimidazole and ethanol
(I) acetic acid and ethanol

Problem 5-5:

- (A) Draw the structure of each of the following hydrogen bonds in the most stable geometry (bond angles and distances). Include all lone pairs of electrons.

- (B) Write the acid dissociations to which the following apparent values of pK_a refer, and correct them for number of protons and number of lone pairs.

	pK_{a1}	pK_{a2}
$\text{CH}_3\text{C}(=\text{O})\text{NH}_2$	0.6	15.70
H_2O	-1.75	15.75
	-7.51	15.10

- (C) Rank the eight hydrogen bonds in order of strength.

Problem 5-6: Draw the structure of only the most stable hydrogen bond that forms between side chains of the following pairs of amino acids. Include all relevant angles and distances around the various hydrogen bonds.

- (A) glutamic acid and histidine
 (B) serine and tyrosine
 (C) glutamine and histidine

Problem 5-7: The panel below is an infrared spectrum of propionamide in carbon tetrachloride.¹²⁴ The bands marked M_1 and M_2 are the absorptions of the monomeric propionamide, and the bands marked P_1 – P_5 are absorptions of hydrogen-bonded species. As the concentration of propionamide is increased, within each of these two sets [(M_1, M_2) and $(P_1$ – $P_5)$] the amplitudes of the individual absorptions remain in constant ratio to each other and must be different absorptions of the same species.

Below is a table of amplitudes from the infrared spectra for various total concentrations of propionamide at 298 K in CCl_4 .

$[\text{propionamide}]_{\text{TOT}}$ (M)	A_{M_1}	A_{P_1}
1.71×10^{-3}	0.415	0.055
2.15×10^{-3}	0.509	0.083
2.43×10^{-3}	0.566	0.102
4.72×10^{-3}	0.981	0.308
6.90×10^{-3}	1.32	0.558
10.40×10^{-3}	1.79	1.020

Recall that, by Beer's law, $[\text{monomer}] = (\epsilon_{M_1})^{-1}A_{M_1}$ and $[\text{polymeric species}] = (\epsilon_{P_1})^{-1}A_{P_1}$. If the hydrogen bonding is a dimerization, it should be described by the following equation:

$$K_{\text{eq}} = \frac{[\text{propionamide}_2]}{[\text{propionamide}]^2}$$

- (A) Show that the data are consistent with a dimerization.
 (B) Use the data to determine K_{eq} at 298 K in units of corrected volume fraction. (Hint: $[\text{propionamide}]_{\text{TOT}} = [\text{propionamide}] + 2[\text{propionamide}_2]$.)

Values of K_{eq} were determined at a number of different temperatures.

temp (K)	$K_{\text{eq}} (\text{M}^{-1})$
303	35.5
313	24.6
329	13.3

- (C) Convert these three equilibrium constants to units of corrected volume fraction.
 (D) Using these three numbers and your value for 298 K, calculate ΔH° for the dimerization.
 (E) The appearance of the species P_1 – P_5 in the infrared spectrum can be adequately explained only if propionamide has two hydrogen bonds that form a cyclic structure. Draw that structure.
 (F) What is ΔH° for each mole of hydrogen bond?

Problem 5-8: Poly[d(AT)·d(AT)] melts at 67 °C and poly[d(GC)·d(GC)] melts at 102 °C. The usual explanation for this observation is that there is one more hydrogen bond in a G-C pair than in an A-T pair. Consider, however, this explanation in terms of Figure 5-18. Assume

that when the heterocyclic bases in single strands of randomly coiled DNA form a double helix, the interior σ faces of the bases are transferred from water to a completely nonpolar environment (Figure 6–48) and that the proper tautomers for base pairing are present at the pH of the experiment.

- (A) Write complete equations for the formation of an A·T pair and a G·C pair as the double helix forms, drawing in all hydrogen-bonded waters to all donors and acceptors on each side of the equation and the hydrogen bonds that form between the residual waters. Assume that the donors and acceptors of hydrogen bonds accessible to water in the major and minor grooves retain their hydrogen bonds with H_2O .
- (B) Why is poly[d(GC)·d(GC)] more stable than poly[d(AT)·d(AT)]?

Problem 5–9: There are two possible hydrogen bonds that can form between the neutral form of phenol, a model for tyrosine, and the free base of imidazole, a model for histidine.

- (A) Draw the full structures of both partners in both of the possible hydrogen bonds with proper hybridization on the central atoms and proper bond angles around the hydrogen bond.
- (B) Which of the two possible hydrogen bonds is the more stable? Why?
- (C) Estimate the standard free energy of formation of the more stable hydrogen bond at 25 °C when it is formed in aqueous solution if the statistically corrected values of $\text{p}K_a$ are 9.65 for phenol and 7.35 for the conjugate acid of imidazole.

Intramolecular and Intermolecular Processes: Molecularity and Approximation

Intramolecular chemical reactions often occur at rates much faster than equivalent intermolecular reactions, and intramolecular associations often occur with association equilibrium constants much larger than those of equivalent intermolecular associations. A particularly informative series illustrating such effects can be gathered¹²⁵ from among the reactions involving intramolecular nucleophilic catalysis of the hydrolysis of phenyl esters by the carboxylate anion. The mechanism for this nucleophilic catalysis has been shown to involve the formation of an intermediate anhydride, which in the intramolecular examples such as phenyl succinate would be cyclic:

The tetrahedral intermediate **5–16** that leads to the anhydride has both a phenolate and a carboxylate as potential leaving groups, and because the latter is the better leaving group, the intermediate should decompose to reactant much more frequently than to anhydride. Therefore, the reaction involves a **preequilibrium** between the reactant and the tetrahedral intermediate. Occasionally the phenolate is ejected from the tetrahedral intermediate in a kinetically irreversible step. It is the ejection of the phenolate that is monitored as the reaction progresses. The first-order rate constant, in units of reciprocal seconds, for the appearance of phenolate would be equal to $K_{\text{eq,TI}}k_E$, where $K_{\text{eq,TI}}$ is the equilibrium constant for the formation of the tetrahedral intermediate. If it is assumed that for all compounds in the series the rate constant k_E , which in all cases is for a chemically equivalent first-order reaction, has the same value, then the differences in observed rates result from differences in $K_{\text{eq,TI}}$, an equilibrium constant.

A comparison of the first-order rate constants of phenolate release for a series of intramolecular reactions¹²⁵ to the estimated pseudo-first-order rate constant for the intermolecular reaction between phenyl acetate and excess acetate anion, when the catalysis by acetate anion proceeds through acetic anhydride as an intermediate,^{126,127} indicates how large these **intramolecular increases in an association constant** can be (Table 5–5). The 6×10^5 increase in the association equilibrium constant for the intramolecular formation of succinic anhydride,¹²⁸ when compared to the association equilibrium constant for the intermolecular formation of acetic anhydride expressed in units of corrected volume fraction, is somewhat greater than the increase seen with phenyl succinate (Table 5–5). This fact suggests that the increases listed in Table 5–5 are reasonable.

A situation similar to the intramolecular hydrolysis of phenyl esters is encountered in the alkaline hydrolyses of *endo*-6-hydroxybicyclo[2.2.1]heptane-*endo*-2-carboxamides in which a preequilibrium between reactant and tetrahedral intermediate precedes the expulsion of the amine:¹²⁹

Table 5-5: Relative Preequilibrium Constants^{125,126} for the Formation of a Tetrahedral Intermediate^a

phenyl ester	relative equilibrium constant ^b	$T\Delta S^\circ_{\text{approx}}{}^c$ (kJ mol ⁻¹)
	1.0	
	100	-11
	2×10^4	-24
	1×10^6	-34
	4×10^6	-38

^aThe first-order rate constants for the ejection of phenol from the several phenyl monoesters of dicarboxylic acids (last four entries) were determined¹²⁵ as a function of pH in the range pH 4–8. From the pH-rate behavior of each of these rate constants, the first-order rate constant for intramolecular nucleophilic catalysis of the respective ejection by the appended carboxylate could be calculated. From these values, the first-order rate constants for intramolecular anhydride formation could be calculated. These rate constants were determined for each phenyl monoester at 25, 30, or 35 °C. The values of these rate constants were adjusted to the same temperature and originally presented relative to the first-order rate constant for intramolecular ejection of phenol from phenyl glutarate.¹²⁵ These first-order rate constants were later related to the pseudo-first-order rate constant for the intermolecular formation of acetic anhydride from excess acetate anion and phenyl acetate during the intermolecular nucleophilic catalysis of the hydrolysis of phenyl acetate by acetate anion.¹²⁶ ^bFirst-order rate constants for the formation of anhydride were originally presented relative to the calculated¹²⁶ pseudo-first-order rate constant for the formation of acetic anhydride from phenyl acetate and acetate anion. The latter intermolecular rate constant was in units of molarity⁻¹ second⁻¹. It has been assumed that all of the rate constants for the formation of the anhydrides are directly proportional to the equilibrium constants for the formation of the respective tetrahedral intermediates (Equation 5-53). The resulting units of molarity⁻¹ for the equilibrium constant for the formation of the tetrahedral intermediate from acetate anion and phenyl acetate were converted to units of corrected volume fraction with Equation 5-13. No correction is required for the intramolecular reactions if it is assumed that they involve only negligible changes in molar volume. All equilibrium constants for the formation of the tetrahedral intermediates are presented relative to that for the reaction of acetate anion with phenyl acetate. ^cStandard entropy of approximation, calculated by Equation 5-60 with the intermolecular equilibrium constant in units of corrected volume fraction and with the assumptions that all of the rate constants are directly proportional to the equilibrium constants for the formation of the tetravalent intermediate and that $\Delta\Delta H^\circ \approx 0$. This entropy of approximation was multiplied by 298 K.

In these reactions the intramolecular increase in association constant $K_{\text{eq,TI}}$ is 1×10^6 relative to that for the formation of the equivalent tetrahedral intermediate from hydroxide ion and a bicyclo[2.2.1]heptane-*endo*-2-carboxamide when concentrations are expressed in corrected volume fraction.

Many other examples of intramolecular accelerations of rates or increases in association equilibrium constants have been reported,^{29,126} but the accelerations

presented in Table 5-5 are among the largest that have been noted for each particular size of ring formed during each of these intramolecular reactions. In some of the other instances, electronic effects are difficult to separate from the effects of approximation. For example, in the intramolecular reaction

the two reactants are connected electronically by the π system in addition to being juxtaposed by the σ system.

At one time it was fashionable to refer to these accelerations in rate or increases in association as the result of an increase in the **effective molarity** of one of the reactants brought about by attaching it covalently to the other. As more exaggerated examples of this phenomenon were reported, however, the unreality of discussing concentrations of millions of molar became apparent,¹²⁸ and a more reasonable view of the situation was required.^{128,130}

In all instances in which an intramolecular association, for example, the intramolecular formation of a hydrogen bond in a folding polypeptide, is compared to an equivalent intermolecular association, the difference observed in the two equilibrium constants $K_{eq,intra}$ and $K_{eq,inter}$ is due in large part to an increase in the change in standard entropy caused simply by the fact that a unimolecular reaction is being compared to a bimolecular reaction. This increase in the standard entropy change for the intramolecular association results from the fact that the standard entropy of approximation is missing from the standard free energy change for the intramolecular association. The **standard entropy of approximation**, ΔS°_{approx} , is the change in standard entropy due solely to bringing the separate reactants together into the same molecule or into the same complex, respectively, prior to the beginning of the reaction. It is a negative number because the intrinsic entropy of two separate reactants relative to the unimolecular product of a reaction is greater than the intrinsic entropy of one molecule containing the two reactants or of one complex into which the two reactants have been assembled relative to the product of the intramolecular reaction. For example, the intrinsic entropy of a free acetate anion and a free phenyl acetate is much larger relative to the tetrahedral intermediate formed when they associate than is the intrinsic entropy of a phenylsuccinate anion relative to the cyclic tetrahedral intermediate in Equation 5-53. Because the standard entropy of approximation is missing from the standard entropy change for the intramolecular reaction, owing to the fact that approximation has

already been accomplished synthetically or biologically, the standard entropy change for the intramolecular reaction is more positive than the standard entropy change for the intermolecular reaction.

These relationships can be expressed in equations. These equations are not intended to reflect actual changes in standard entropy, which are often dominated by changes in solvation, but to represent the quantitative consequences of approximation underlying the enhancements in rate or equilibrium constant. The standard entropy change of the intramolecular reaction, ΔS°_{intra} , should be related to the standard entropy change of the intermolecular reaction, ΔS°_{inter} , by

$$\Delta S^\circ_{inter} = \Delta S^\circ_{intra} + \Delta S^\circ_{approx} \quad (5-56)$$

if the same reaction with the same change in standard enthalpy is occurring once the reactants have been approximated. If this were an adequate description of the situation and the same change in standard enthalpy did occur in each reaction, then

$$R \ln \left(\frac{K_{eq,intra}}{K_{eq,inter}} \right) = \Delta S^\circ_{intra} - \Delta S^\circ_{inter} = -\Delta S^\circ_{approx} \quad (5-57)$$

Because $\Delta S^\circ_{approx} < 0$, $K_{eq,intra} > K_{eq,inter}$.

The magnitude of the standard entropy of approximation is determined by the difference between two other standard entropy changes, the standard entropy of molecularity and the standard entropy of rotational restraint.^{128,130} The formation of a unimolecular product during an intermolecular reaction requires that two or more independent molecules become one molecule, and this involves a considerable decrease in standard entropy. The standard entropy change responsible for this decrease, the standard entropy of molecularity, ΔS°_{molec} , has a negative value and is a major, unavoidable, unfavorable term in the change in standard free energy in any intermolecular reaction. In an intramolecular reaction, however, the decrease in standard entropy due to the standard entropy of molecularity does not occur, because reactants are already on only one molecule, and this has the effect of increasing dramatically the change in standard entropy for the intramolecular reaction relative to the intermolecular reaction and hence increasing its yield of product. There is affiliated with an intramolecular reaction, however, a standard entropy of rotational restraint, which, conversely, is irrelevant to an intermolecular reaction. The **standard entropy of rotational restraint** is the increase in standard entropy that results from the fact that the formation of the transition state or product during an intramolecular reaction requires that a portion of the rotational entropy in the molecule be

eliminated because only a fraction of the accessible rotational isomers can participate in the reaction productively. The standard entropy change accompanying this decrease in the number of rotational isomers, the standard entropy of rotational restraint, $\Delta S^\circ_{\text{rot}}$, has a negative value and its inclusion causes the standard entropy change for the reaction to be smaller than it would be if no rotational freedom were lost during the reaction because only a productive rotational isomer was present.

The relationships between the standard entropy of approximation and the standard entropy of molecularity and standard entropy of rotational restraint are

$$\Delta S^\circ_{\text{approx}} = \Delta S^\circ_{\text{molec}} - \Delta S^\circ_{\text{rot}} \quad (5-58)$$

The magnitudes of each of these terms can be discussed in turn.

The **standard entropy of molecularity** is the decrease in standard entropy that should accompany the change of an intermolecular reaction to a rigidly oriented intramolecular reaction.¹²⁸ In the specific case of a bimolecular reaction, the two independent reactants have six translational and six rotational degrees of freedom, but the one molecule, formed by the association of the two others, should have only three translational and three rotational degrees of freedom. The standard entropy change associated with the loss of the three translational and three rotational degrees of freedom during this inescapable association, calculated for the situation in which the two reactants and the transition state or product are dissolved in a solution at 25 °C with a standard state of 1 M in solutes, has been estimated¹²⁸ to be between -190 and $-210 \text{ J K}^{-1} \text{ mol}^{-1}$. This estimate can be compared to the standard entropy change observed for a simple bimolecular reaction, such as the dimerization of cyclopentadiene in the liquid phase, during which the standard entropy change is -130 to $-170 \text{ J K}^{-1} \text{ mol}^{-1}$ with the same choice of standard state. The difference between the calculated standard entropy change and the observed standard entropy change in the particular instance of cyclopentadiene can be completely accounted for by the presence of low-frequency vibrations in the dimer that could not be present in the two monomers because of their smaller size. It has been concluded¹²⁸ that -190 to $-210 \text{ J K}^{-1} \text{ mol}^{-1}$ is an adequate estimate for $\Delta S^\circ_{\text{molec}}$, the maximum decrease in standard entropy change expected from converting a bimolecular reaction into a unimolecular reaction, when molarities are used as units of concentration for standard states. If corrected volume fractions are used as units of concentration for standard states and the partial molar volumes of the solutes are in the range between 40 and 150 mL mol⁻¹, the range for expected standard entropy of approximation for a bimolecular reaction would be -165 to $-195 \text{ J K}^{-1} \text{ mol}^{-1}$ (Equation 5-13).

As the example of the dimerization of cyclopentadi-

ene illustrates, an intramolecular reaction, because it usually involves a larger and more flexible molecule than any of the reactants in an intermolecular reaction, can never realize all of this favorable standard entropy of molecularity. Major factors in decreasing the portion of the standard entropy of molecularity that an intramolecular reaction will enjoy are the internal rotations within the intramolecular reactant itself. These rotations decrease the probability that the necessary juxtaposition of reactants will occur. For example, in the case of phenyl succinate (Equation 5-53) the dihedral angles around three carbon-carbon single bonds must be appropriate if the carboxyl oxygen is to be placed adjacent to the acyl carbon. It has been estimated^{128,130} from the results of thermodynamic and kinetic measurements from a number of intramolecular reactions that the standard entropy of rotational restraint decreases by about $20 \text{ J K}^{-1} \text{ mol}^{-1}$ for every bond that lies between the two atoms participating directly in the reaction and about which free rotation can occur.

When two similar intramolecular associations are compared, for which it is assumed that differences between their standard enthalpies of formation are negligible¹²⁶

$$\Delta \Delta S^\circ = R \ln \left(\frac{K_{\text{eq1}}}{K_{\text{eq2}}} \right) \quad (5-59)$$

where $\Delta \Delta S^\circ$ is the difference between their standard entropy changes and K_{eq1} and K_{eq2} are the respective association equilibrium constants. The change in relative rate of phenoxide release in going from phenyl glutarate to phenyl succinate (Table 5-5) is 230-fold and in going from phenyl succinate to the phenyl ester of the fused ring is also 230-fold. In each comparison, one less carbon-carbon bond around which free rotation is allowed is found in the more constrained member of the pair. The changes in rate, presumably reflecting differences in $K_{\text{eq,TP}}$, are equivalent in each comparison to $45 \text{ J K}^{-1} \text{ mol}^{-1}$. It has been noted, however, that the case of nucleophilic catalysis of the hydrolysis of phenyl esters provides the largest standard entropy of rotational restraint (carbon-carbon bond)⁻¹ yet observed.¹²⁸ It has been proposed that any increase in the apparent entropy of approximation in excess of 20 J K^{-1} that is accomplished by freezing the rotation around a carbon-carbon bond may be due to a **decrease in the strain** encountered by the reaction over and above the decrease in the rotational degrees of freedom.¹³⁰ This decrease in strain would be effected by an unintended improvement in the orientation and alignment of the two reactants in the productive conformation produced by the changes in the structure of the molecule that were required to freeze the rotation.

With small molecules, the effect of approximation on an equilibrium constant is usually significant only when the two central atoms that participate in the asso-

ciation become involved in a **five-membered or six-membered ring** in the product. A four-membered ring is usually too strained, because of the normal bond angles of commonly encountered molecules, to provide any favorable approximation. A seven-membered ring, if there is free rotation about every bond, has too small a value of $\Delta S^\circ_{\text{rot}}$ to exhibit a $\Delta S^\circ_{\text{approx}}$ small enough to overcome the strain of the ring and have a noticeable effect on equilibrium. For example, even in the intramolecular nucleophilic catalysis of phenyl ester hydrolysis, a series of reactions unusually prone to intramolecular catalysis, phenyl adipate would show a rate of phenolate release due to nucleophilic catalysis only 4-fold greater than that for the same reaction of phenyl acetate in 1.0 M sodium acetate. Large, rigid molecules in which the two atoms that must react are more than six atoms apart yet close enough to collide have been synthesized,^{131,132} but proteins and nucleic acids are the ultimate examples.

The magnitude of the actual difference in the change in standard entropy between a given intramolecular reaction and the corresponding intermolecular reaction will be less than the magnitude of the standard entropy of approximation because vibrational degrees of freedom, unavailable to the reactants in the intermolecular reaction, are available to the necessarily larger reactant in the intramolecular reaction and because steric effects that do not apply to the intermolecular reaction are often unavoidable consequences of designing the intramolecular reactant. For example, the intramolecular rates of lactonization for a series of bicyclic γ -hydroxy-carboxylic acids decrease as the strain energies of the rigid five-membered rings of the tetrahedral intermediate (see Equation 5-54) increase,¹³⁰ even though in each case the hydroxy group and the acyl carbon are positioned rigidly in the same orientation and at about the same distance from each other.

If the magnitude of $\Delta\Delta S^\circ$, the actual difference between the standard entropy changes in the reactions, must be less than the magnitude of $\Delta S^\circ_{\text{approx}}$, then

$$T\Delta S^\circ_{\text{approx}} < -RT \ln \left(\frac{K_{\text{eq,intra}}}{K_{\text{eq,inter}}} \right) + \Delta\Delta H^\circ \quad (5-60)$$

where $K_{\text{eq,intra}}$ and $K_{\text{eq,inter}}$ are the intramolecular and intermolecular association equilibrium constants. If the differences in the actual standard enthalpies of formation, $\Delta\Delta H^\circ$, are known, the estimates of the upper limits for $\Delta S^\circ_{\text{approx}}$ can incorporate them. If they are unknown, they can be assumed to be zero, for the sake of argument, but such an assumption can be misleading.

In relating the change observed in an equilibrium constant to the entropy of approximation, the **difference in standard enthalpy change** resulting from the chemical strategy used to accomplish the approximation, $\Delta\Delta H^\circ$, complicates the interpretation (Equation 5-60). In several reactions displaying large increases in the rate of

the reaction or the yield of the product due to covalent approximation of the reactants, the major effect of the approximation is on the standard enthalpy change of the reaction rather than the standard entropy change.²⁹ For example,¹³³ 2,2,3,3-tetramethylsuccinamide at pH 5 displays a rate of aniline release 1200 times greater than that of succinamide itself. This increase in rate, however, which is equivalent to a change in the standard free energy of activation of -18 kJ mol^{-1} , is accompanied by a change in the standard enthalpy of activation, $\Delta\Delta H^\ddagger$, of -25 kJ mol^{-1} . Therefore, in this case the standard entropy of activation actually decreases as the rate of the reaction is enhanced by approximation. It is difficult, however, to interpret such observed changes in the thermodynamic parameters of activation because they are usually dominated by solvent effects that mask the underlying effects of approximation on the rates or equilibrium constants.¹³⁰ In the case of the intramolecular catalysis manifested in the alkaline hydrolyses of *endo*-6-hydroxybicyclo[2.2.1]heptane-*endo*-2-carboxamides (Equation 5-54), it has been concluded that the rate enhancement of 1×10^6 ($T\Delta S^\circ_{\text{approx}} \leq -34 \text{ kJ mol}^{-1}$) "results almost entirely from the entropy effect", probably because there is no strain involved in the formation of the additional five-membered ring of the tetrahedral intermediate.¹²⁹

When the upper limits of $T\Delta S^\circ_{\text{approx}}$ are calculated from the relative rates between the intramolecular and bimolecular nucleophilic catalysis of the hydrolysis of phenyl esters, on the assumption that $\Delta\Delta H^\circ$ is equal to 0,¹²⁵ they are all equal to or greater than -38 kJ mol^{-1} (Table 5-5). The upper limit of $T\Delta S^\circ_{\text{approx}}$ calculated from the increase in the equilibrium constant for the formation of the tetrahedral intermediates in the hydrolyses of *endo*-6-hydroxybicyclo[2.2.1]heptane-*endo*-2-carboxamides is -34 kJ mol^{-1} . If it is assumed that the fused rings retain two rotational axes, which is a generous assumption, $\Delta S^\circ_{\text{approx}}$ (Equation 5-58) should be about $-140 \text{ J K}^{-1} \text{ mol}^{-1}$ and $T\Delta S^\circ_{\text{approx}}$ about -40 kJ mol^{-1} when units of corrected volume fraction are used. The upper limit of $T\Delta S^\circ_{\text{approx}}$ calculated from the increase in the equilibrium constant for the formation of tetrahedral intermediates in the hydrolyses of *endo*-6-hydroxybicyclo[2.2.1]heptane-*endo*-2-carboxamides is -34 kJ mol^{-1} .

At least three points are illustrated by this exercise. First, the largest intramolecular increases in rate or degree of association yet measured, with the educational exceptions of the cases involving severe compressive steric effects in the transition states or products, are of a magnitude less than that expected simply for the transformation of an intermolecular reaction into a fully constrained intramolecular reaction. Second, the **maximum decrease in standard free energy** of association to be expected when a bimolecular association such as the formation of a hydrogen bond is turned into an intramolecular association is about -55 kJ mol^{-1} , which would produce an increase in its association equilibrium constant, when the units are corrected volume fraction, of 5×10^9 . Third, the larger the

number of bonds about which rotation can occur between the two atoms—for example the heteroatom of the donor and the acceptor—that must be juxtaposed during a reaction, the smaller will be the decrease in standard free energy to be expected when an intermolecular association becomes an intramolecular association.

With these points in mind, the issue of **intramolecular hydrogen bonds** in aqueous solution can be addressed. The standard enthalpy change for a hydrogen bond forming in water should be quite small, but possibly of a negative value (Equation 5–49). The competition of water molecules for donor and acceptor seems to contribute an entropic effect the magnitude of which is $-38 \text{ J K}^{-1} \text{ mol}^{-1}$, which is $R \ln 100$, when concentrations of donor and acceptor are expressed in units of molarity. In an intramolecular association, the consequent elimination of the standard entropy of approximation should be able to compensate for the entropic deficit caused by the presence of the water.

Evidence for the existence of intramolecular hydrogen bonds within solutes dissolved in aqueous solution has been reported. The extensive lore surrounding involvement of hydrogen bonds in the equilibrium acid–base behavior of the monoanions of **dicarboxylic acids** is by and large equivocal,²⁹ but it has been noted⁴⁵ that decreases in the rates of the reactions of the acidic hydrogens in the monoanions of salicylates (**5–17**) with hydroxide ion

5–17

suggest that they contain intramolecular hydrogen bonds the standard free energies of formation of which are around -15 kJ mol^{-1} . A series of compounds capable of forming intramolecular hydrogen bonds either between the pyrrole nitrogen–hydrogen bond on imidazole as donor ($pK_a = 15$) and a carboxylate as acceptor ($pK_a = 5$) or between the pyridinyl lone pair on imidazole ($pK_a = 7.5$) as acceptor and the nitrogen–hydrogen bond on an ammonium cation as donor ($pK_a = 10$) has been described (Table 5–6). As the standard entropy of approximation was decreased by confining the juxtaposed donor and acceptor more severely, or as the difference in pK_a was decreased, the equilibrium constant for the intramolecular hydrogen bond

$$K_{\text{AHB}} = \frac{[\text{B}\oplus\text{HA}]}{[\text{B}\oplus + \text{HA}]} \quad (5-61)$$

increased in magnitude (Table 5–6).

Table 5–6: Intramolecular Hydrogen Bonds in Water

hydrogen bond	ΔpK_a^a	$K_{\text{intra,AHB}}^b$
	3	2^c
	10	$<1^c$
	10	1.5^c
	13	13^c
	3	100^d

^aDifference in pK_a between intermolecular equivalents of donor and acceptor.

^bValue for $K_{\text{intra,AHB}}$ is for the ratio of the concentration of the hydrogen-bonded species (see column 1) to the concentration of the same tautomer not hydrogen-bonded. The equilibrium constants $K_{\text{intra,AHB}}$ for the formation of the noted intramolecular hydrogen bonds in aqueous solution were estimated from values of the N1–N3 tautomeric equilibrium constants (Equation 2–31) for the respective 4-substituted imidazoles determined by ^{15}N nuclear magnetic resonance.¹³⁴ It was assumed that a difference between the value of the tautomeric equilibrium constant for a 4-substituted imidazole in which a hydrogen bond can form and the value of the tautomeric equilibrium constant for a similar compound in which a hydrogen bond cannot form is due to the formation of the noted hydrogen bond. It was also assumed that the value of the tautomeric equilibrium constant for the form of the hydrogen-bonding species in which the bond is not formed is equal to that of the reference compound and that the observed excess of one of the two tautomers represents entirely the hydrogen-bonded form. ^cEstimated from the difference between the second macroscopic acid dissociation constants of *cis*- and *trans*-urocanic acid and the N1–N3 tautomeric ratios for neutral *cis*-urocanic acid.¹⁰⁹

The question that these results raise is whether or not the hydrogen bond in a conformation such as an α helix, a hairpin of β structure, or a β turn can be made favorable by sufficient standard entropy of approximation. Certain cyclic hexapeptides are rigid enough to enforce the conformation of a β turn in which an intramolecular hydrogen bond is formed between the acyl oxygen of one of the six amino acids and the amido nitrogen–hydrogen of the amino acid three positions to the amino-terminal side of it (Figure 4–16D),¹³⁵ and the conformation of the β turn can be varied by changing the sequence of the cyclic peptide. In fact, the first tight turn

to be observed was in such a cyclic hexapeptide.^{136,137} An α helix or β structure, however, cannot be encompassed so easily.

If it is assumed that either an α helix or a hairpin of β structure has already been initiated, could the standard free energy of formation for the next hydrogen bond (Figure 5-19) during the propagation have a negative value? In Figure 5-19, the next donor and acceptor in each structure are marked with asterisks. Because each of these reactions occurs in aqueous solution, the standard enthalpy of formation for such a hydrogen bond is close to 0 (Equation 5-49). The value for the standard free energy of formation for the hydrogen bond will be determined in part by the difference between the unfavorable competition of the water and the favorable elimination of entropy of approximation that the structures provide. For the α helix, there are two bonds about which rotation

Figure 5-19: Intramolecular formation of a hydrogen bond to elongate an α helix or a β hairpin. (A) To add the next hydrogen bond in an elongating α helix, the acyl oxygen marked with the asterisk must combine with the amide nitrogen-hydrogen marked with the other asterisk. The two bonds about which rotation can occur between the last acyl group fixed in the α helix and the acyl oxygen in question have been highlighted with arrows. (B) To add the next hydrogen bond in an elongating antiparallel β hairpin, the acyl oxygen marked with the asterisk must combine with the amide nitrogen-hydrogen marked with the other asterisk.

can occur between donor and acceptor;¹³⁸ for the hairpin of β structure, there are four. It should, however, be remembered that when the problem is stated in these terms, the difficulties involved in the initiation of either of these structures are ignored, and these can be even more formidable.¹³⁸

Recently, several short peptides (8–16 aa in length) have been shown to form antiparallel β structure in aqueous solution by folding back on themselves to form a hairpin.^{139,140} These hairpins of antiparallel β structure have marginal stability at room temperature and the pairing across the sheet is as yet unpredictable. Short stretches of parallel β structure (encompassing three or four pairs of amino acids) have been observed in aqueous solution in molecules in which two short peptides are coupled at their carboxy-terminal ends to two properly spaced positions in a somewhat rigid molecular template that assists in properly orienting them.¹⁴¹ These results suggest that approximation and the cooperative formation of the hydrogen bonds between the two strands in these parallel and antiparallel β structures can overcome the competition of the water for donors and acceptors, but only barely.

All short, linear peptides examined so far fail to form α helices when they are dissolved at room temperature in water at neutral pH, even if they have the same amino acid sequence as an α helix in a crystallographic molecular model.¹⁴² This is almost certainly due to the difficulty of forming the first few hydrogen bonds required to initiate the α helix rather than the formation of the hydrogen bonds that fall in line after it has been initiated (as in Figure 5-19). When short peptides are attached to rigid structural templates that provide properly oriented acceptors for hydrogen bonds and thereby promote initiation, those peptides display a considerable fraction of α helix even at room temperature.¹⁴³

It was noted that when a cyanogen bromide fragment containing the first 12 amino acids of ribonuclease, KETAAAKFERQHHse (where Hse is homoserine), was dissolved in 33 mM Na_2SO_4 between pH 4 and 5, an equilibrium existed between the structureless form of the peptide and an α -helical form. At 0 °C, 15% of the peptide was in the α -helical form at equilibrium.¹⁴² From this original observation, it was eventually^{144–146} discovered that when the peptide acetyl-AAQAAAAQAAAAQAAY- α -amide is dissolved at 0 °C in 1.0 M NaCl, about 50% of it is α -helical and 50% is structureless at equilibrium.¹⁴⁷ This peptide, however, even with as peculiar a sequence as it has, exhibits significant α -helical content only at low temperature. No other simple peptide examined so far displays a significantly higher amount of α helix at equilibrium.^{144,148,149} Considerably higher α -helical content, however, is displayed even at room temperature by continuous segments of polyalanine (4–19 alanines in length) when they are appropriately isolated from the charged amino acids at the two ends of these hybrid molecules that are required to dissolve the polyalanine in

water.¹⁵⁰ Polyalanine, however, is considerably different from the variable and almost unbiased amino acid sequences of the α helices in proteins. All of the peptides displaying α -helical structure, because of the marginal stability of those α helices and the peculiar sequences required, reemphasize the difficulty of overcoming the competition of the molecules of water for donors and acceptors.

The existence of marginally stable synthetic α helices, albeit at 0 °C, has provided a biochemically relevant framework on which to examine the advantages provided by such a structure and its resulting standard entropy of approximation to the formation of intramolecular hydrogen bonds. Because the side chains protrude from an α helix at intervals of 99°, ^{151–153} the side chain four amino acids to the amino terminus of any position in an α helix lies almost directly (396°) below the side chain at that position (Figure 4–17). A hydrogen bond will form between a donor and an acceptor placed synthetically at the i and $i + 4$ positions of an α -helical peptide.¹⁴⁴ For example, in the peptide acetyl-AAQAAEAQAKAAQAAY- α -amide, a hydrogen bond can form between the glutamate and the lysine when the two are held rigidly above and below each other in the α -helical conformation of the peptide. The free energy of formation of this hydrogen bond can be assessed by measuring the differences between the equilibrium constant at 0 °C for the formation of the α helix of this peptide and those for the α helices of various controls in which the hydrogen bond is unable to form.

A series of such measurements have been made (Table 5–7). None of these free energies of formation is remarkable, again presumably because the standard entropy of approximation in such a situation barely overcomes the competition for donors and acceptors from the water. An important point that should be reiterated is that these small negative free energies of formation do

not state that the hydrogen bond is a net contributor to the stability of the α helix; in fact, each of the α helices that contains hydrogen bonds is less stable than an α helix in which the donor and acceptor are replaced by alanine.¹⁴⁷ Rather, it is the formation of the α helix itself that provides the standard entropy of approximation necessary to make the standard free energy of formation of each of these intramolecular hydrogen bonds less than 0.

The difference in standard free energy of formation between the hydrogen bond of a lysinium cation and a glutamate anion and the hydrogen bond of a lysinium cation and a glutamic acid is -0.3 kJ mol^{-1} ; that between the hydrogen bond of a lysinium cation and an aspartate anion and the hydrogen bond of a lysinium cation and an aspartic acid is -0.2 kJ mol^{-1} ; that between the hydrogen bond of a histidinium cation and a glutamate anion and the hydrogen bond of a histidinium cation and a glutamic acid is -0.5 kJ mol^{-1} ; and that between the hydrogen bond of a histidinium cation and an aspartate anion and the hydrogen bond of a histidinium cation and an aspartic acid is -0.7 kJ mol^{-1} (Table 5–7). Because in each case the carboxylate is more basic than the carboxylic acid, and hence a better acceptor, Equation 5–51 predicts that these differences should be -3.5 , -3.5 , -6.5 and -6.5 kJ mol^{-1} , respectively. The fact that the actual differences are significantly less negative than the expected differences is further evidence for the fact that an **ion pair** is unstable in aqueous solution relative to the separated ions because the conversion of the monocationic hydrogen bond into an ion pair actually destabilizes. This conclusion is reinforced by the fact that the difference in standard free energy of formation between the hydrogen bond of a glutamine and aspartic acid and the hydrogen bond of a glutamine and aspartate anion, neither of which is an ion pair, is -2.3 kJ mol^{-1} , even though glutamine is a much weaker acid than either lysinium cation or histidinium cation (Table 2–2).

One could imagine that the standard **base pairs** between adenine and uracil or between guanine and cytosine might form in water because the formation of the second hydrogen bond or the second and third hydrogen bonds in the respective complexes would be aided by standard entropy of approximation gained by the formation of the first. Such a cooperative enhancement of hydrogen bond strength has been observed in complexes between glutaric acid and a cyclic tetraresorcinol in CHCl_3 . In these complexes the two carboxylic groups of the diacid form hydrogen bonds with the phenolic hydroxyls of resorcinols on opposite sides of the ring.¹⁵⁶ The advantage, however, to the formation of the second hydrogen bond, a cooperative but intermolecular situation, was only -10 kJ mol^{-1} , and the hydrogen-bonded complex could be observed only in aprotic solvents such as CHCl_3 . In a similar fashion, standard and nonstandard base pairs between two nucleic acid bases will form in organic solvents or within micelles, but they do not form

Table 5–7: Standard Free Energies of Formation of Hydrogen Bonds within an α Helix^a

donor/acceptor	standard free energy of formation (kJ mol^{-1})

glutamine/aspartate anion ¹⁵⁵	-4.1

^aStandard free energy of formation for a hydrogen bond between the i and $i + 4$ positions of an α -helical peptide.

in water.¹⁵⁷ In fact, the normal bases in DNA itself can be replaced by isosteres that cannot form any hydrogen bonds, and the complementary base pairs form as efficiently from steric complementarity as from base pairing.^{158–161}

The **hydrogen bonds in DNA** contribute to the specificity of the pairing of its bases, but in a negative sense. For example, in order to compensate partially for the strongly unfavorable act of removing the two donors and the one acceptor of guanine and the two acceptors and one donor of cytosine from water, the three hydrogen bonds of the base pair must be formed in a double helix. When only the thymine in the base pair with adenine is replaced by a 2,4-difluoro-5-methylphenyl group so that the two hydrogen bonds cannot form, the base pair is less stable¹⁶² by about 7 kJ mol^{-1} .

There are, however, situations in which hydrogen bonds to nucleic acid bases can be sufficiently assisted by standard entropy of approximation so as to be marginally stable in aqueous solution. The complex between 9-ethyladenine and a specifically designed host

5-18

has an association constant of 28 M^{-1} at 27°C in water at pH 6 and an ionic strength of 0.05 M , but it was estimated that each hydrogen bond in the complex contributed only -0.8 kJ mol^{-1} to its stability even though the standard entropy of approximation must be significant.¹⁶³ It is also possible to form in aqueous solution a hydrogen-bonded dimer of the deoxydinucleotide 5'-phosphodeoxyguanylyl(3'-5')deoxycytidine (pdG-dC). A hydrogen-bonded dimer of this self-complementary dinucleotide forms with an association equilibrium constant of 8 M^{-1} at 2°C and pH 7.5.¹⁶⁴ If it has the common base pairing, six hydrogen bonds hold the two halves together. The rings of the bases are rigid, and once two of the hydrogen bonds in each base pair form, the standard free energy of formation of the third must incorporate the undiluted standard entropy of molecularity. Furthermore, the nucleotide bases on the two monomers are probably already stacked one on top of the other,¹⁶⁵ an association that at least brings all six donors and

acceptors to the same side of the monomer if not in proper alignment. This stacking of the bases results from the hydrophobic effect. It must contribute significantly to this association by roughly aligning the bases before the dimerization occurs. All of these observations demonstrate that the hydrogen bonds between the base pairs of a double-stranded nucleic acid do not contribute significantly to its stability.

Problem 5-10:

- Draw the structure of a hydrogen bond between the propionate anion and a proton on N3 of neutral 4-methylimidazole (see Equation 2-31 for numbering). Include all lone pairs of electrons in your drawing.
- Use Equation 5-51 and a value of 0.013 for τ to estimate the apparent equilibrium constant in units of molarity⁻¹ for the formation in water of a hydrogen bond between one of the lone pairs on a propionate anion ($\text{p}K_a = 4.88$) and a proton on N3 of 4-methylimidazole (microscopic $\text{p}K_a = 15.1$).
- The equilibrium constant for the formation of the intramolecular hydrogen bond in the 3-(3*H*-imidazol-4-yl)propionate anion in which carbons 2 and 3 have been locked by a cyclopentene is 1.5 (Table 5-6). Using the estimated value of the apparent equilibrium constant for the intermolecular formation of the same type of hydrogen bond, from section B, calculate an upper limit for the value of $\Delta S^\circ_{\text{approx}}$ for the conversion of the intermolecular reaction into the intramolecular reaction. Convert the apparent equilibrium constant for the intermolecular formation of the hydrogen bond into units of corrected volume fraction (Equation 5-13) before performing this calculation. Assume that $\Delta\Delta H^\circ$ is 0.

Problem 5-11: Why might it be that the peptide with the amino acid sequence SEEEEKKKKKEEEKKKKF displays 35% α helix at pH 8.3 and 4°C ?¹⁶⁶

The Hydrophobic Effect

The hydrophobic effect is exemplified by the fact “that oil and water are hostile”¹⁶⁷ and do not mix. The reason is that water is more stable when the oil is not dissolved in it than when the oil is. This failure of oil and water to mix is only the most extreme manifestation of the tendency of liquid water to expel solutes that are not ions and that

do not have significant numbers of donors and acceptors of hydrogen bonds. An ionic solute is held in water by large, negative standard enthalpies of hydration. Solutes that have donors and acceptors of hydrogen bonds are held in water by the hydrogen bonds they form with it. Solutes that neither are ions nor have donors and acceptors of hydrogen bonds are expelled from liquid water. This expulsion is the **hydrophobic effect**.

The nature of the hydrophobic effect has been succinctly described by G.S. Hartley.¹⁶⁸

The antipathy of the paraffin chain for water is, however, frequently misunderstood. There is no question of actual repulsion between individual water molecules and paraffin chains, nor is there any very strong attraction of paraffin chains for one another. There is, however, a very strong attraction of water molecules for one another in comparison with which the paraffin-paraffin or paraffin-water attractions are very slight.

Aside from the overuse of “very”, it is clear from this description that the term hydrophobic is misleading, if its etymology is examined closely.¹⁶⁹ The oil does not dislike the water. In fact, measurements of interfacial energies suggest that the oil prefers the water to itself.¹⁷⁰ Rather, **water** ejects the oil because water molecules have a greater like for other water molecules.

The hydrophobic effect upon a hydrophobic solute A can be represented formally by the transfer of the solute from water to another solvent *j*.^{171,172}

It has been proposed¹⁶⁹ that the hydrophobic effect can also be represented by the formation of a macroscopic interface between an immiscible phase of hydrocarbon and water. There are, however, significant differences between the physical properties of such a macroscopic interface and those of the microscopic layer of hydration surrounding an isolated molecule of hydrocarbon dissolved in water.¹⁷³ Because, upon the folding of a molecule of protein, individual side chains of the amino acids are transferred from the water to the interior of the folded structure, the transfer of a molecule of solute from water to another phase (Equation 5-62) seems to be the more appropriate process to examine for the present purposes.

In the case of the failure of oil and water to mix, solute A in Equation 5-62 is a molecule of oil and solvent *j* is the liquid oil itself. Because, in general, pure phases of the different solutes A in a comparison may in themselves have unique peculiarities, the transfer of a solute from water to a nonpolar solvent should be studied in a systematic fashion by choosing a common solvent for all of the transfers.^{174,175} The hydrophobic effect can be quantified^{24,176} by measuring a standard free energy for this transfer (Equation 5-18). The **standard free energy of transfer** of solute A between water and solvent *j*, $\Delta G^\circ_{A, \text{H}_2\text{O} \rightarrow j}$, is the change in standard free energy that results only from the

change in solvation of solute A between the other solvent and the water experienced when solute A, dissolved in water at standard state, is transferred from the water into that other solvent at standard state.

As expected from everyday experience, the standard free energies of transfer of hydrophobic solutes between water and an organic solvent such as benzene, carbon tetrachloride, or the liquid solute itself are negative (Table 5-8). It is this negative change in standard free energy that produces the hydrophobic effect. The hydrophobic effect is the only noncovalent force in aqueous solution that proceeds with a net negative change in standard free energy, and it is thought to provide all of the driving force for the folding of polypeptides, the association of ligands with a protein, and the formation of interfaces between subunits in oligomeric proteins.

The explicit reason for the negative standard free energies of transfer at physiological temperatures is that the **standard entropies of transfer** are larger than the standard enthalpies of transfer (Table 5-8). At 25 °C, the standard enthalpy of transfer, which in most cases is positive and thus unfavorable, is overcome by a much larger positive and thus favorable standard entropy of transfer. This peculiarity has led to the maxim that the hydrophobic effect is entropy-driven, but this is a misleading view. Edsall and Scatchard¹⁸⁰ noted that the incremental standard entropies of solution for $-\text{CH}_2-$ groups in water had anomalously large negative values, but they also pointed out that because of the large changes in standard molal heat capacity, these incremental standard entropies of solution would become less and less significant as the temperature was raised (Figure 5-20).¹⁸¹ As the temperature increases, the standard enthalpy of transfer becomes more and more exothermic. At high enough temperatures the standard entropy of transfer passes through zero and becomes endergonic. As a result, at intermediate temperatures the reaction changes from an entropically driven process to an enthalpically driven process, and at high temperatures the standard entropy of transfer is actually unfavorable even though the transfer itself remains favorable because the standard free energy of transfer does not vary significantly with temperature.

This behavior illustrates the fact, first noted by Edsall, that the most characteristic feature of the hydrophobic effect is not its change in standard entropy but its **change in standard heat capacity**.¹⁸² The anomalously large, positive incremental change in standard molal heat capacity of solution for solutes in water remains the most reliable signature of the hydrophobic effect.¹⁸¹

The changes in the standard thermodynamic state functions, such as standard entropy, standard enthalpy, and standard heat capacity, that are associated with the hydrophobic effect (Table 5-8) have been assigned to **changes in the thermodynamic properties of the water** surrounding the solute as it leaves the aqueous phase and changes in the thermodynamic properties of the nonpolar solvent as it enters; in other words, to differences in

^aValues were calculated from the thermodynamic behavior of the partition coefficients (Equation 5–17). Original published values for the partition coefficients were in units of mole fraction at infinite dilution. These units were converted to units of molarity by dividing them by the appropriate molar volumes of the respective solvents. The partition coefficients in units of molarity were then converted to free energies of transfer and entropies of transfer for units of corrected volume fraction (Equation 5–18). All values are for a temperature of 25 °C.

Figure 5–20: Dependence on temperature (Kelvin) of the changes in standard free energy (ΔG°), standard enthalpy (ΔH°), and standard entropy multiplied by temperature ($T\Delta S^{\circ}$) for the transfer of benzene between water and benzene (left panel) and the transfer of pentane between water and pentane (right panel).¹⁸¹ The activities are expressed in units of mole fraction rather than as corrected volume fraction as in Table 5–8; and the three state functions, free energy, enthalpy, and entropy, are expressed in units of kilojoules mole⁻¹. The lines were calculated from the values of the thermodynamic state functions measured in the range from 0 to 40 °C and either the assumption that the observed behavior of ΔC°_p can be fit by an analytic function of temperature and that analytic function can be extrapolated beyond the range of measurement (solid lines) or the assumption that ΔC°_p is independent of temperature and has a value that is the mean of the observed values (dashed lines). The values of ΔC°_p over the range of measurements seem to decrease somewhat with increasing temperature and this deviation is the basis for considering adjusted values of ΔC°_p for changes in temperature. The trends are the same regardless of the assumption. Reprinted with permission from ref 181. Copyright 1988 Academic Press.

the solvation of the solute by the two solvents. The reason that these changes of the thermodynamic state functions are assigned to the respective solvents rather than the solutes is that the solutes in most cases are too small, as in the case of methane, ethane, or propane, or too rigid, as in the case of benzene, to account internally for the significant changes that are observed.

There are several observations which suggest that a more **rigid hydrogen-bonded lattice**, similar to the lattice in ice Ih, surrounds hydrophobic solutes when they are dissolved in water.^{183,184} Macroscopic solids known as clathrates form spontaneously when hydrocarbons are mixed with pure water at proper molar ratios. **Clathrates** are solid, crystalline hydrates that are composed of isolated individual molecules of hydrocarbon encased in rigid hydrogen-bonded networks of water molecules. The thermodynamic parameters associated with these solids are of a magnitude sufficient to lead to the conclusion that similar rigid networks of water molecules should also surround hydrophobic solutes when they are present at dilute concentration.¹⁸⁵ Whether or not clathrates are of relevance to the hydrophobic effect, their very existence has subconsciously influenced our views of the process. The unusually large changes in standard heat capacity (Table 5-8)¹⁸² associated with the hydrophobic effect are believed to result from an increase in the order of the water surrounding the solute.¹⁸⁶ It should be recalled that it is the gradual melting of the hydrogen-bonded lattice that is supposed to be responsible for the anomalously high heat capacity of liquid water itself, and increasing the amount or the degree of structure of this lattice should produce even greater capacity for melting and, hence, greater heat capacities. The **partial molar volume** of a hydrophobic solute in water is usually about 13 cm³ mol⁻¹ less than that of the same solute in other solvents,²³ and this difference has been thought to result from the efficient packing of the solute within a cage of hydrogen-bonded waters that resembles the networks in clathrates. It has already been noted, however, that ice Ih, and presumably liquid water, contain a large amount of vacant space that a solute could occupy (Figure 5-2), and this occupation by itself could explain the smaller values for partial molar volume. The increase in the **dielectric relaxation time**¹⁸⁷ and the anomalously large increase in the **viscosity**²⁹ observed when a hydrophobic solute is added to water and the expansion of the structure of water around hydrophobic solutes detected by **neutron scattering**,¹⁸⁴ however, also indicate that a more rigid and structured shell of water forms around the solute than the water in the bulk solvent.

If it is the case, however, that the water surrounding a hydrophobic solute is more structured and held within a more rigid hydrogen-bonded lattice than water in the bulk phase, there should be **compensatory thermodynamic changes**^{29,186} associated with this increase in structure. Specifically, the standard enthalpy of the aqueous solution of hydrocarbon should be less than the

standard enthalpy of liquid water because the hydrogen bonds in this more structured cage should be stronger. If a noncovalent chemical transformation occurs in any solution, the change in standard entropy observed is usually compensated by a change in standard enthalpy. This observation can be stated mathematically⁷ as

$$\Delta H^\circ(\alpha) = \Delta H' + T_c \Delta S^\circ(\alpha) \quad (5-63)$$

where α refers to any noncovalent process and $\Delta H'$ and T_c are parameters peculiar to that process. Many noncovalent processes occurring in water¹⁸⁸ satisfy this relationship with $T_c = 280 \pm 10$ K.*

In the particular case of the hydrophobic effect, it has been noted²⁹ that the decrease in standard entropy associated with the formation of a rigid cage of hydration as the solute enters water is not accompanied (Table 5-8) by the decrease in standard enthalpy (Equation 5-63) to be expected from such compensation.¹⁷ The argument is that the **missing enthalpy** in this reaction is the enthalpy that was required to crack open the lattice of the liquid water to form a cavity for the hydrophobic solute. Because standard entropy and standard enthalpy should compensate almost completely in the formation of the more rigid shell of hydration and have little effect on the overall reaction because of this cancellation, it is actually this positive enthalpy of opening the lattice to form a cavity or, conversely, the negative enthalpy realized upon collapsing the cavity that produces the hydrophobic effect.

The positive enthalpy required to open the lattice could result from the fact that some of the hydrogen bonds of the fluid lattice within liquid water must be broken irretrievably when a cavity is formed for a hydrophobic solute. The empty donors and acceptors of such **broken hydrogen bonds** can be observed in molecular dynamics simulations of aqueous solutions of hydrophobic solutes.⁵⁶ Water, however, is presumably adept at rearranging around small nonpolar solutes to form cages like those formed in the clathrates and in the process retaining as many hydrogen bonds as there would be in the absence of those solutes, and other simulations indicate that it is only when all of the dimensions of a nonpolar solute are more than twice the diameter of a molecule of water that significant numbers of hydrogen bonds are lost upon the formation of the cavity.¹⁸⁹ Nevertheless, in this view, the magnitude of the expulsion of hydrophobic solutes from aqueous solution should depend on the number of hydrogen bonds that must be broken to form the cavity.

If this picture of the driving force propelling the

* This value for T_c means that values of changes in standard enthalpy or changes in standard entropy for most processes occurring entirely in aqueous solution are monotonously uninformative because they register mainly compensatory changes in the structure of the solvent.

hydrophobic effect were correct, then it would follow that only the **size of the cavity** should determine the magnitude of the hydrophobic effect. It is the case that the larger the solute, the greater the hydrophobic effect (Table 5-8, Figure 5-21),^{23-25,190} but there is a peculiar aspect to this relationship.

The only feature of a molecule that determines the magnitude of the hydrophobic effect exerted upon it is the number of **hydrogen-carbon bonds** that it contains.¹²⁰ This conclusion follows from the following facts.

First, the change in standard heat capacity upon dissolving a molecule in water, which is the fundamental thermodynamic manifestation of the hydrophobic effect,¹⁸² correlates with high precision ($r \geq 0.985$) to the number of hydrogen-carbon bonds that it contains in 15 different sets containing among themselves a total of 120 molecules.¹⁸⁶ Furthermore, the slopes of each of the 15 correlations are all the same [$30 \pm 2 \text{ J K}^{-1} (\text{mol hydrogen-carbon bond})^{-1}$].

Second, it has long been noted^{24,176,191} that the standard free energies of transfer for linear acyclic alkanes (the lines connecting the symbols \circ in Figure 5-21) from water to any solvent (hexadecane in the case of Figure 5-21) correlate with the number of hydrogen-carbon bonds they contain. The high precision of this correlation ($r > 0.9999$ for the data calculated with units of corrected volume fraction, the lower line) is one of the most remarkable facts concerning the hydrophobic effect.¹⁹² This high precision seems to belie explanations of the hydrophobic effect based on the dimensions of the cavity formed by the solute because these dimensions should depend on the particular length and conformational flexibility of the particular alkane.

Third, the standard free energies of transfer from water to hexadecane for branched alkanes, cyclic alkanes, alkenes, alkadienes, cyclic alkenes, cyclic alkadienes, cyclic alkatrienes, arenes, and alkynes¹⁹⁰ all fall close to the line governing the behavior of linear alkanes (lower solid line in Figure 5-21) when they are plotted as a function only of the number of hydrogen-carbon bonds that the molecules contain. The data fall even closer to the line for linear alkanes when molarities are used as units (upper lines in Figure 5-21).^{*} The same

* The scatter in the data for the free energies of transfer plotted in Figure 5-21 when they are calculated from activities with units of corrected volume fraction (lower line) is more pronounced than when they are calculated from activities with units of molarity (upper line). This may be due to the fact that, in the former case, the partial molar volumes of the solutes have a large effect on the final values for free energies of transfer, yet these partial molar volumes are from estimates rather than direct measurements. It does seem, however, that the standard free energies of transfer for most of the other classes deviate systematically from the line correlating the standard free energies of transfer based on corrected volume fraction for linear alkanes. If this is a real effect, not one due only to the fact that the partial molar volumes used are inaccurate, then a phenyl ring is worth about 1.4 hydrogen-carbon bonds during transfer from water to hexadecane.

Figure 5-21: Standard free energy of transfer from water to hexadecane as a function of the number of hydrogen-carbon bonds in a hydrocarbon. It was found that when the values for the partition coefficients for transfer from water to hexadecane for the linear alkanes listed by Abraham et al.¹⁹⁰ were treated as the quotients of the molarities of the hydrocarbons in the two phases and inserted into Equation 5-18, standard free energies of transfer resulted that were almost identical to those for the transfer of the same hydrocarbons from water to their own liquid calculated with Equation 5-18 from the solubilities tabulated by McAuliffe.²⁵ Consequently, it was assumed that the units on the dimensionless partition coefficients listed by Abraham et al. were molarity molarity⁻¹. These partition coefficients were either inserted into Equation 5-18 directly to obtain standard free energies of transfer for activities in units of corrected volume fraction (lower set of data) or inserted into Equation 5-18 modified so that it did not include the exponential term within the argument of the natural logarithm to obtain standard free energies of transfer for activities in units of molarity (upper set of data). The partial molar volumes for hydrocarbons in hexadecane were calculated with Equation 5-9, and those in water with the algorithms of Traube.^{23,24} The sets of hydrocarbons included (in descending order on the graph for each number of hydrogen-carbon bonds) branched acyclic alkanes (\diamond ; $n = 18$), linear acyclic alkanes (\circ ; $n = 10$), cyclic alkanes (\times ; $n = 6$), acyclic monoenes ($+$; $n = 13$), acyclic dienes (\triangle ; $n = 3$), primary alkynes (∇ ; $n = 6$), cyclic monoenes (\diamond ; $n = 2$), alkyl arenes containing only one phenyl ring (\square ; $n = 17$), and alkenyl arenes containing only one phenyl ring (\ast ; $n = 2$). Consequently there are 78 independent data points in each set. The acidic hydrogens on the primary alkynes were not counted as hydrogen-carbon bonds. The solid lines drawn are fit to only the respective data for the linear acyclic alkanes (\circ) in each set. The dotted line and the line of short dashes were fit to the respective points for nine representative acyclic alkanes, nine representative acyclic monoenes, the nine acyclic dienes and alkynes, nine representative alkyl arenes, and the two alkenyl arenes in each set of data, the upper set calculated with units of molarity and the lower set calculated with units of corrected volume fraction. Each of these lines was forced to pass through the origin. All of the representatives chosen contained between 4 and 16 carbons, and within each class the representatives chosen spanned the largest possible range of lengths. The line of long dashes was fit to all of the data for the alkyl arenes in the data set calculated with units of corrected volume fraction.

results are observed for the standard free energies of transfer from water to the pure liquid calculated from the solubilities of a similar set of hydrocarbons in water.²⁵

Fourth, both the upper and lower solid lines in Figure 5-21 intersect the ordinate so close to the origin that the hydrophobic effect represented by these standard free energies of transfer is for all practical purposes directly proportional to the number of hydrogen-carbon bonds a molecule contains. The upper dotted line in Figure 5-21 is a line forced to pass through the origin that was fit to a representative set of data for acyclic alkanes, acyclic monoenes, acyclic dienes and alkynes, alkyl arenes, and alkenyl arenes, and this fit is statistically indistinguishable from a line fit to the same representative set but not forced to pass through the origin ($r = 0.992$ and $r = 0.992$, respectively). The line of short dashes in Figure 5-21 is a line forced to pass through the origin that was fit to a representative set of data for acyclic alkanes, acyclic monoenes, acyclic dienes and alkynes, alkyl arenes, and alkenyl arenes, and the fit is almost statistically indistinguishable from a line fit to the same set of representative data but not forced to pass through the origin ($r = 0.973$ and $r = 0.977$, respectively).

The mean of the slopes of the four linear fits of the data spanning the largest range of hydrogen-carbon bonds, those for linear acyclic alkanes (lower solid line in Figure 5-21), branched acyclic alkanes, acyclic alkenes, and acyclic arenes (lower line of long dashes in Figure 5-21), for the standard free energies of transfer from water to hexadecane, based on units of corrected volume fraction, is $-2.80 \pm 0.08 \text{ kJ (mol hydrogen-carbon bond)}^{-1}$, which agrees with the value given by Pace.¹⁹³

The significant advantage of the fact that the magnitude of the hydrophobic effect exerted upon a molecule is determined only by its content of hydrogen-carbon bonds is that the change in standard free energy of transfer [$-2.8 \text{ kJ (mol hydrogen-carbon bond)}^{-1}$] or change in standard heat capacity of transfer [$30 \text{ J K}^{-1} \text{ (mol hydrogen-carbon bond)}^{-1}$] due to the hydrophobic effect for a structural transformation can be estimated simply by counting the number of hydrogen-carbon bonds removed from or inserted into water during that transformation.

The hydrophobic effect can be dissected more finely if the process of transfer itself is dissected further. The most reliable way to measure the transfer of a volatile solute between water and another solvent is to place a vessel of water and a vessel of that other solvent containing the solute into a sealed chamber and allow equilibration to occur. In this way, the solute dissolved in the water and the solute dissolved in the other solvent both come into equilibrium with the vapor of solute that fills the sealed chamber. In practice, this experiment dissects the transfer into the following thermodynamic cycle:^{181,194,195}

Ideally, the two standard free energies of transfer between the gas phase and the two liquid phases have the usual function of measuring the two separate **standard free energies of solvation**.

The partition coefficients for the transfer of a number of alkanes between the gas phase and various solvents have been collected.¹⁹⁵ The standard free energies of transfer calculated from these partition coefficients can be presented graphically by plotting the standard free energy of transfer for a given solute into a given solvent as a function of the standard free energy of transfer for that solute into benzene, which can be used arbitrarily as a reference solvent (Figure 5-22).¹⁹⁵ The solvents hexane, cyclohexane, carbon tetrachloride, toluene, phenyl bromide, and phenyl iodide all yield standard free energies of transfer between those of benzene and decane; the solvents phenyl chloride, *N*-methylpyrrole, 1-octanol, 1-butanol, 1-propanol, and ethanol all give standard free energies of transfer intermediate between those of benzene and methanol; and the solvents acetonitrile, propylene carbonate, and nitromethane all display free energies of transfer between those of methanol and dimethyl sulfoxide.

The solvation of most hydrophobic solutes by most solvents proceeds with a negative change in standard free energy, and all of these solvents show clear decreases in standard free energy of solvation as the size of the solute is increased (Figure 5-22). This is to be expected because the **van der Waals forces** that arise as the solute is surrounded by solvent have negative standard enthalpies of formation and increase in magnitude as the size of the solute increases. Water, however, is the clear exception among the solvents examined because it displays positive standard free energies of solvation for all of the hydrocarbons and these standard free energies of solvation increase as the size of the solute increases. With the exception of ethylene glycol, which is also strongly hydrogen-bonded, the nonaqueous solvent showing the least negative standard free energy of transfer is dimethyl sulfoxide, which has been included in Figure 5-22. Even dimethyl sulfoxide, however, fails to demonstrate the extreme behavior of water. The difference in behavior between water and all of the other solvents is the hydrophobic effect: the exclusion of hydrophobic solutes from aqueous solution.

Water must participate in van der Waals interactions with hydrophobic solutes just as the other solvents do. Nevertheless, the unfavorable hydrophobic effect must be greater in magnitude than these favorable van

Figure 5-22: Standard free energy of transfer (kilojoules mole⁻¹) for a given alkane from the gas phase into a given solvent, plotted as a function of the standard free energy of transfer for that alkane from the gas phase into benzene.¹⁹⁵ The values tabulated for partition coefficients, originally in units of atmosphere for the vapor and mole fraction for the solute dissolved in a solvent, were converted to moles liter⁻¹ for the vapor and corrected volume fraction for the solute in a solvent (Equation 5-5) by use of estimates of the partial molar volumes for the hydrocarbons in water^{23,24} or Equation 5-9 for the partial molar volumes of the hydrocarbons in the other solvents. The standard free energies of transfer from the gas phase into the various solvents were then calculated (Equation 5-21). The solvents chosen for display were decane (○), benzene (□), methanol (◇), dimethyl sulfoxide (×), and water (+). The alkanes chosen were methane, ethane, propane, *n*-butane, isobutane, *n*-pentane, neopentane, *n*-hexane, *n*-heptane, and *n*-octane. Benzene was chosen as the reference solvent because more values for standard free energy of transfer into benzene were available and benzene has behavior similar to decane.

der Waals forces and more than overcomes them. As the polarities of the solvents increase, the slopes of the lines in Figure 5-22 become less negative. This effect might be explained by noting that as the solvents become more polar, more standard free energy is required to form a cavity within them, and this change is deducted from the favorable standard free energy of interaction between solute and solvent. In this view, water would simply be the extreme example of the difficulty in forming a cavity.

The solutes chosen for the free energies of transfer from the gas phase to the various solvents in Figure 5-22 were all acyclic alkanes. Further insight into the hydrophobic effect is gained when the free energies of transfer from the gas phase into hexadecane and from the gas phase into water are plotted for linear alkanes, branched alkanes, cyclic alkanes, alkenes, alkadienes, cyclic alkenes, alkynes, cyclic alkadienes, saturated arenes, and unsaturated arenes (Figure 5-23)^{175,196} as a

function of the number of their hydrogen-carbon bonds. The difference between each pair of lines, the one for transfer from gas to hexadecane and the one for transfer from gas to water, is the line for the standard free energy of transfer from water to hexadecane for the respective class of compounds (Figure 5-21). As the degree of unsaturation increases, each of these pairs of lines in Figure 5-23 is found at a lower level on the graph [about -2.2 kJ mol⁻¹ (level of unsaturation)⁻¹ for water and -2.4 kJ mol⁻¹ (level of saturation)⁻¹ for hexadecane].* It is the difference between these two values for the incremental free energies of transfer that causes each of the lines for the standard free energies of transfer for the other classes of hydrocarbons presented in Figure 5-21 (lower set of data) to fall progressively below the line for the linear alkanes.

With the notable exception of cyclization, when any two hydrocarbons are compared that have the same number of hydrogen-carbon bonds, the more unsaturated one will be the larger one, and the larger one should display stronger van der Waals interactions with the hexadecane. To the extent that the incremental decreases in standard free energies of solvation by hexadecane for hydrocarbons with the same number of hydrogen-carbon bonds but different levels of unsaturation (offsets of the lower set of lines in Figure 5-23) represent increases in van der Waals interactions, the similar incremental decreases observed for transfer of the same hydrocarbons into water suggest that water also participates in similar van der Waals interactions.

The standard enthalpies of transfer from the gas phase to water for the linear alkanes can be described by the relationship¹⁹⁷

$$\Delta H_{g \rightarrow H_2O}^\circ = -17 \text{ kJ mol}^{-1} - 1.7 \text{ kJ (mol hydrogen-carbon bond)}^{-1} \quad (5-65)$$

This inclusive, exothermic standard enthalpy of transfer must arise from the establishment of van der Waals interactions between water and the alkane during its entry. If so, this also provides evidence that water does participate in van der Waals interactions with hydrocarbon.

In Figure 5-23, the lines for the transfer of the linear alkanes from the gas phase into water and from the gas phase into hexadecane intersect on the ordinate at +4 kJ mol⁻¹, in agreement with the intersection of all of the lines in Figure 5-22 at +5 kJ mol⁻¹. In Figure 5-23, this

* The offsets of the lines for aqueous solutions in Figure 5-23 suggest that it is the only the degree of unsaturation that is of consequence in the solvation experienced by hydrocarbons in water, but the offsets of the lines for solutions in hexadecane suggest that, unlike in water where they are equivalent to only one degree of unsaturation, the solvation of a ring in hexadecane is equivalent to the solvation of two degrees of unsaturation.

Figure 5-23: Standard free energies of transfer from the gas phase to water (upper set of lines) and from the gas phase to hexadecane (lower set of lines) as a function of the number of hydrogen-carbon bonds in a hydrocarbon. It was found that when the values for the partition coefficients for transfer from hexadecane to the gas phase calculated with Equation 1-10 from the mobility of linear alkanes on gas-liquid chromatography with a stationary phase of hexadecane¹⁷⁵ were treated as the quotients of the molarities of the hydrocarbons in the two phases and inserted into Equation 5-21, standard free energies of transfer resulted that were almost identical to those for the transfer of the same hydrocarbons from the gas phase to their own liquid, calculated with Equation 5-21 from the data of Hine and Mookerjee.¹⁹⁶ Consequently, it was assumed that the units on the dimensionless partition coefficients listed by Abraham were molarity molarity⁻¹, and they were inserted as such into Equation 5-21 directly to obtain standard free energies of transfer from the gas phase to hexadecane for activities in units of corrected volume fraction. The standard free energy of transfer for each hydrocarbon from the gas phase to water was obtained by summing its standard free energy of transfer from the gas phase to hexadecane and the standard free energy of transfer from hexadecane to water (Figure 5-21, lower set of data). The partial molar volumes for hydrocarbons in hexadecane were calculated as in Figure 5-21. The classes of hydrocarbons included, in descending order at each numerical value for hydrogen-carbon bonds, were branched acyclic alkanes (\diamond), linear acyclic alkanes (\circ), acyclic monoenes ($+$), cyclic alkanes (\times), acyclic dienes (\triangle), primary alkynes (∇), cyclic monoenes (\diamond), cyclic dienes (\times), alkyl arenes containing only one phenyl ring (\square), alkenyl arenes containing only one phenyl ring (\times), and diphenylmethane (\triangle). The acidic hydrogens on the primary alkynes were not counted as hydrogen-carbon bonds for transfer to water. The lines drawn are fit to the respective data for the linear acyclic alkanes (solid line), the acyclic monoenes (long dashes), the primary alkynes (intermediate dashes), and the alkyl arenes (short dashes). These four sets contained the largest spreads in the number of hydrogen-carbon bonds.

intersection corresponds to the standard free energy of transfer of a linear alkane with no hydrogen-carbon bonds from the gas phase to either condensed phase, which is the transfer of nothing. It is reassuring that the **transfer of nothing** from water to hexadecane proceeds with no change in standard free energy, but the fact that the standard free energy of transfer of nothing from the gas phase to either of these condensed phases is $+4 \text{ kJ mol}^{-1}$ suggests that, not surprisingly, there remains some difference in standard free energy between the gas phase and either condensed phase unaccounted for by the choices of standard state. If, as has been stated,¹⁹⁷ an additional term equal to RT ($+2.5 \text{ kJ mol}^{-1}$) must be added to all of the standard free energies of transfer, this correction would only increase this difference.

As the amount of unsaturation in the sets of hydrocarbons increases, the standard free energies of transfer at the respective intersections decrease in value. Each of these latter intersections corresponds to the free energy of transfer of the unsaturated hydrocarbon in that set

with no hydrogen-carbon bonds, which would be the particular carbon-carbon double bonds alone. These intersections decrease monotonically in value as the number of carbon-carbon double bonds increases because van der Waals interactions are realized when each of these carbon-carbon double bonds are transferred from the gas phase to either water or hexadecane.

The slope of the line in Figure 5-23 correlating the standard free energies of transfer from the gas phase to water for the linear alkanes is $+1.45 \text{ kJ (mol hydrogen-carbon bond)}^{-1}$, that for branched alkanes is $+1.48 \text{ kJ (mol hydrogen-carbon bond)}^{-1}$, and that for arenes is $+1.50 \text{ kJ (mol hydrogen-carbon bond)}^{-1}$. These values, which are for hydrocarbons related to the side chains of the amino acids, define the magnitude of the **active exclusion of hydrogen-carbon bonds from water**.

It is the separate solvations dissected in Figure 5-23, the one accomplished by hexadecane and the one accomplished by water, that together further illustrate the unique contribution of hydrogen-carbon bonds to

the hydrophobic effect. When any two hydrocarbons are compared that have the same number of hydrogen-carbon bonds, the more unsaturated one will be the one with the larger **surface area**. As the degree of unsaturation and hence the surface area increases at a constant number of hydrogen-carbon bonds, the standard free energy of solvation exerted by the hexadecane becomes more negative. As the degree of unsaturation and hence the surface area increases at a constant number of hydrogen-carbon bonds, the standard free energy of solvation exerted by the water becomes more negative. As the number of hydrogen-carbon bonds and hence the surface area increases at a constant degree of unsaturation, the standard free energy of solvation exerted by the hexadecane becomes more negative. In distinct contrast to these three trends, however, as the number of hydrogen-carbon bonds increases at a constant degree of unsaturation, the standard free energy of solvation exerted by the water becomes more positive. It is only the water that responds to an increase in the surface area of the solute by rejecting it more and more strongly but only when that increase in the surface area is accomplished by adding hydrogen-carbon bonds.

When the standard free energies of transfer from the gas phase to water for an even larger set of organic solutes than those displayed in Figure 5-23 are examined,¹⁹⁸ small differences in the standard free energy of transfer (mole hydrogen-carbon bond)⁻¹ for different types of hydrogen-carbon bond become apparent, and these differences have been quantified by defining a value for the contribution of each type to the overall standard free energy. For pairs of molecules otherwise identical except that one contains $-\text{CH}_2\text{CH}_2-$ and the other $-\text{CH}(\text{CH}_3)-$, the free energies of transfer from gas to water differ by $+0.4 \text{ kJ mol}^{-1}$ (15%), and for pairs of molecules, otherwise identical except that one contains $-\text{CH}_2\text{CH}_2\text{CH}_2-$ and the other contains $-\text{C}(\text{CH}_3)_2-$, the standard free energies of transfer from gas to water differ by $+0.6 \text{ kJ mol}^{-1}$ (15%). These differences might be taken as evidence that branched alkanes are more hydrophobic than unbranched alkanes except for the fact that when standard free energies of transfer from water to hexadecane (Figure 5-21) are examined instead of those from gas to water, branched alkanes (\diamond in Figure 5-21) are less hydrophobic than unbranched. These opposite conclusions bring into focus the unfortunate fact that currently there are two ways of defining the hydrophobic effect: one stressing only solvation by water, and the other, transfer from water to hydrocarbon.

There are **two significant contributions to the hydrophobic effect** (Figure 5-23): the active exclusion of hydrogen-carbon bonds from water and the solvation of those hydrogen-carbon bonds by the new surroundings in which they find themselves. If a hydrogen-carbon bond is transferred from water to the gas phase, the new

surroundings, by definition, do not solvate it; only the former contribution is expressed, and the hydrophobic effect is only the exclusion of the hydrogen-carbon bonds from water. If, however, the hydrogen-carbon bond is transferred to a condensed phase, such as hexadecane, half of the magnitude of the hydrophobic effect is its solvation by the new solvent. The more recent habit of equating the hydrophobic effect only with the transfer from gas to water^{26,198,199} avoids dealing with this half of the hydrophobic effect as it was defined traditionally.^{171,177} Both views, however, the one emphasizing solvation and the other transfer, persist.^{19,198}

It is hard to argue that transfer from water to gas is relevant to biochemical events such as the folding of a protein or the association of a substrate or inhibitor with an enzyme. In such instances the hydrogen-carbon bonds are transferred from water into a condensed phase that bears no resemblance to the gas phase. But the condensed phase in such situations does not resemble hexadecane either; rather, it is the interior of the irregular solid that is the native protein itself. There is no reason to assume that the interior of a molecule of protein behaves as if it were an isotropic solvent.

These considerations bring the argument back to the van der Waals forces between the hydrogen-carbon bond and its new surroundings. Regardless of whether or not water engages in van der Waals interactions with a hydrogen-carbon bond that are of the same magnitude as those of the new surroundings, the results in Figure 5-23 suggest that water *behaves* as though it does not engage in van der Waals interactions with a hydrogen-carbon bond at all. Once the hydrogen-carbon bond has been expelled from water, the standard free energy of its transfer is significantly affected by the standard free energy of the van der Waals forces between it and its new surroundings. As a result, and ironically, it is these van der Waals forces that determine much of the magnitude of the hydrophobic effect in any particular circumstance, and it is the magnitude of the van der Waals force felt by a hydrophobic functional group in the interior of the folded molecule of protein that significantly affects the strength of the hydrophobic effect it is able to exert during the folding of the polypeptide.

When a polypeptide is present in water in its unfolded state, the hydrophobic hydrogen-carbon bonds scattered along its length are unstable relative to any state in which they are in contact with each other and out of contact with water. This is the hydrophobic effect that drives the process of **folding**. Because ions and donors and acceptors of hydrogen bonds are more stable in the hydrated state than in any state in which they are isolated from water, even if they are fully joined in ion pairs and hydrogen bonds, they cannot provide net favorable standard free energy to the process of folding. The hydrophobic effect is the only noncovalent force that provides net favorable standard free energy to drive the folding of a polypeptide.

Problem 5–12: The anomalously high isopiestic heat capacity C_p of liquid water is presumably due to the fact that as the liquid is heated, a certain amount of its hydrogen-bonded structure is lost. This extra heat capacity, beyond that calculated from vibrations and translations of the molecules, is the configurational heat capacity ($C_{p,cf}$). For water, $C_{p,cf} \approx 30 \text{ J K}^{-1} \text{ mol}^{-1}$ ($T = 273\text{--}373 \text{ K}$).

- (A) Calculate ΔS_{cf} and ΔH_{cf} , the configurational standard entropy and standard enthalpy changes, that are associated with heating water from 293 to 313 K.

It is difficult to say with certainty what fraction of the hydrogen bonding is lost over this temperature range, but these numbers give a rough estimate of the ratio of the changes of standard enthalpy and standard entropy ($\Delta H/\Delta S$) to be expected when the structure of water increases or decreases in the liquid. Consider the following phase transfer reaction:

- (B) If all the change in standard entropy (Table 5–8) is due to a decrease in water structure as the more structured regions that surrounded the alkane melt, what standard enthalpy change must accompany this decrease in water structure?
- (C) What is the contribution in percent to the change in standard free energy (ΔG°) in the above reaction that results from the melting of structured water around the alkane?

Problem 5–13: Consider the following transfer reaction:

This chemical equation describes the transfer of an alcohol from water to a pure phase. As such it describes the tendency of the alcohol to remove itself from water, a hydrophobic effect. For any substance A under any circumstances there is associated an intrinsic standard free energy, or chemical potential (μ):

$$\mu_A = \mu_A^\circ + RT \ln \left\{ \phi_{A,j} \exp \left[1 - \left(\bar{V}_{A,j} / \bar{V}_j \right) \right] \right\}$$

where μ_A is the chemical potential of solute A under the experimental circumstances, μ_A° is the chemical potential of solute A at standard state and unit concentration, and $\phi_{A,j}$ and \bar{V} are defined by Equations 5–6 and 5–8. The free energy change for the transfer reaction is

$$\Delta G_{\text{alc,H}_2\text{O} \rightarrow \text{alc}} = \mu_{\text{alc}} - \mu_{\text{alc,H}_2\text{O}} = \mu_{\text{alc}}^\circ - \mu_{\text{alc,H}_2\text{O}}^\circ -$$

$$RT \ln \left\{ \phi_{\text{alc,H}_2\text{O}} \exp \left[1 - \left(\bar{V}_{\text{alc,H}_2\text{O}} / \bar{V}_{\text{H}_2\text{O}} \right) \right] \right\}$$

where μ_{alc} is the chemical potential of pure alcohol and $\mu_{\text{alc,H}_2\text{O}}$ is the chemical potential of the alcohol dissolved in water at a concentration of $\phi_{\text{alc,H}_2\text{O}}$. At equilibrium, when alcohol saturates the water phase, $\Delta G = 0$ and

$$\mu_{\text{alc}}^\circ - \mu_{\text{alc,H}_2\text{O}}^\circ = \Delta G_{\text{alc,H}_2\text{O} \rightarrow \text{alc}}^\circ =$$

$$RT \ln \left\{ \phi_{\text{alc,H}_2\text{O,sat}} \exp \left[1 - \left(\bar{V}_{\text{alc,H}_2\text{O}} / \bar{V}_{\text{H}_2\text{O}} \right) \right] \right\}$$

It is easy to measure the concentration of alcohol in moles liter^{−1} at saturation when H₂O and pure alcohol are shaken in a two-phase system (separatory funnel) and the aqueous phase is clarified and removed. The following results²⁰⁰ were obtained at 25 °C:

alcohol	[alcohol] _{sat} (mol L ^{−1})
<i>n</i> -butanol	0.97
<i>n</i> -pentanol	0.25
<i>n</i> -hexanol	0.059
<i>n</i> -heptanol	0.0146
<i>n</i> -octanol	0.0038

- (A) Change these numbers into

$$\phi_{\text{alc,H}_2\text{O,sat}} \exp \left[1 - \left(\bar{V}_{\text{alc,H}_2\text{O}} / \bar{V}_{\text{H}_2\text{O}} \right) \right]$$

- (B) Calculate $\Delta G_{\text{alc,H}_2\text{O} \rightarrow \text{alc}}^\circ$ for each case, and plot $\Delta G_{\text{alc,H}_2\text{O} \rightarrow \text{alc}}^\circ$ as a function of the hydrogen–carbon bonds (*n*).

- (C) Determine the slope of your plot, $\Delta G_{\text{HC,H}_2\text{O} \rightarrow \text{alc}}^\circ$:

$$\Delta G_{\text{alc,H}_2\text{O} \rightarrow \text{alc}}^\circ = \Delta G_{\text{alc}}^\circ + n \Delta G_{\text{HC,H}_2\text{O} \rightarrow \text{alc}}^\circ$$

- (D) The term $\Delta G_{\text{HC,H}_2\text{O} \rightarrow \text{alc}}^\circ$ is the standard free energy change associated with the transfer of a hydrogen–carbon bond from H₂O to pure aliphatic alcohol. Is this transfer favored or unfavored?

- (E) The term $\Delta G_{\text{alc}}^\circ$ is the standard free energy change due to the fact that the molecule you are using is an alcohol. Is the transfer of the hydroxyl group favored or unfavored?

- (F) Extrapolate to determine $\Delta G^\circ_{\text{alc,H}_2\text{O} \rightarrow \text{alc}}$ for *n*-propanol.
- (G) Determine $\Delta S^\circ_{\text{HC,H}_2\text{O} \rightarrow \text{alc}}$ in the equation $\Delta S^\circ_{\text{alc,H}_2\text{O} \rightarrow \text{alc}} = \Delta S^\circ_{\text{alc}} + n\Delta S^\circ_{\text{HC,H}_2\text{O} \rightarrow \text{alc}}$ and $\Delta H^\circ_{\text{HC,H}_2\text{O} \rightarrow \text{alc}}$ in the equation $\Delta H^\circ_{\text{alc,H}_2\text{O} \rightarrow \text{alc}} = \Delta H^\circ_{\text{alc}} + n\Delta H^\circ_{\text{HC,H}_2\text{O} \rightarrow \text{alc}}$ from the values in Table 5-8.
- (H) Is ΔH° or ΔS° the major contributor to the hydrophobic effect on a hydrogen-carbon bond at 25 °C?

Problem 5-14: Calculate the standard enthalpy of transfer and the standard entropy of transfer of *n*-butane from water to liquid *n*-butane at 50, 70 and 90 °C. Recall that

$$d\Delta H = \Delta C_p dT$$

and

$$d\Delta S = \frac{\Delta C_p}{T} dT$$

and assume that all partial volumes and ΔC_p are invariant with temperature over the range 20–100 °C.

Problem 5-15: The partition coefficients of *N*-methylindole and 3-methylindole

between water and cyclohexane were examined²⁰¹ to investigate the effect of the hydrogen-bond donor in tryptophan on its partition between water and the anhydrous interior of a protein. The coefficients for partition from water to cyclohexane in the following table are expressed in units of molarity and have been extrapolated to infinite dilution.

- (A) Calculate the standard enthalpy of transfer for each compound from the behavior of its partition coefficient as a function of the temperature.
- (B) If a hydrogen bond were lost every time a 3-methylindole was transferred from water to cyclohexane and no hydrogen bond were lost every time *N*-methylindole was transferred from water to cyclohexane, which standard enthalpy of transfer should be more negative?
- (C) When a molecule of 3-methylindole leaves water for cyclohexane, what is the net change in hydrogen bonding for the entire system?
- (D) Why isn't the standard enthalpy change for the transfer of 3-methylindole more negative than that for the transfer of *N*-methylindole?

Problem 5-16: The *N*-acetyl- α -amides of a series of amino acids were synthesized, and the partition of each of them between 1-octanol and water was assayed. The measured distribution coefficients for the reaction

in units of (moles of solute) (liter of water)⁻¹ (moles of solute)⁻¹ (liter of 1-octanol) at 20 °C are presented in the following table.²⁰²

<i>N</i> -acetylamide of amino acid	distribution coefficient $\left(\frac{\text{mol of solute (L of 1-octanol)}^{-1}}{\text{mol of solute (L of water)}^{-1}} \right)$
isoleucine	0.93
leucine	0.75
methionine	0.25
valine	0.24
alanine	0.030
threonine	0.027
serine	0.0135
glutamine	0.0089
asparagine	0.0038

- (A) Estimate the partial molar volumes of the *N*-acetylammides in water by using the algorithm of Traube.

Because partial molar volumes in 1-octanol are unavailable, assume that they are equal to those in water + 13 cm³ mol⁻¹. In all cases, the final concentrations of the model compounds in each phase were less than 10 mM.

- (B) Calculate the standard free energy of transfer in kilojoules mole⁻¹ for each of these model compounds from water into 1-octanol, $\Delta G^{\circ}_{A,H_2O \rightarrow \text{octanol}}$.
- (C) Plot $\Delta G^{\circ}_{A,H_2O \rightarrow \text{octanol}}$ against the number of hydrogen-carbon bonds in each *N*-acetylammide.
- (D) Draw a line across your plot with a slope of -2.8 kJ (mol hydrogen-carbon bonds)⁻¹ that passes through the four points for leucine, isoleucine, valine, and alanine on your plot. Why did you do this?
- (E) Why don't the points for glutamine and asparagine lie 52 kJ mol⁻¹ above the line and the points for serine and threonine lie 26 kJ mol⁻¹ above the line?

Hydropathy

As ionic interactions, hydrogen bonds, and the hydrophobic effect are considered in turn, it becomes clear that the functional groups participating in each of these processes—ionic groups, donors and acceptors of hydrogen bonds, and hydrogen-carbon bonds—experience strong favorable and unfavorable interactions with water. Ionic solutes display large negative standard enthalpies of hydration that dominate their behavior in water. When these ions are withdrawn from water, large investments of free energy must be made to strip the shells of hydration from them. Solutes with donors and acceptors form hydrogen bonds with water molecules that have significant negative free energies of formation because of the high molar concentration of the water in

the solution. When donors and acceptors of hydrogen bonds are withdrawn from water, significant investments must be made to counter these free energies. Hydrophobic solutes leave aqueous solution with a preference for almost any other condensed or uncondensed phase because when they are dissolved in water, they cannot form any net favorable interactions with it. When they are withdrawn from water into another phase, significant favorable changes in free energy are realized. Each of these particular outcomes arises from the respective changes in the structure of water that accompany the transfer of the functional groups between water and a nonaqueous phase.

Viewed in this light, few solutes elicit indifferent responses from water. Solutes are either hydrophilic, demonstrating a compatibility with water, or hydrophobic, demonstrating an incompatibility with water. These strong responses together are hydropathy. **Hydropathy** is the continuous spectrum from compatibility to incompatibility with water, at one end of which is hydrophilicity, and at the other, hydrophobicity.

It was suggested by Hine and Mookerjee¹⁹⁶ that the hydropathy of a solute could be judged from its standard free energy of **transfer between water and the gas**. Assembling values from the tables of Hine and Mookerjee¹⁹⁶ and providing several previously unmeasured values, Wolfenden, Andersson, Cullis, and Southgate^{199,203} have tabulated the standard free energies of transfer between water and the gas for model compounds of the side chains of the amino acids in which the α carbon has been replaced by hydrogen (Table 5-9). These values reflect the magnitudes of the standard free energies realized when the various functional groups present in the amino acids are removed from water at pH 7. As previously noted, the hydrocarbons among the side chains are expelled spontaneously from water with standard free energies of transfer between about -5 and -20 kJ mol⁻¹.

The hydroxyl groups on ethanol and methanol increase their respective standard free energies of transfer from water to the gas phase by +27 kJ mol⁻¹ relative to alkanes of the same number of hydrogen-carbon bonds. In part, these unfavorable incremental standard free energies of transfer arise from the fact that a net of one hydrogen bond is lost to the system when a **hydroxyl group** is removed from water into the gas phase. Methanethiol, however, has a standard free energy of transfer only +10 kJ mol⁻¹ greater than an alkane with the same number of hydrogen-carbon bonds, while ethyl methyl sulfide has a standard free energy of transfer +12 kJ mol⁻¹ greater than an alkane with the same number of hydrogen-carbon bonds. A comparison of these two values with those for ethanol and methanol suggests that it is the **sulfur** that is hydrophilic, not the potential hydrogen-bond donor on the methanethiol.

Propionamide and acetamide have standard free energies of transfer +44 kJ mol⁻¹ greater than alkanes of

Table 5-9: Standard Free Energies of Transfer of Model Compounds for the Amino Acids between Water and the Gas Phase at 25 °C and pH 7^a

amino acid	model compound	$\Delta G^\circ_{\text{H}_2\text{O} \rightarrow \text{g}}$ (kJ mol ⁻¹)	amino acid	model compound	$\Delta G^\circ_{\text{H}_2\text{O} \rightarrow \text{g}}$ (kJ mol ⁻¹)	amino acid	model compound	$\Delta G^\circ_{\text{H}_2\text{O} \rightarrow \text{g}}$ (kJ mol ⁻¹)

						R	methylguanidine ^b	+73
			peptide bond	N-methylacetamide	+34 kJ mol ⁻¹			

^aThe values for the standard free energies of transfer from water to the gas phase for the various model compounds were obtained from several tables.^{196,199,203} They were usually presented as the transfer of the compound between the standard state of the real gas at infinitely low partial pressure with concentration expressed in atmospheres and the standard state of the infinitely dilute solution with concentration expressed in molarity. The units of concentration were changed to moles liter⁻¹ for the gas and corrected volume fraction (Equation 5-5) for the solution. The partial molar volumes of the solutes²⁶ were calculated²⁴ for each solute from the formulas developed by Traube.²³ The standard free energies of transfer from water to the gas phase were calculated with Equation 5-21. ^bValues for the pK_a of the various amino acids in a polypeptide (Table 2-2) were used to correct the standard free energies of transfer of the neutral compounds^{199,203} for the standard free energy of neutralization required at pH 7 (Equation 5-66).

the same number of hydrogen-carbon bonds. An argument can be made that these large positive standard free energies of transfer for the **primary amides** arise simply because each of them has two acceptors and two donors so that a net loss to the system of two hydrogen bonds occurs upon their transfer to the gas phase. Consequently, their standard free energies of transfer relative to alkanes of the same number of hydrogen-carbon bonds should be about twice those of ethanol and methanol, which they are. The standard free energies of transfer for acetamide or propionamide are about +12 kJ mol⁻¹ greater than those for neutral acetic acid or neutral propionic acid, respectively. The transfer of the **carboxylic acid** on either of these two acids involves the net loss of only one hydrogen bond to the solution. Although all of these explanations seem reasonable, they leave unexplained the fact that the standard free energy of transfer for *N*-methylacetamide, the model for the **peptide bond**, is actually greater than that for propionamide, which has the same number of hydrogen-carbon bonds, even though a net loss of only one hydrogen bond occurs when the former is removed from water. It was suggested after the fact that in the case of the amides the acceptors may be more important than the donors,²⁰⁴ and subsequently spectroscopic evidence consistent with this suggestion was reported, demonstrating that each of the two acceptors on the acyl oxygen of *N*-methylacetamide interacts with water with about twice the standard enthalpy as that for the interaction of the single donor.^{116,205,206}

The transfers of the **heterocyclic side chains** are dominated by their donors and acceptors of hydrogen bonds. 3-Methylindole and 4-cresol have standard free energies of transfer +18 and +21 kJ mol⁻¹, respectively, greater than an arene with the same number of hydrogen-carbon bonds. These increments arise from the

presence of the pyrrole donor and the hydroxyl, respectively, that form hydrogen bonds with the donors and acceptors of water that must be broken during transfer. The standard free energy of transfer for neutral 4-methylimidazole is +39 kJ mol⁻¹ greater than that of an arene with the same number of hydrogen-carbon bonds, in part because its acceptor (pK_a = 7.5) is much stronger than that of either 4-cresol (pK_a = 10.2) or 3-methylindole (pK_a = -2).

In the case of the amino acids that are charged at pH 7, such as glutamic acid, aspartic acid, histidine, lysine, and arginine, the tabulated partition coefficients for transfer of the model compounds between water and the gas are for acidic solutions or basic solutions in which those model compounds are dissolved entirely as the neutral conjugate acids or neutral conjugate bases, respectively. At pH 7 only a fraction of the actual amino acid will be present as the neutral species, and this will decrease the value of the partition coefficient for transfer from water to the gas. This decrease in the partition coefficient can be incorporated into the standard free energy of transfer with the formula²⁰³

$$\Delta G^\circ_{\text{A}_{\text{TOT}}, \text{H}_2\text{O} \rightarrow \text{g}} = \Delta G^\circ_{\text{A}_0, \text{H}_2\text{O} \rightarrow \text{g}} - RT \ln \alpha_{\text{A}} \quad (5-66)$$

where A₀ refers to the un-ionized form of the model compound, A_{TOT} is the sum of the neutral form and the charged form, and α_A is the fraction that is un-ionized at pH 7. The values for α_A were calculated with the values of pK_a for the amino acids in a polypeptide (Table 2-2) rather than with the values of pK_a for the model compounds themselves. The fraction of un-ionized species, α_A, varies from 0.8 for histidine to 10⁻⁶ for arginine. Even the standard free energy necessary to neutralize *N*-methylguanidium and transfer the neutral compound into the gas

(+73 kJ mol⁻¹) is still less than the standard free energy that would be required to transfer it into the gas as a cation (Figure 5-8). Therefore, all of the tabulated values should refer to the most likely reactions, namely, neutralization followed by transfer. For example, the only reasonable reaction for the transfer of *n*-butylammonium ion, dissolved in H₂O at pH 7, to the gas would be

One of the most striking, and perhaps informative, facts about the charged amino acids in a polypeptide is that all of them can be **neutralized** in simple acid-base reactions. This is a common property of almost all organic cations and anions found in biological systems, with the tetraalkylammonium cation among the notable exceptions. Nevertheless, it could be argued that this latter functional group, which does appear in biological settings, has been purposely excluded from among the amino acids by natural selection because it cannot be neutralized. When charged amino acid side chains are transferred to a region with a low relative permittivity, such as the gas phase, they will enter as the uncharged conjugate acids or conjugate bases. The standard free energy required to neutralize the charges of propionic acid, acetic acid, and *n*-butylamine and then remove their donors and acceptors for hydrogen bonds from water is greater by about +45 to +48 kJ mol⁻¹ than the standard free energy of transfer for an alkane with the same number of hydrogen-carbon bonds.

The point emphasized by these experimental results is that water has a high affinity for many of the side chains of the amino acids, and a good deal of standard free energy must be spent whenever they are removed from it. This is the complement of the fact that the only favorable standard free energy gained from removing side chains of the amino acids from an aqueous solution arises from the removal of their hydrogen-carbon bonds from contact with water. At the beginning, every amino acid within a newly synthesized, unfolded polypeptide is completely solvated by water. During the **folding** of the polypeptide, the formation of an interface between subunits, or the binding of a ligand, there is a net transfer of side chains of individual amino acids, segments of polypeptide backbone, and small solutes from water to the interior of a native protein. In analogy with Equation 5-64, the first half of the reaction can be represented by the standard free energies of transfer between water and the gas (Table 5-9). Those

solutes removed from water, however, are transferred into a new environment, the **interior of the protein**. The standard free energies of transfer into this new environment are the second half of the reaction, but the standard free energies of transfer into the interior of a protein from the gas cannot be predicted with any certainty because the interior of a protein is a heterogeneous solid.

Presumably, noncovalent forces with negative standard free energies of formation arise as the amino acids and the polypeptide backbone are packed into the interior. The standard free energy of transfer for the removal of hydrogen-carbon bonds from the aqueous phase is a negative change in standard free energy, but a small one compared to the favorable hydration of the polar side chains (Table 5-9). These hydrogen-carbon bonds, however, are being transferred into a new environment that should not have the aversion displayed by liquid water but should respond with favorable van der Waals forces, perhaps resembling in their magnitude the favorable negative standard free energies of solvation for nonpolar solutes displayed by all solvents other than water (Figure 5-22). The standard free energies of transfer for the removal of the hydrogen-bond donors and acceptors from the aqueous phase, especially those of the polypeptide backbone itself, are large positive standard free energies of transfer (Table 5-9). In the interior of the protein, however, these donors and acceptors participate in hydrogen bonds the standard free energies of formation of which are even more negative than they would be in solution because standard entropies of approximation are often not required for the associations (Figure 5-19). Standard entropies of approximation are at a minimum whenever a set of hydrogen bonds forms cooperatively as in an α helix or β structure.

The interior of a properly folded molecule of protein is tightly packed in a defined conformation. It thus resembles closely the interior of a solid rather than a liquid, and the van der Waals forces arising when amino acids or segments of polypeptide backbone are transferred into it are those that would arise in a solid rather than in a liquid. This is a significant difference because in solids dipoles and polarizable regions remain fixed in their relative orientations rather than being averaged over all orientations as they are in a liquid. Even more troublesome, when the question of reproducing the behavior of this solid is considered, is the fact that the interior of a protein is not a systematic solid, such as a crystalline or microcrystalline mineral or an amorphous glass. Although it is a highly integrated system, shaped by natural selection for the performance of a definite function, little uniformity can be found in the interior of a particular molecule of protein. Because it is the product of evolution by natural selection, the interior has all of the haphazard character of an acre of woodland. It is unlikely that any solvent could reproduce its properties.

Nevertheless, it has been proposed that the standard free energy of transfer of an amino acid, a segment

of polypeptide, or a small solute from water to the interior of a protein should be similar to the standard free energy of transfer for a model compound of that amino acid or segment of polypeptide between water and a solvent the properties of which resemble those of the interior of a protein. **Scales of hydrophathy** for the side chains of the amino acids based on this proposal have been presented. They differ in the personal preferences of their proponents for the type of model compounds and the particular solvent chosen as the basis of the scale.

The first of these was the scale of hydrophobicity proposed by Nozaki and Tanford,²⁰⁷ which, as its name implies, was confined to only one end of the spectrum. It relied on the solubilities of the zwitterionic amino acids in ethanol that had been previously tabulated by Cohn and Edsall.²⁴ By subtracting the standard free energy of transfer for glycine between water and **ethanol** from the standard free energies of transfer for hydrophobic amino acids between water and ethanol, they estimated the standard free energies of transfer for the side chains alone between water and ethanol. The implication in formulating a scale of this type is that the interior of a protein resembled ethanol in its interaction with hydrophobic amino acids, and this may not be far from the truth because all nonaqueous solvents display similar standard free energies of solvation for hydrophobic solutes (Figure 5-22).

Since this first scale was proposed, at least 35 others have appeared,¹⁸⁹ and they have usually been expanded spectra including all 20 of the amino acids, hydrophilic as well as hydrophobic. Most have been based on standard free energies of transfer. The original description of the hydrophobic effect was based on observations of abnormal decreases in the surface tension of water that result when hydrophobic solutes display a preference for the surface of an aqueous solution rather than its interior,^{7,208} and a scale of hydrophathy based on the change in the **surface tension** of an aqueous solution with the change in concentration of the different amino acids has been presented.²⁰⁹ The scale of hydrophobicity based on the solubilities of the amino acids in ethanol has been expanded to include uncharged, hydrophilic amino acids.²¹⁰ The standard free energies of transfer of the model compounds for the amino acids between water and the **gas** (Table 5-9) have also been used to create scales of hydrophathies.^{198,199,203} The standard free energies of transfer of various solutes between water and **1-octanol** have been proposed as the parameters for a general scale for the hydrophobic effect.²¹¹ The standard free energies of transfer of the *N*-acetyl- α -amides of each of the amino acids (Figure 2-1) between water and 1-octanol have been determined, and they have been used to construct a scale of hydrophathies.²⁰² It has been proposed that *N*-cyclohexyl-2-pyrrolidone would be a better solvent to use as reference for standard free energies of transfer into the interior of a protein, and standard free energies of transfer for the amino acids between

water and *N*-cyclohexyl-2-pyrrolidone have been measured and used to construct a scale of hydrophathies.²¹²

In competition with these scales of hydrophathy based on standard free energies of transfer are scales derived from the locations of the various amino acid side chains in crystallographic molecular models of native proteins. The logic in this case is that the purpose of all of these scales is to estimate contributions due to changes in solvation during the folding of a polypeptide and the degree with which particular amino acids are buried in the interior or exposed to the solvent should directly indicate how hydrophobic or hydrophilic, respectively, they are. In these computations, the surface area of each amino acid that is accessible to water^{213,214} in a set of crystallographic molecular models is individually determined. These individual **accessibilities to water** are then grouped by amino acid, and average accessibilities for each amino acid are calculated. The uncertainty in these calculations is in the calculation of these averages, and the three scales of hydrophathy based on the accessible surface area in molecular models of folded polypeptides²¹⁵⁻²¹⁷ are not equivalent, even though they are based on similar raw data.

Finally, there are the scales of hydrophathies for the amino acids that are based on mixtures of the pure scales discussed so far. In one case,²¹⁸ a scale based on the accessible surface area of amino acids in crystallographic models was modified by a theoretical calculation of the standard free energy required to break hydrogen bonds and neutralize charge. In another,²⁶ the standard free energies of transfer between water and the gas and a tabulation of accessible surface areas were combined with personal preference to produce a scale of hydrophathies. In a third case,²¹⁹ a consensus scale of hydrophathies was inferred from two scales based on standard free energy of transfer and three scales based on accessible surface area in folded polypeptides. In a fourth case,²²⁰ a correlation between accessible surface area and the hydrophobic effect, the standard free energy required to neutralize charged amino acids (Equation 5-66), and semi-empirical estimates of the standard free energy for withdrawing each individual hydrogen-bond donor and acceptor from water were combined to obtain a scale of estimated standard free energies of transfer for each of the amino acids, when located in an α helix, from water to a phase of hydrocarbon.

At low resolution all of these scales are similar to each other. The amino acids the side chains of which are alkanes, namely, leucine, isoleucine, and valine, are the most hydrophobic amino acids; the charged amino acids the pK_a of which is farthest from pH 7, arginine, lysine, glutamate, and aspartate, are the most hydrophilic; and neutral but polar amino acids such as serine and threonine reside in the middle; but the details of the ranking and the relative magnitudes of the parameters are dramatically different.¹⁸⁹ At the moment, each of these attempts to estimate the standard free energy of transfer for each of the amino acids between water and the interior of a protein has its particular proponents, some

more forceful than others, and there is no unambiguous way to choose among them or assess whether any of them is realistic or unrealistic.

The usual criterion for the reliability of each scale is to demonstrate either that it correlates with the distribution of amino acids between the surface and the interior of a protein, if it is based on standard free energy of transfer (Figure 5-24),^{199,202,216} or that it correlates with standard free energies of transfer, if it is based on the distribution of amino acids between the surface and the interior.²¹⁶ None of these correlations suggest that any one of the scales is more realistic than any of the others.

Problem 5-17: Consider a saturated solution of the solute A in solvent *j*. In this case, the solution of A is in equilibrium with solid A and

$$\mu_{A,\text{sat},j} = \mu_{A,\text{solid}}$$

$$\mu_{A,j}^{\circ} + RT \ln \left\{ \phi_{A,\text{sat},j} \exp \left[1 - \left(\bar{V}_{A,j} / \bar{V}_j \right) \right] \right\} = \mu_{A,\text{solid}}^{\circ}$$

Figure 5-24: Correlation between the standard free energies of transfer of *N*-acetyl- α -amides of the amino acids between octanol and water with the degree to which the amino acids are buried in the interior of a molecule of protein.²⁰² The partition coefficients for the distribution of the *N*-acetyl- α -amides of the 20 amino acids between water at pH 7 and octanol at room temperature were measured (concentrations in molarity) and standard free energies of transfer, $\Delta G^{\circ}_{\text{aa},\text{H}_2\text{O} \rightarrow \text{octanol}}$, were calculated. Each of the 5220 amino acids in the crystallographic molecular models of 22 proteins was identified as either buried (less than 0.2 nm² of accessible surface area) or accessible to water (greater than 0.2 nm² of accessible surface area).²¹⁶ For each type of amino acid a partition ratio [number buried (number accessible)⁻¹] was calculated, and from this partition ratio, a standard free energy of transfer, $\Delta G^{\circ}_{\text{aa},\text{H}_2\text{O} \rightarrow \text{interior}}$ was calculated. Adapted with permission from ref 202. Copyright 1983 Elsevier.

If one wishes to compare two different solvents and their effects on A

$$\mu_{A,1}^{\circ} + RT \ln \left\{ \phi_{A,\text{sat},1} \exp \left[1 - \left(\bar{V}_{A,1} / \bar{V}_1 \right) \right] \right\} = \mu_{A,\text{solid}}^{\circ}$$

$$\mu_{A,2}^{\circ} + RT \ln \left\{ \phi_{A,\text{sat},2} \exp \left[1 - \left(\bar{V}_{A,2} / \bar{V}_2 \right) \right] \right\} = \mu_{A,\text{solid}}^{\circ}$$

$$\mu_{A,2}^{\circ} - \mu_{A,1}^{\circ} = \Delta G^{\circ}_{A,1 \rightarrow 2}$$

$$\Delta G^{\circ}_{A,1 \rightarrow 2} = RT \ln \left[\frac{[A]_{\text{sat},1}}{[A]_{\text{sat},2}} \exp \left(\frac{\bar{V}_{A,2}}{\bar{V}_2} - \frac{\bar{V}_{A,1}}{\bar{V}_1} \right) \right]$$

where $\mu_{A,1}^{\circ}$ is the chemical potential of A in solvent 1 at a concentration of 1 corrected volume fraction, $\phi_{A,\text{sat},2}$ is the concentration of A in a saturated solution in solvent 2 in units of volume fraction, and $\Delta G^{\circ}_{A,1 \rightarrow 2}$ is the standard free energy change when A is transferred from solvent 1 to solvent 2. The quantity $\Delta G^{\circ}_{A,1 \rightarrow 2}$ is a measure of the change in standard free energy for the following type of reaction:

where ethanol serves as a model for the interior of a protein.

The following data^{24,207} are for 25 °C

amino acid	concn at saturation [g (100 g of solvent) ⁻¹]		partial molar volume (mL mol ⁻¹)
	H ₂ O	EtOH	
glycine	25.16	0.00382	43.5
leucine	2.17	0.0196	108

- Calculate $\phi_{A,\text{sat},j} \exp[(1 - \bar{V}_{A,j}/\bar{V}_j)]$ for these four situations. Assume $\bar{V}_{A,\text{H}_2\text{O}} = \bar{V}_{A,\text{EtOH}}$
- Calculate $\Delta G^{\circ}_{A,\text{H}_2\text{O} \rightarrow \text{EtOH}}$ for glycine and leucine.
- Use the value you have for glycine to subtract away the contribution of $^-\text{OOCCH}_2\text{NH}_3^+$ to the solubility of leucine. The remainder is an estimate of the standard free energy of transfer of the leucine side chain from H₂O to ethanol.
- Draw the structure of the glutamine side chain and divide it into hydrophobic or hydrogen-bonding regions. Label each region on your drawing and indicate all hydrogen-bond donors and acceptors with D or A, respectively.
- Estimate the $\Delta G^{\circ}_{\text{glutamine},\text{H}_2\text{O} \rightarrow \text{ethanol}}$ contributed only by the hydrogen-carbon bonds of the side chain.

- (F) The solubility of glutamine (concentration at saturation) in water is $4.6 \text{ g (100 g of H}_2\text{O)}^{-1}$, the solubility of glutamine in ethanol is $4.59 \times 10^{-4} \text{ g (100 g of ethanol)}^{-1}$, and the partial molar volume of glutamine in water is 96.5 mL mol^{-1} . Calculate $\Delta G^\circ_{\text{transfer, H}_2\text{O} \rightarrow \text{ethanol}}$ of the glutamine side chain.
- (G) Estimate $\Delta G^\circ_{\text{transfer, H}_2\text{O} \rightarrow \text{ethanol}}$ for the $-\text{CONH}_2$ functional group of glutamine.

Problem 5-18: Consider the following table:

A	0.25	G	0.16	P	-0.07
R	-1.76	H	-0.40	S	-0.26
N	-0.64	I	0.73	T	-0.18
D	-0.72	L	0.53	W	0.37
C	0.04	K	-1.10	Y	0.02
E	-0.62	M	0.26	V	0.54
Q	-0.69	F	0.61		

- (A) What are the letters and what is the intention of assigning these numbers to these letters?
- (B) What common property is shared by the letters with the positive numbers?
- (C) What common property is shared by the letters with the negative numbers?
- (D) Divide the letters with the positive numbers into two groups based on differences in chemical properties. Why are the numbers in one of these groups less positive than the numbers in the other?
- (E) On what types of measurements could the numbers assigned to the letters be based?
- (F) Draw the interactions with water that are one of the reasons that R has a value of -1.76 . There are two reasons that R has such a low value: the interactions you have just drawn and another of its properties. What are these two reasons?

Chapter 6

Atomic Details

It is within the crystallographic molecular model of a protein that the consequences of the noncovalent forces just described can be viewed. As the polypeptide folded to form the actual native structure of the protein that is represented by the model, a significant fraction of its backbone had to be withdrawn from water. Secondary structure formed because it offered an efficient way to maintain the total number of hydrogen bonds in the solution. As the polypeptide folded, the donors and acceptors of hydrogen bonds in the side chains of the amino acids, as well as any ionized side chains, remained, by and large, on the surface of the structure to maintain their hydration. The networks of hydrogen-bonded water molecules hydrating the surface of the folded structure are prominent features of the crystallographic molecular model. The core of the model is formed mostly from hydrophobic amino acids, the exclusion of which from the water drove the folding process.

As remarkable as these energetic consequences are in a crystallographic molecular model, it has become clear upon close inspection that they do not, except indirectly, produce the final structure. The most important determinant of the final native structure is the steric effect. In retrospect, this should not be so surprising. Steric effects are always the most overwhelming among the different forces influencing the outcome of a chemical reaction. They are rarely discussed at great length because they are so easy to understand. No two fragments of matter may occupy the same place at the same time. The folding of a polypeptide, however, is a steric nightmare. Not only must all of the functional groups fit together in a confined space without overlapping, but all of the functional groups are connected together by the polypeptide. Although the outcome of any one of these games of packing atoms cannot be predicted, the ultimate solutions to the vast array of steric problems encountered during each game can be appreciated by examining the final native structure. Both the steric effects operating along the polypeptide backbone and those engendered between the side chains as the elements of secondary structure attempt to fit together to produce the final native structure of the protein are represented by the crystallographic molecular model. These steric effects and the noncovalent forces are the players in each of the games.

Secondary Structure of the Polypeptide Backbone

Because of its π molecular orbital system (Figure 2-3), the amide of the **peptide bond** is planar. The dihedral angle ω assigned to this amide is defined by looking down the carbon–nitrogen bond from carbon to nitrogen:

The sign of the angle is determined by the right-hand rule. In *trans* peptide bonds, the angle ω is 180° , and the two strands of polypeptide leaving the amide depart in opposite directions from the carbon–nitrogen bond. In *cis* peptide bonds (6-3), the angle ω is 0° , and the two α carbons of the two departing strands are eclipsed. In a protein, at any particular location in the amino acid sequence, the peptide bond is either *trans* in every molecule of that particular protein or *cis* in every molecule of that particular protein. The reason for this is that the stereochemical difference between these two conformers is substantial, and only one will be compatible with the structure at that location in the folded polypeptide.

In the available crystallographic molecular models, only 0.3% of the peptide bonds¹ are ***cis* peptide bonds** (Figure 6-1),² and most of the locations where a *cis* peptide bond is found (87%) have proline as the amino acid on the carboxy-terminal side:¹

In such peptide bonds, the proline provides the amido nitrogen; consequently, the amide formed is secondary. In this secondary amide, there is little preference for the *trans* stereochemistry because both positions on the amido nitrogen are sterically similar, and the equilibrium constants between the *cis* and *trans* conformations for peptide bonds involving proline are between 0.1 and 1.³ In proteins, about 6% of the peptide bonds in which proline provides the amido nitrogen are *cis* peptide bonds.¹ Unlike proline, the other amino acids form primary amides. Because the hydrogen of a primary amide is much smaller than the alkyl substituent, the equilibrium constant heavily favors the *trans* form. *cis* Peptide bonds in which an amino acid other than proline provides the amido nitrogen are rare (0.04% of all peptide bonds). These are presumably locations where a *cis* peptide bond is unavoidable, but evolution by natural selection has not yet replaced the carboxy-terminal amino acid of that peptide bond with a proline. Other than proline at its carboxy-terminal side, there seems to be little preference for the other amino acids at either location in a *cis* peptide bond.^{1,4} In the rare instances in which there is a cystine between two adjacent cysteines, the peptide bond between them is necessarily *cis*.⁵

Aside from the occasional situations in which *cis* peptide bonds occur, the peptide bonds in crystallographic molecular models are *trans*. In a set of eight crystallographic molecular models,⁶ all built from data sets to Bragg spacings of less than 0.12 nm, the values of the angle ω equal $179^\circ \pm 6^\circ$. Observations from a much larger set of crystallographic molecular models give the same result.⁷ Deviations from 180° as large as 15° have been observed.^{7,8} Were the amide, however, to be distorted too far from planarity by the structure of the protein, it would become susceptible to rapid hydrolysis.⁹

It was noted by Ramachandran, Ramakrishnan, and Sasisekharan,¹⁰ before crystallographic molecular models of atomic resolution became available, that there are severe **steric effects** hindering rotation about the single bonds of a polypeptide. The dihedral angle of the bond between an α carbon and the adjacent amido nitrogen is designated as ϕ ; and that of the bond between an α carbon and the adjacent acyl carbon, as ψ (Figures 6-2 and 6-3).¹⁰ Each amino acid in the protein is assigned a dihedral angle ϕ and a dihedral angle ψ associated with its α carbon. Although it has been noted that it would be more reasonable to assign values of the **dihedral angles ϕ and ψ** to each peptide bond rather than to each amino

Figure 6-1: *cis* Peptide bonds in the crystallographic molecular model (Bragg spacing ≥ 0.20 nm) of lectin IV of *Griffonia simplicifolia*.² By chance, this protein happens to have three *cis* peptide bonds (highlighted with black bonds and atoms) near each other. Only one of these contains a proline (Proline 87). In the other two, the position normally taken by the proline in the *cis* bond is occupied by a glycine (Glycine 222) and an aspartate (Aspartate 89), respectively. In this figure and those that follow, the amino acids are numbered according to their positions in the amino acid sequences in the data base published by the Swiss Institute of Bioinformatics (us.expasy.org). These numbers often differ from those of the preliminary amino acid sequences used by the crystallographers to construct the crystallographic molecular models. This drawing was produced with MolScript.⁵⁷³

Figure 6-2: Designation of the two dihedral angles ϕ and ψ to the amino-terminal and carboxy-terminal sides, respectively, of the α carbon ($C\alpha$) of an amino acid in a polypeptide.¹⁰ The first carbon of a side chain ($C\beta$) corresponds to that of amino acids in the L-configuration. Adapted with permission from ref 10. Copyright 1963 Academic Press.

acid,¹¹ this suggestion has yet to be adopted. The signs of the dihedral angles ϕ and ψ are determined by the right-hand rule (Figure 6-3). To follow what is about to be described, you should build a model of the structure shown in Figure 6-2.

When the view from an α carbon down the bond to an amido nitrogen is observed, it can be seen that in every *trans* peptide bond, the acyl oxygen O1 of the previous amino acid in the polypeptide leans forward (Figure 6-3B,C). When the dihedral angle ϕ is greater than $+310^\circ$ (-50°), the amido N2-C2-O2 collides with acyl oxygen O1, and when the dihedral angle ϕ is less than $+180^\circ$, the H-C β -C γ of the side chain collides with acyl oxygen O1. Therefore, values of dihedral angle ϕ greater than $+310^\circ$ (-50°) and less than $+180^\circ$, with the exception of a small gap at angle ϕ of $+60^\circ$ (Figure 6-3C), are forbidden.

When the view from an α carbon down the bond to an acyl carbon is observed, it is clear that in all *trans* peptide bonds the hydrogen H2 on the amido nitrogen of the next amino acid leans forward (Figure 6-3D,E). When the dihedral angle ψ is greater than $+200^\circ$ (-160°), the H-C β -C γ of the side chain collides with this hydrogen, and when dihedral angle ψ is between $+300^\circ$ (-60°) and $+30^\circ$, the amido N1-C1-O1 collides with this hydrogen (Figure 6-3D,E). The latter collision is not a serious one so long as the value of dihedral angle ϕ remains around 270° (-90°) or $+90^\circ$ so the amido N1-C1-O1 can squeeze past the hydrogen H2 sideways (Figure 6-3C,F), but values for dihedral angle ϕ of $+90^\circ$ are only permitted for glycine, which lacks a β carbon. When dihedral angle ψ is between $+290^\circ$

Figure 6-3: Definitions of the dihedral angles ϕ and ψ and the steric effects of rotation. (A) Pattern in which the bonds with the dihedral angles ϕ and ψ are distributed along a polypeptide. (B) View down the bond between $C\alpha$ and the amido nitrogen N1 that precedes it along the polypeptide. The dihedral angle ϕ is defined as that between the bond connecting N1 and C1 and the bond connecting $C\alpha$ and C2 (Figure 6-2). Its sign is determined by the right-hand rule. Note that the direction of the arrow is irrelevant to the assignment of the sign of the angle. In the configuration shown, angle ϕ is $+260^\circ$ (-100°). This dihedral angle is in the most sterically free range for angle ϕ (-45° to -180°) because in this range the hydrogen on $C\alpha$ can slip under the acyl oxygen O1. (C) View down the same bond as in panel B but with angle ϕ at $+90^\circ$, produced from the conformation in panel B by rotation about only the bond on the axis of the view. When angle ϕ is $+60^\circ$, the acyl oxygen, O1, sits between the carbon of the next peptide bond at C2 and the first carbon of the side chain, $C\beta$. This would be the value of angle ϕ in a left-handed α helix. (D) The same conformation presented in panel B is viewed along the bond between $C\alpha$ and the acyl carbon C2. The eyes indicate the views interconverting panels B and D. The dihedral angle ψ is defined as that between the bond connecting $C\alpha$ and N1 and the bond connecting C2 and N2 (Figure 6-2). Its sign is determined by the right-hand rule. The configuration shown ($\psi = +105^\circ$) is in the most sterically free range for angle ψ ($+15^\circ$ to $+190^\circ$) because the hydrogen on $C\alpha$ can slip below H2. (E) View down the same bond as in panel D but with angle ψ at $+285^\circ$ (-75°). When angle ψ is $+300^\circ$ (-60°), H2 lies between the first carbon of the side chain, $C\beta$, and the nitrogen of the amino-terminal peptide bond, N1. This is near the value of angle ψ (-39°) in a right-handed α helix. (F) Steric effect between H2 and either N1 or H1 that occurs when angle ψ is near 0° .

(-70°) and $+320^\circ$ (-40°), hydrogen H2 on the amido nitrogen N2 can fit between amido nitrogen N1 and the side chain with little difficulty (Figure 6-3E).

All of these steric effects can be summarized in a **Ramachandran plot** (Figure 6-4A).¹² Using your model, you should verify the noted boundaries on the plot.

Refinements of crystallographic molecular models by use of Equation 4-15 for calculation of the function θ usually do not constrain the values for dihedral angles ϕ and ψ . Even though they are not constrained, however, their values converge upon the **allowed regions** in a Ramachandran plot during the refinement. For example, although many of the values for dihedral angles ϕ and ψ for the various amino acids along the polypeptide in the initial molecular model of deoxyribonuclease I were scattered beyond the allowed regions in a Ramachandran plot before refinement was performed (Figure 6-5A), they clustered within the enclosures after the refinement had been completed (Figure 6-5B).⁸ Because this convergence was not enforced by the choice of $(d_{s,q}^2 - d_{c,q}^2)$ in Equation 4-15, its occurrence can be used as evidence that the refined structure is closer to reality than the unrefined.

When the dihedral angles for the amino acids in eight crystallographic molecular models, all built from data sets to Bragg spacings of less than 0.12 nm, are plotted on a Ramachandran plot (Figure 6-4B),⁶ the points themselves define what should be the **actual regions of lowest energy**. It might have been the case that the three clusters of open squares in Figure 6-4B are more the result of preferences enforced by secondary structures than the steric effects first pointed out by Ramachandran (Figure 6-4A). When, however, dihedral angles are plotted for amino acids not involved in secondary structures, from a much larger collection of crystallographic molecular models (402) but from data sets gathered to minimum Bragg spacings of only 0.2 nm or less, the distribution still shows the same three clusters with the same shapes and extents.^{13,14} Consequently, the extent and magnitude of the actual steric effects in the backbone of a polypeptide are delineated in the distribution of the points in a plot such as that in Figure 6-4B.

With the exception of the region where dihedral angle ϕ is between -70° and -180° and dihedral angle ψ is between 30° and 110° , which should be sterically unhindered anyway, almost all of the amino acids found

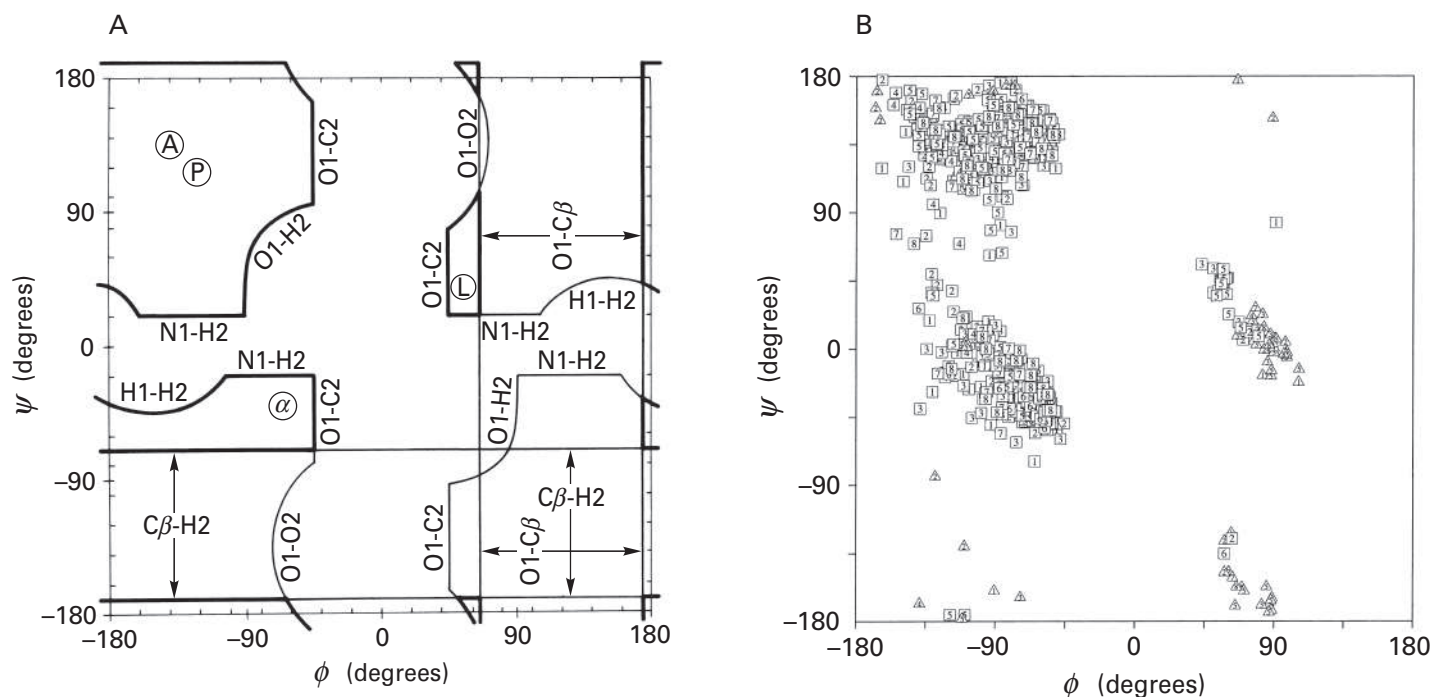

Figure 6-4: Ramachandran plot. (A) Diagram illustrating the steric effects producing the Ramachandran plot.¹² The two dimensions of the plot are the dihedral angles ψ and ϕ (Figure 6-3). Boundaries are drawn between allowed and forbidden regions obtained from a molecular model in which each atom is a hard sphere of the appropriate van der Waals radius. The clashing atoms are identified on the forbidden side of the boundary with the same numbering system as in Figures 6-2 and 6-3. There are only four allowed regions: the large region including the values for parallel (P) and antiparallel (A) β sheet, the region including the values for right-handed α helix (α), the region including the values for left-handed α helix (L), and a small triangle at $\phi = +60^\circ$ and $\psi = +180^\circ$. The clashes can be understood by referring to Figure 6-3. For example, if $\phi = -100^\circ$ and $\psi = +105^\circ$ (Figure 6-3B,D) and angle ϕ is increased to -45° , O1 clashes with C2; if angle ψ is decreased to $+20^\circ$, N1 clashes with H2. If $\phi = -60^\circ$ and $\psi = -60^\circ$ and angle ϕ is decreased to -185° , O1 runs into C β ; if angle ψ is decreased to -70° , H2 runs into C β . Adapted with permission from ref 12. Copyright 1977 *Journal of Biological Chemistry*. (B) Dihedral angles ψ and ϕ from eight crystallographic molecular models of high accuracy.⁶ The crystallographic molecular models and the minimum Bragg spacings of their data sets were cytochrome c_6 (0.12 nm), cutinase (0.10 nm), lysozyme (0.0925 nm), a fragment of protein G (0.11 nm), ribonuclease Sa (0.12 nm), repressor of primer protein (0.11 nm), rubredoxin from *Desulfovibrio vulgaris* (0.092 nm), and rubredoxin from *Clostridium pasteurianum* (0.11 nm). The numbers in the points indicate the respective models. Triangles are glycines, and squares are amino acids other than glycine.

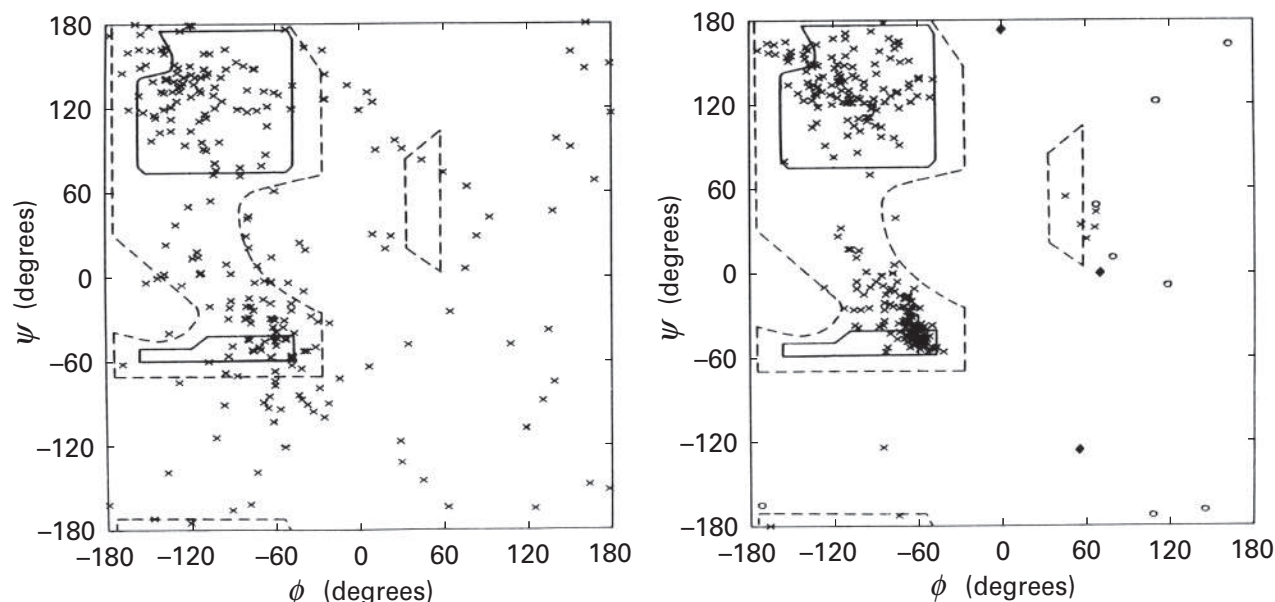

Figure 6-5: Effect of refinement on the values of ϕ and ψ for the amino acids in bovine deoxyribonuclease I.⁸ Each \times in one of the diagrams represents the values for the dihedral angles ϕ and ψ of one of the amino acids in a crystallographic molecular model of the protein. The boundaries in the Ramachandran plot are defined by the steric effects represented diagrammatically in Figure 6-4A. Unbroken lines surround regions of no hindrance; broken lines, regions of little hindrance. (A) Unrefined, initial molecular model. (B) Refined, final molecular model. Glycines are denoted by open circles, cystines by filled squares, and all other amino acids by \times . Reprinted with permission from ref 8. Copyright 1986 Academic Press.

outside of the three clusters of open squares in Figure 6-4B are **glycines**. In addition to being able to reside in cramped locations, glycine lacks a β carbon, and all of the steric collisions involving the β carbon (Figures 6-3 and 6-4A) are irrelevant. Therefore, the dihedral angles around a glycine have a larger compass. In particular, the regions of the Ramachandran plot in which dihedral angle ϕ lies between $+70^\circ$ and $+180^\circ$ or dihedral angle ψ lies between -70° and -180° represent areas where either O1 or H2, respectively, clash with the side chain of any amino acid other than glycine. In Figure 6-4B, the points for glycine (Δ) and the points for all other amino acids (\square) define distinct regions on the plot. In fact, most of the glycines in crystallographic molecular models have dihedral angles ϕ and ψ outside of the traditional enclosures on a Ramachandran plot defined by the dihedral angles ϕ and ψ of the other amino acids.^{15,16} This fact suggests that glycine is selected for situations in which such otherwise unpermitted dihedral angles are unavoidable.

It has been noted that when an amino acid other than glycine has angles ϕ and ψ outside of the enclosures, that amino acid is usually involved intimately in the function of the protein.⁴ For example, Serine 120 is the nucleophile in the active site of cutinase, and Alanine 30 is in the center of the crucial tight turn between the two α helices in the repressor of the primer protein.⁶

The region of the Ramachandran plot bounded by values of dihedral angle ϕ between -140° and -60° and values of dihedral angle ψ between -20° and $+20^\circ$ was originally predicted to be disallowed because when these dihedral angles are within these boundaries, either atom

N1 or atom H1 should be overlapping atom H2 (Figure 6-4A). Nevertheless, the dihedral angles of many amino acids fall within this supposedly disallowed region (Figure 6-4B). One way the overlap between either atom N1 or atom H1 and atom H2 can be prevented is to increase the bond angle $\text{N1-C}\alpha\text{-C2}$ beyond the usual 109.5° of a carbon hybridized sp^3 . In crystallographic molecular models this angle is observed to be wider¹⁷ than expected, with a mean of 112° and deviations up to 120° . In addition, this widening is dependent on the values for the dihedral angles ϕ and ψ . The angle $\text{N1-C}\alpha\text{-C2}$ is equal to 109° for β structure, the dihedral angles ψ and ϕ of which fall in the largest unhindered area of the plot, but is wider by 3° in α helices,¹⁸ the dihedral angles ψ and ϕ of which fall within the lower left cluster in Figure 6-4B immediately adjacent to the supposedly disallowed region. All of these results suggest that the existence of so many amino acids the dihedral angles ϕ and ψ of which fall within a region of the Ramachandran plot originally predicted to be disallowed results from a widening of this bond angle to accommodate the steric effect. The same argument would apply to the glycines the dihedral angles ϕ and ψ of which fall within the boundaries $+60^\circ$ to $+110^\circ$ and -20° to $+20^\circ$, respectively, also previously thought to be disallowed.

In a set of eight crystallographic molecular models, all built from data sets to Bragg spacings of less than 0.12 nm ,⁶ the amino acids within right-handed α helices (Figure 6-6)¹⁹ have dihedral angles of $\phi = -66^\circ \pm 13^\circ$ and $\psi = -39^\circ \pm 10^\circ$ (Figure 6-3E), and these values fall within one of the enclosures in a Ramachandran plot (Figure

Figure 6-6: α Helix from the crystallographic molecular model (Bragg spacing ≥ 0.15 nm) of cytochrome *c* from *Thunnus alalunga*.¹⁹ Only the peptide backbone and the β carbons are included in the figure. The dihedral angles $\phi = -66^\circ$ (Figure 6-3B turned 34° further) and $\psi = -39^\circ$ (Figure 6-3E turned 36° further) of an α helix are most easily observed at amino acids 99 and 96, respectively. The hydrogen bonds are between the acyl oxygen of amino acid *i* and the amide nitrogen of amino acid *i* + 4. Compare this actual α helix with the one drawn in Figure 4-16A by pushing over the pages in between. This drawing was produced with MolScript.⁵⁷³

6-4A). This location suggests that there are no severe steric problems along the polypeptide in a right-handed α helix. A left-handed α helix of L-amino acids would have dihedral angles of $\phi = +65^\circ$ and $\psi = +40^\circ$, also within one of the enclosures (Figure 6-4A). This latter enclosure, however, is a small one arising from the conformation in which acyl oxygen O1 fits between the side chain and C2 and O2 of the next acyl group (Figure 6-3C). In crystallographic molecular models, about 2% of the amino acids other than glycine usually have dihedral angles ϕ and ψ clustered around this enclosure (Figure 6-4B). This fact demonstrates that these are accessible conformations, yet **left-handed α helices** are almost²⁰ never seen. It may be that an extended sequence of such conformers, which would be required to form a left-handed α helix, in contrast to the few isolated examples that are observed, would be sterically unstable.

The original **right-handed α helix** (Figure 4-16A), built before crystallographic structures were available, was constructed with 3.69 amino acids for every turn, which would have produced a rotational angle for each amino acid of 98° and a rise of 0.147 nm for each amino

acid.²¹ In crystallographic molecular models of proteins,^{8,22} in which these dimensions were not constrained, right-handed α helices display rotational angles for each amino acid of $99^\circ \pm 7^\circ$ and a rise for each amino acid of 0.15 ± 0.02 nm.

The paradigm of an α helix is a linear rod such as the one from cytochrome *c* in Figure 6-6, but only about 15% of those found in crystallographic molecular models of proteins are straight enough to fit the paradigm.²³ A significant proportion (60%) of α helices are **smoothly curved**. The original molecular model of the α helix was built so that each acyl oxygen along the α helix participates as an acceptor to only one hydrogen bond, namely, the one in which the nitrogen-hydrogen bond from the appropriate amide was the donor (Figure 4-16A). The tacit assumption was that the hydrogen bond would be one in which the nitrogen-hydrogen bond would pivot on the lone pairs of the acyl oxygen (Figure 5-10D). The geometric constraints of the α helix itself are such that the carbon-oxygen-nitrogen bond angle²⁴ is about $155^\circ \pm 10^\circ$ (Figure 6-6) rather than 180° . This causes the carbon-oxygen double bond to tilt outward²⁵ from the axis of an α helix (Figure 6-6). This tilt permits the oxygen to form a **second hydrogen bond** with a donor on a side chain of the protein (Figure 6-7A)^{24,26} or a molecule of water (Figure 6-7B).²⁷ This second hydrogen bond can be detected crystallographically (Figure 6-7B) or by a decrease in the frequency of the infrared absorption of the peptide bond.²⁸

The formation of this second hydrogen bond changes the carbon-oxygen-nitrogen bond angle by less than 10° ,^{24,29} and this fact suggests that each acyl oxygen in an α helix presents a second acceptor whether or not it is occupied. The occupation of these second acceptors, however, by donors located on only one side of the α helix, for example, the side facing the solvent (the right side of the α helix in Figure 6-7B), is thought to be a sufficient perturbation to cause the α helix to curve.^{23,29} One type of donor that can occupy these second acceptors on the acyl oxygens in an α helix are the hydroxyl groups on serines and threonines.

It has been observed that when an α helix contains a **serine or threonine**, the hydroxyl on the side chain has a tendency to be located in a position similar to that occupied by one of the waters in Figure 6-7B with respect to the acyl oxygens on the amino acid three or four positions ahead of that serine in the α helix (Figure 6-7A).²⁶ The proton on the hydroxyl group of the serine acts as a donor in a second hydrogen bond to one of these acyl oxygens just as a molecule of water does in the other situation. Threonine 35 in the α helix in Figure 6-7B participates in such a hydrogen bond with the acyl oxygen of Phenylalanine 31. This hydrogen bond occupies the donor on Threonine 35, which would otherwise be difficult to bury, and consequently turns its side chain from an apathetic one (Table 5-9) into a hydrophobic one, suitable to its surroundings. If Alanine 29 in Figure 6-7B

Figure 6-7: Occupation of the second hydrogen-bond acceptor on the acyl oxygen of a peptide bond in an α helix by the hydroxyl of a serine (A) or water (B). (A) Drawing of a molecular model of an α helix in which the hydroxyl of the side chain of a serine is shown acting as a donor of a hydrogen bond to the acyl oxygen of the amino acid either three or four positions ahead of it in the amino acid sequence.²⁶ The serine hydroxyl group can swing to complete a hydrogen bond to either acyl oxygen. Reprinted with permission from ref 26. Copyright 1984 Academic Press. (B) α Helix between Proline 25 and Valine 36 in the crystallographic molecular model (Bragg spacing ≈ 0.17 nm)²⁷ of dihydrofolate reductase from *E. coli*. The detached circles are positions of water molecules in the vicinity of the α helix. Four of the waters occupy locations consistent with the formation of hydrogen bonds to the adjacent acyl oxygens, those on Proline 25, Alanine 26, Alanine 29, and Arginine 33, in addition to the hydrogen bonds those oxygens accept from the appropriate amido nitrogens. The donor in the side chain of Threonine 35 forms a hydrogen bond with the acyl oxygen of Phenylalanine 31, and one of the donors in the side chain of Asparagine 34 forms a hydrogen-bond with the acyl oxygen of Tryptophan 30. This gradually curved α helix runs along the outer surface of the protein with its left side toward the interior and its right side toward the water. This drawing was produced with MolScript.⁵⁷³

were a serine, its hydroxyl would take the place of one of the waters in the respective hydrogen bonds to acyl oxygens on Proline 25 or Alanine 26. Such intramolecular hydrogen bonds are quite frequently encountered in α helices. In the molecular model of myoglobin, a protein with a large amount of α helix, 6 out of the 11 serines and threonines in the protein form hydrogen bonds with the acyl oxygens on amino acids three or four positions ahead of them in the sequence of the protein.³⁰ Asparagine can also participate in such an intrahelical hydrogen bond (Asparagine 34 in Figure 6-7B).

About 20% of the α helices in crystallographic molecular models are kinked.²³ The most common cause of an abrupt kink in an α helix is a **proline**. For example, Proline 183 in the middle of an α helix 30 amino acids long in citrate (*Si*)-synthase³¹ causes the α helix to bend abruptly by 40° . The mean value for the angles of the abrupt kinks produced in α helices by prolines is 26° .²³ In proteins where such a kink is found naturally, the presumption is that it serves the purpose of fitting the α helix properly into the overall structure. When a proline is inserted into an otherwise straight α helix by site-directed mutation, the α helix, if it tolerates the substitution, displays a kink with a much smaller angle, and the protein becomes significantly less stable.³²

There are also examples of **local distortions** in α helices that seem to be caused by the incompatibility of an undistorted α helix with the surrounding structure of the protein. If the α helix is too short, a gap develops in which molecules of water or donors and acceptors from side chains occupy the acceptors and donors broken by opening the gap;^{33,34} if the α helix is too long, one or more of its amino acids is pushed out of the structure as an aneurysm or loop.^{35,36}

At the **amino-terminal end** of an α helix there are unoccupied nitrogen-hydrogen donors, and at the carboxy-terminal end, unoccupied acyl oxygen acceptors (Figure 6-6). Because each peptide bond has two acceptors for hydrogen bonding but only one donor and because the side chains of the amino acids also have an excess of acceptors over donors, a solution of protein contains more acceptors than donors of hydrogen bonds. Consequently, when a donor remains unoccupied in the native structure, there was a loss of one hydrogen bond from the solution upon folding. Therefore, it comes as no surprise that the donors at the amino-terminal end of an α helix are occupied, or **capped**,^{26,37-40} but the acyl oxygens at the **carboxy-terminal end** are often capped as well.

About half of the time, the side chain of an amino acid such as asparagine, serine, threonine, or aspartate in the position immediately before the beginning of the α helix, the *N*-cap position, provides one or more of the necessary acceptors to occupy the open donors at the amino-terminal end (Figure 6-58). When such an amino acid is replaced by site-directed mutation with one that is of the same size or smaller but that cannot provide an acceptor, the resulting protein is less stable^{41,42} because a hydrogen bond is lost to the solution upon its folding that is not lost when the wild-type protein folds.⁴² Proline often (10%) occurs at the first position in an α helix³⁷ because it does not have a nitrogen-hydrogen donor that requires capping. About a third of the time, the amino acid immediately after the end of an α helix is a glycine, which can readily (Figure 6-4B) adopt the necessary dihedral angles ϕ and ψ ($+70^\circ$ and $+20^\circ$, respectively) that permit the amido nitrogen-hydrogen of the next amino acid to occupy the open acceptor of the first unoccupied acyl oxygen (that on the amino acid 98 in Figure 6-6) at the carboxy-terminal end of the helix.⁴³

The dipole moment of an isolated peptide bond is estimated to be 3.5 D,⁴⁴ and the peptide bonds in an α helix are held with their dipoles almost parallel to the axis (Figure 6-6) so that the positive poles point to the amino-terminal end of the α helix and the negative poles to the carboxy-terminal end. Such an arrangement of dipoles creates an electrostatic field of the respective polarity, the magnitude of which is 1 V at 0.3 nm and 0.5 V at 0.5 nm from each end of the α helix, if the α helix is greater than 10 amino acids long and located in a medium of relative permittivity equal to 2.⁴⁴ These voltages would produce electrostatic potentials equal to about 100 and 50 kJ mol⁻¹, respectively, for a univalent ion. Although these **electrostatic potentials** are less than twice those that would be felt at the same distances from two adjacent, isolated peptide bonds, it is thought that the amplification produced by aligning the peptide bonds in an α helix is significant.

Experimental observations equivocally consistent with this idea have been presented. For example, the upfield shift (+0.4 ppm) in the absorption in a nuclear magnetic resonance spectrum for the proton in a hydrogen bond between an amide and an acyl oxygen in an α helix relative to one in random meander has been attributed to the **α -helical dipole**,⁴⁵ but an unexplained downfield shift of the same magnitude is found in a β sheet. The location of a sulfate ion at the intersection of the amino-terminal ends of three α helices in sulfate binding protein suggests that the positive ends of the dipoles of these α helices stabilize the anion,⁴⁶ but the amino-terminal ends of these helices could simply be providing the properly oriented amido donors that occupy several of the many σ lone pairs of electrons on the sulfate (2-28). The location of Glutamate 35 of lysozyme adjacent to the amino-terminal end of an α helix suggests that this arrangement would stabilize its

anionic conjugate base,¹⁶ but it is usually argued that the acidity of Glutamate 35 must be weakened rather than strengthened so that it will be protonated when substrate binds to the enzyme.

It is unfortunate that the original calculations of the magnitude of the electric field generated by an α helix assumed that it existed in a uniform dielectric with a **relative permittivity** of 2 and no account of the relative permittivity of the medium surrounding it was taken. For example, electrostatic potentials of only 2.5 kJ mol⁻¹ have been observed for univalent elementary charges positioned at the amino-terminal ends of α helices in water ($\epsilon = 78$ at 25 °C),⁴⁷ but even these small potentials disappear when the ionic strength of the solution is increased. Later calculations⁴⁸ have incorporated the contribution of the dielectric surrounding the α helix, and it was found that if the protein was approximated by a solid sphere of relative permittivity 3.5 in a solvent of relative permittivity 80 (water), even when the α helix was completely within the sphere of low relative permittivity, the electric field around the α helix was dramatically less than the electric field in a uniform dielectric with a relative permittivity of 3.5. Furthermore, if the ends of the α helix were at the surface of the sphere, in contact with the solvent, the electric field decreased even further to negligible levels. This effect of the dielectric may explain why the apparent electrostatic potentials exerted on aspartates positioned by site-directed mutation at the amino-terminal ends of the two α helices on the surface of T4 lysozyme were only about -2 kJ mol⁻¹.⁴⁹ If the relative permittivity of the interior of a protein is greater than 3.5, the magnitude of the electric field would decrease accordingly in inverse proportion. Finally, the solution around a molecule of protein always contains electrolytes that would further diminish the electric field.⁴⁷ For all of these reasons, electrostatic free energies of significant magnitude are probably not exerted by an α helix within a protein, although the possibility is often discussed.

When an α helix traverses the surface of a protein as a continuous rod, its face directed toward the protein is hydrophobic and its face directed toward the solution is hydrophilic. The α helix in Figure 6-7B has such an orientation with the surface formed by Leucine 28, Tryptophan 30, Phenylalanine 31, and Threonine 35 facing the protein and the opposite surface facing the solvent, as indicated by the locations for molecules of water. This asymmetry of hydropathy is sometimes reflected in the amino acid sequence of the protein and can be identified by constructing a **helical wheel**.^{50,51} Around a circle, successive amino acids in the sequence are placed at 100° intervals (Figure 6-8). This represents the view down an α helix (Figure 6-46), much as a Newman projection represents the view down a carbon-carbon bond. Any asymmetry in the distribution of hydropathy is easily observed. If a segment of amino acid sequence in a polypeptide, when placed upon a helical wheel, reveals such an asymmetric pattern of

Figure 6-8: Two segments of amino acid sequence displayed on helical wheels. (A) Sequence from Lysine 60 to Proline 77 (KKVADALTNAVAHVDDMP) in the α polypeptide of human hemoglobin. In the crystallographic molecular model of hemoglobin, this sequence is an α helix running across the surface of the protein. In the diagram, the amino terminus is the lysine at the 10:30 position and the sequence is read at 100° intervals. (B) Amphipathic helical sequence from Proline 455 to Lysine 472 (PDVKSAIEGVKYIAEHMK) from the α polypeptide of acetylcholine receptor. The lines in both panels divide the hydrophilic and hydrophobic surfaces of these two amphipathic α helices.

hydropathy, as do those in Figure 6-8, this pattern is evidence that that segment is an α helix in the folded polypeptide. Such α helices are referred to as amphipathic α helices. An **amphipathic α helix** is an α helix that is enriched in hydrophobic side chains on one of its sides and enriched in hydrophilic side chains on the other.

A single-stranded amphipathic α -helical peptide in a mixed solvent of trifluorethanol and water, unattached to a protein, displays an **intrinsic curvature** with the hydrophobic amino acids on the concave face and the hydrophilic on the convex.⁵² In an α helix running across the surface of a protein, the same orientation of curvature is often observed.²³ Whether this curvature is due to the fact that such an α helix is amphipathic,⁵² or to the fact that the acyl oxygens of its peptide bonds on the face exposed to the solvent form hydrogen bonds with water,²³ or to the fact that such curvature simply allows it to adhere more closely to the underlying structure, or to more than one of these reasons is unclear.

It has been proposed that certain amino acids or short sequences of amino acids may impose upon a folding polypeptide biases toward the formation of particular secondary structures at locations where they reside in the native structure of a protein. One hears terms such as “helix-forming” or “helix-breaking” amino acids.⁵³ Originally, these distinctions were based on the observed preferences of homopolymers of the various amino acids to assume α helices or sheets of β structure or to remain structureless at various temperatures, ionic strengths, concentrations of cosolvents, and values of pH.⁵⁴ The propensities of the various amino acids to favor an α -helical conformation have also been examined, either by placing each of them in turn in the center of an α helix in a native protein by site-directed mutation⁵⁵⁻⁵⁷ or by incorporating them in turn into a position in the center

of a peptide that assumes an α -helical conformation in water⁵⁸⁻⁶⁰ and then measuring the changes in stability to that protein or to that unsupported α helix that result.

Although there are significant differences in the various scales that result from these measurements, all agree that, of the 20 amino acids, alanine has the greatest **propensity to stabilize an α helix** and glycine the least and that the differences in free energy of stabilization between these extremes are about 4 kJ mol^{-1} . These preferences presumably explain how antifreeze peptide 3 from the winter flounder, in which 23 of the 37 amino acids are alanines, can naturally assume the conformation of a long, unbroken, unsupported α helix,⁶¹ but in an illustration of the unpredictability of the structure of proteins, all of the alanines in the alanine-rich regions of spider dragline silk are found in β sheets.⁶²

The propensities of the 17 primary amino acids other than alanine, glycine, and proline to stabilize or destabilize an α helix are much less obvious. If the values for their helical propensities in eight different scales⁶³ are averaged, the difference between the mean values for any two of them is rarely as large as the standard deviation of the value for either. Consequently, with the possible exception of methionine and leucine (both at $-2.8 \pm 0.5 \text{ kJ mol}^{-1}$) assigning the rest a value halfway between that of glycine (arbitrarily set at 0 kJ mol^{-1}) and that of alanine (-3.6 kJ mol^{-1}) would be as statistically significant as assigning them each an individual value.

There are several other types of helical structures that occur rarely in crystallographic molecular models of native proteins. The **polyproline helix**, of which there is an example 13 aa long in benzoylformate decarboxylase,⁶⁴ has dihedral angles ϕ and ψ of -75° and 145° , respectively,^{11,65} which places it within the largest allowed region of the Ramachandran plot (Figure 6-4B). It is a much more extended structure than an α helix,

having a rise of 0.31 nm aa^{-1} and 3.0 aa turn^{-1} , and it is a left-handed helix rather than a right-handed one. As their name suggests, polyproline helices in crystallographic molecular models of proteins usually contain a high frequency (25–70%) of proline.⁶⁶ Even though they contain no internal hydrogen bonds and usually occur in situations where they are supported by surrounding structures, there are sequences of amino acids in naturally occurring proteins that form unsupported polyproline helices.⁶⁷ The π helix, of which there is an example 13 aa long in arachidonate 15-lipoxygenase,⁶⁸ is a wider, squatter version of the α helix in which the hydrogen bonds are between the acyl oxygen of amino acid i and the nitrogen–hydrogen bond of amino acid $i + 5$ rather than amino acid $i + 4$.

The values for the dihedral angles ϕ and ψ found in ideal β structure ($\phi = -130^\circ$, $\psi = +120^\circ$) lie within one of the two largest allowed regions of the Ramachandran plot (A and P in Figure 6-4A). These dihedral angles place the hydrogen on the α carbon under the preceding acyl oxygen, O1 (Figure 6-3B), and under the next amide hydrogen, H2 (Figure 6-3D), respectively. This is the least hindered of all the conformations, and β structure experiences no serious steric problems around its α carbons. Because β structure is usually found in the most deeply buried regions of a protein, its polypeptide backbone usually displays the least thermal motion⁶⁹ even though its dihedral angles ϕ and ψ are the least sterically constrained. Nevertheless, it is obvious from an examination of the polypeptide backbones of the proteins presented in Chapter 4 that, because of the size of this region, β structure is far more pliant and unpredictable than an α helix, and efforts to define regular patterns have been less informative than time spent looking at different crystallographic molecular models. The original β -pleated sheets (Figure 4-16B,C) have turned out to be highly idealized. There are, however, several notable structural features of β structure.

When a number of β strands do form a sheet, the sheet usually has a negative, **left-handed twist** to its surface (Figure 6-9).⁷⁰ This is supposed to arise from the fact that the enclosure on the Ramachandran plot in which the dihedral angles ϕ and ψ for parallel and antiparallel β sheets reside has more open area for smaller values of dihedral angle ϕ and larger values of dihedral angle ψ beyond the values of these two dihedral angles that would give a flat sheet. Deviations tend to be biased toward these smaller values of dihedral angle ϕ and larger values of dihedral angle ψ , and this bias creates the twist in the sheet.⁷¹ It may simply be the case, however, that twisted β sheets have surfaces against which other segments of secondary structure, such as α helices, can be more efficiently packed and that packing efficiency dictates the hand and magnitude of the twist because β sheets almost as flat and regular as the idealized version (Figure 4-16B,C) have been observed.⁷²

Another feature of β structure is the **β bulge**.⁷³ In

this arrangement one of the amino acids is skipped in the regular pattern of hydrogen bonding between two antiparallel strands. The hydrogen bond that would have incorporated the nitrogen–hydrogen bond of the skipped amide incorporates the nitrogen–hydrogen bond of the next amide instead. This causes the β structure to bulge at the location of the skipped amino acid (Figure 6-10),⁷³ and the bulge is located where the strands change direction. This change in direction can take two forms. If the β structure remains as a sheet in roughly the same plane, the β bulge puts a bend in the structure. A β bulge, however, also can occur at a location where a large sheet of β structure folds over upon itself to form a sandwich of two opposed β sheets.

As with α helices that contain gaps where a turn is pulled apart, a β sheet can contain a **gap** between two strands. In such a gap, the donors and acceptors that have been pulled apart from each other are occupied by acceptors and donors on the side chains of their amino acids or by ordered molecules of water filling the gap.⁷⁴

Most β structure is **buried** in the middle of a protein, but even in a small protein such as fatty-acid-binding protein from *Escherichia coli*,⁷⁵ that is only a sandwich of two β sheets, there is only a very weak amphipathic pattern of alternating hydrophobic and hydrophilic amino acids along the β strands. Consequently, β structure cannot be identified in an amino acid sequence.

There are three **cylindrical arrays** formed from β structure: a **β barrel** (Figure 6-11)⁷⁶ of 4–12 strands,⁷⁷ a **β helix** (Figure 6-12),^{78,79} and a **β propeller** (Figure 6-13)⁸⁰ with 6–8 blades.^{81,82} In a β barrel, the hydrogen bonds between the β strands are perpendicular to the axis of the cylinder and perpendicular to its radius; in a β helix, they are parallel to the axis of the cylinder and perpendicular to its radius; and in a β propeller, they are parallel to the radius of the cylinder and perpendicular to its axis. Therefore, each of the three orthogonal axes of a cylinder is represented.

The most common type of β barrel has eight β strands (Figure 6-11). Usually β barrels are of eight strands or fewer so that the core can be tightly packed with side chains, but there is a β barrel of 11 strands through the core of which runs an α helix.^{83,84} The β strands in a β barrel reside in a surface that can be approximated quite closely by a twisted hyperboloid.⁸⁵ A hyperboloid is an ellipsoidal cylinder that is narrowest at its center and gradually and continuously widens away from its center in both directions (notice the flare to the hyperboloid in Figure 6-11). In a β barrel of eight strands, the strands are tilted^{77,86} with respect to the axis of the hyperboloid by a mean angle of -34° to -47° (the mean angle of tilt in Figure 6-11 is -34°), but in β barrels of less than eight strands, the angle of tilt gradually increases to -43° to -59° when there are only five.⁷⁷ As in a normal β sheet (Figure 6-9), the sheet that forms the hyperboloid has a negative twist and the mean angles of twist between adjacent strands are between -21° and -30° .

Figure 6-9: Parallel β -pleated sheet within the crystallographic molecular model (PDB filename 20HX; Bragg spacing ≥ 0.18 nm) of alcohol dehydrogenase.⁷⁰ The 12-stranded β sheet is composed of six parallel strands from each of the subunits of the dimer joined in an antiparallel orientation. The two identical series of numbers are those for the respective amino acid sequences of the two identical polypeptides comprising the protein. This drawing was produced with MolScript.⁵⁷³

in barrels of eight strands (the mean angle of twist in Figure 6-11 is -25°), but this angle increases to between -28° and -44° in β barrels of five strands. β Barrels can be constructed from parallel β strands of polypeptide of identical sequence,^{87,88} from an antiparallel β sheet wrapped into a cylinder,^{83,84,89} or from two identical sheets of parallel β strands arranged antiparallel to each other,⁹⁰ but the most common arrangement is parallel β strands of non-identical sequence. In such parallel β barrels the strands are often distributed around the barrel in the order in which they occur in the sequence of the polypeptide, and the carboxy-terminal end of one strand is connected to the amino-terminal end of the next by an α helix. Such β barrels are designated $(\alpha\beta)_n$, where n is the number of β strands.

The β helix displayed in Figure 6-12 is one in which there are three β sheets running up the tube at roughly 60° angles to each other. This configuration seems to be the most common type, but there are β helices in which only two β sheets run up the tube on opposite sides and the two sheets are flattened against each other.^{91,92} Extrusions of random meander (amino acids 167–175 in Figure 6-12) are common features of β helices. There is also an example of a hybrid structure in which each of the β strands in one of the three β sheets in a β helix is replaced by an α helix.⁹³

A third regular structure, in addition to α helices and β structure, universally encountered in the crystallographic molecular models of proteins is the β turn. A **β turn** is any structure that has a hydrogen bond between the acyl oxygen of the first amino acid in the turn and the amido nitrogen–hydrogen of the fourth amino acid in the turn (Figure 6-14).⁹⁴ Usually such a hydrogen bond

Figure 6-10: Five examples of β bulges from the crystallographic molecular models of various proteins, superposed upon themselves to indicate their uniformity.⁷³ The skipped amido nitrogen–hydrogen in each case is in the center left of the structure. Hydrogen bonds are indicated by dotted lines. The five β bulges are formed by Phenylalanine 41, Cysteine 42, and Leucine 33 of bovine chymotrypsin; Alanine 86, Lysine 87, and Lysine 107 of bovine chymotrypsin; Leucine 107, Serine 108, and Alanine 196 of con-canavalin A from *Canavalia ensiformis*; Isoleucine 90, Glutamine 91, and Valine 120 of human carbonate dehydratase II; and Isoleucine 15, Lysine 16, and Lysine 24 of micrococcal nuclease from *Staphylococcus aureus*, where the first two amino acids listed flank the vacant amido nitrogen–hydrogen and the third provides the amido nitrogen–hydrogen and acyl oxygen from the other strand. Only the side chains of the three central amino acids are included in the figure. Reprinted with permission from ref 73. Copyright 1978 National Academy of Sciences.

Figure 6-11: β Barrel within the crystallographic molecular model (Bragg spacing ≥ 0.20 nm) of indole-3-glycerol-phosphate synthase from *E. coli*.⁷⁶ The β barrel contains eight parallel β strands. The numbers are those for the amino acid sequence of the protein, and the positions of the β strands around the β barrel are in the same order in which they are found in the sequence of the protein. In the crystallographic molecular model between the end of each β strand and the beginning of the next is an α helix that lies across the outer surface of the β barrel running antiparallel to the two β strands that it connects. This drawing was produced with MolScript.⁵⁷³

causes the polypeptide to reverse its direction (Figure 4-15D). The original description of β turns by Venkatachalam⁹⁵ was based on structures built with molecular models. He proposed that there would be six types of β turns. A fundamental distinction is that between type I and type II (Table 6-1). A β turn of type I (Figure 6-14) is represented by the β turn in Figure 4-15D with its second acyl oxygen into the page, and a β turn of type II is represented by the β turn in Figure 4-15D with its second acyl oxygen out of the page. Each of these two fundamental types could also be built with molecular models in such a way that each of their four dihedral angles, ϕ_2 , ψ_2 , ϕ_3 , and ψ_3 , had the opposite sign, respectively (Table 6-1). These alternative conformations with opposite signs to their dihedral angles are called type IA and type IIA, respectively. In each of these two latter types, the polypeptide backbone is the mirror image of the polypeptide backbone in the corresponding β turns of type I and type II in Figure 4-15D, but the amino acids must remain L-amino acids.

Two other types of β turns, of historical significance, were originally defined by Venkatachalam⁹⁵ as type III and type IIIA. The prototype for β turns of type III, however, is the **3_{10} helix**¹⁰¹ originally proposed by Taylor¹⁰² and included by Bragg, Kendrew, and Perutz¹⁰¹ in their catalogue of all helices that would have rotational angles for each amino acid that were integral quotients of 360° . This is a helix that has hydrogen bonds between the acyl oxygen of amino acid i and the nitrogen-hydrogen bond of amino acid $(i+3)$, the pattern that is the primary definition of the β turn. The smaller repeat produced by this shorter connection makes a 3_{10} helix narrower than an α helix. Short segments of 3_{10} helix are occasionally seen in crystallographic molecular models,²³ but they are never more than five or six amino acids in length. Short segments of 3_{10} helix five or six amino acids in length have distorted bond angles along the polypeptide, and this observation suggests that the strain in such a tight helix is considerable.¹⁰³ This steric effect would explain their rarity. Segments of synthetic poly(2-amino-2-methylpropionic acid), however, crys-

Table 6-1: Frequency and Dihedral Angles of the Most Common Types of β Turns

type	frequency ^a (%)	dihedral angles ^b (deg)			
		ϕ_2	ψ_2	ϕ_3	ψ_3
I	41 ^c	-64 ± 8	-19 ± 8	-90 ± 9	-2 ± 11
IA	6	52 ± 3	41 ± 4	87 ± 6	-11 ± 14
II	26	-61 ± 6	132 ± 1	82 ± 12	3 ± 15
IIA	6	63 ± 5	-126 ± 5	-80 ± 9	-11 ± 10

^aThese are the frequencies in which these types of β turn occur in 59 crystallographic molecular models built from data sets gathered to Bragg spacing of ≤ 0.2 nm.⁹⁶ ^bMean and standard deviations of the dihedral angles for amino acids $i+1$ and $i+2$ in the β turns from the crystallographic molecular models of lysozyme,²² α -lytic protease,⁹⁷ deoxyribonuclease I,⁸ and penicillopepsin.⁹⁸ Values from crystallographic molecular models built from data sets gathered to even narrower Bragg spacing^{99,100} fall within these ranges. ^cDoes not include segments judged to be 3_{10} helix. If these had been included, the frequency of β turns of type I would rise to 50%.

tallize as 3_{10} helices.¹⁰⁴ The most frequent location for a short segment of 3_{10} helix is at the end of an α helix. A turn of 3_{10} helix in the middle of an α helix can put an elbow into it. For example, a turn of 3_{10} helix at Serine 143 and Leucine 144 in the center of an α helix in deoxyribonuclease I⁸ causes an abrupt bend of 22° .

A 3_{10} helix of four amino acids with one hydrogen bond is similar to a β turn of type I because it has mean values for its dihedral angles ϕ and ψ of -71° and -18° , respectively, but with wide ranges²³ that include those for β turns of type I, and it performs the same role as a β turn of type I. Almost all (96%) of the stretches of amino acids in crystallographic molecular models of proteins assigned as 3_{10} helix²³ are four or less amino acids in length, so most instances of 3_{10} helix could as easily be assigned as β turns of type I. Usually, however, they are not classified as such, and if not they are assigned as either 3_{10} helix or β turns of type III, depending on the preferences of the crystallographer. For every segment of amino acids assigned as 3_{10} helix or β turn of type III instead of β turn of type I, there are about 4.5 β turns of type I^{23,96} so the confusion is not a major one.

In crystallographic molecular models, β turns are designated both by the existence of a hydrogen bond between the acyl oxygen on the first amino acid and the amido nitrogen-hydrogen on the fourth amino acid and by the proximity of the α carbons of the first and fourth amino acids. In general, these two α carbons are 0.5–0.6 nm apart.¹⁰⁵ Those configurations designated by these rules as β turns can be grouped into the categories proposed by Venkatachalam (Table 6-1) as well as several other minor categories.⁹⁶ It was only after refined crystallographic molecular models became available that the clear tendency of these structures to fall into specific categories became apparent, because in unrefined structures the orientation of the polypeptide backbone could not be defined with sufficient accuracy.

β Turns of type I are the most common (Table 6-1). The dihedral angles at both of the α carbons in β turns of type I fall in the enclosure on the Ramachandran plot between dihedral angles of $\phi = -50^\circ$ and -130° and $\psi = 20^\circ$ and -30° (Figure 6-4B). This is the region in which the two successive amides are squeezed against each other (Figure 6-3F). Presumably the return on the investment of energy necessary to squeeze them against each other and widen the tetrahedral bond at the α carbon is the efficient reversal of the direction of the polypeptide. It is probably the case that β turns of type I and segments of 3_{10} helix²³ account for most of the amino acids that fall in this well-populated region of the Ramachandran plot.

The values for the dihedral angles ϕ_2 and ψ_2 for **β turns of type II** fall in the largest enclosure on the Ramachandran plot, but those for the dihedral angles ϕ_3 and ψ_3 fall in a region that can be occupied only by an amino acid without a β carbon (Table 6-1, Figure 6-4A), so only glycine should occupy the third position in a β turn of type II. Although this is usually the case (74%),⁹⁶

Figure 6-12: β Helix within the crystallographic molecular model (Bragg spacing ≈ 0.22 nm) of 2,3,4,5-tetrahydroxy-2,6-dicarboxylate *N*-succinyltransferase from *Mycobacterium bovis*.⁷⁹ There are five complete turns of the left-handed β helix, which is an equilateral prism, the three faces of which are parallel pleated β sheets. Protruding from one of the edges of the prism is a loop of random meander. This drawing was produced with MolScript.⁵⁷³

there are exceptions, about half of which are asparagines such as Asparagine 69 in α -lytic endopeptidase.⁹⁷

The mirror image conformations, in which the polypeptide backbone mirrors the respective basic β turn but the amino acids remain, of necessity, L-amino acids, are rare. The third amino acid in a **β turn of type IA** and the second amino acid in a **β turn of type IIA** should be a glycine, but again a few exceptions have been observed, such as Cysteine 170 in deoxyribonuclease I.⁸ It has been noted^{106,107} that when an antiparallel β hairpin reverses itself in the tightest possible β turn, where the hydrogen bond of the β turn is also the last hydrogen bond between the tines of the hairpin, the β turn is usually type IA or type IIA.

Several **minor classes** of β turn have been defined. β Turns of types VIA and VIB with dihedral angles ϕ and ψ of $(-60^\circ \pm 30^\circ, 120^\circ \pm 30^\circ, -90^\circ \pm 30^\circ, 0^\circ \pm 30^\circ)$ and

Figure 6-13: β Propeller within the crystallographic molecular model (Bragg spacing ≥ 0.19 nm) of methanol dehydrogenase from *Methylophilus methylotrophus* W3A1.^{80,569} This β propeller is composed of eight blades, each of which is an antiparallel β sheet. The left-handed twists of the β sheets forming each blade have been incorporated into the propeller. Each blade is composed of four antiparallel β strands that occur consecutively in the sequence; in each, the amino-terminal strand is toward the center and the carboxy-terminal strand is toward the outer edge. The order in which the blades occur around the propeller is also the same order in which they occur in the amino acid sequence with the exception of the outermost β strand of the last blade, which is the amino-terminal β strand of the polypeptide. With the exception of the sixth and eighth blades, each blade is presented in its entirety, its polypeptide unbroken. The missing segments of polypeptide connecting the blades and forming connections within blades six and eight are mostly long stretches of random meander.⁵⁷³ This drawing was produced with MolScript.⁵⁷³

$(-120^\circ \pm 30^\circ, 120^\circ \pm 30^\circ, -90^\circ \pm 30^\circ, 0^\circ \pm 30^\circ)$, respectively, together account for less than 3% of all β turns. β Turns of type VIII, however, with dihedral angles ϕ and ψ of $(-60^\circ \pm 30^\circ, -30^\circ \pm 30^\circ, -120^\circ \pm 30^\circ, 120^\circ \pm 30^\circ)$ ⁹⁶ are somewhat more common (12%), but the dihedral angles ϕ and ψ required to encompass this class are

much less tightly clustered than those for types I and II.¹⁰⁸

Aside from the requirement that glycine occupy certain positions of a β turn for steric reasons, there are some clear **preferences**^{96,103,109} for other amino acids. Because β turns are almost always at the surface of a protein, they contain hydrophilic amino acids more frequently than hydrophobic amino acids. About 25% of all β turns have proline at their second position (Figure 6-55). About 30% of all β turns of type I have either aspartate, asparagine, or cysteine at their third position. Each of these three amino acids has a hydrogen-bond acceptor that is properly situated to accept a hydrogen bond from the amido nitrogen-hydrogen of the amino acid in the next position just beyond the β turn.¹¹⁰

A **γ turn** is another type of turn that occurs rarely in crystallographic molecular models of proteins.^{111,112} A γ turn has a hydrogen bond between the nitrogen-hydrogen of the amide of the first amino acid in the turn and the acyl oxygen of the third amino acid in the turn, causing the dihedral angles ϕ and ψ of the central amino acid of the three to be around 80° and -60° , respectively, which is presumably why such structures are so rare (Figure 6-4B).

In every protein there are also segments of polypeptide that do not assume the configuration of an α helix, β structure, or β turn. These segments of **random meander** pass about the protein as would an α helix or a strand of β structure. They are usually found on the surface of the molecule, and occasionally one of them will loop out a significant distance from the core of the structure. Although there is no regular pattern to this configuration, each of the amino acids in a segment of random meander usually assumes a fixed position in the crystallographic molecular model and has specific values for its dihedral angles ϕ and ψ . These values, however, are still confined to the minima in the Ramachandran plot because these minima are defined by inescapable local steric effects. This places the angles for random meander within the same regions defined by the clusters in Figure 6-4B. The distinction between α helix, β structure, and random meander cannot be made by comparing single values of the dihedral angles ϕ and ψ but only by identifying repeating patterns that extend over several amino acids or several strands of polypeptide. In random meander, no such pattern is evident.

Almost all of the regular structures in which the polypeptide participates are given their regularity by **hydrogen bonds** between the amido nitrogen-hydrogens and acyl oxygens of the backbone. These hydrogen bonds can be readily identified in crystallographic molecular models, and it can be safely assumed that they exist. The **bond length** for such unambiguous hydrogen bonds, expressed as the distance between nitrogen and oxygen, is 0.29 ± 0.015 nm.^{20,97,98,113}

The **angular dependence** of these hydrogen bonds can be expressed either in reference to the nitrogen-hydrogen bond of the one amide (Figure 6-15A,B)^{22,97} or

the carbon–oxygen bond of the other amide (Figure 6–15C–G).¹¹³ As expected, the angles around the amido nitrogen–hydrogen of the donor are much more confined than those around the lone pairs on the acyl oxygen of the acceptor. A deviation from 0° of either of the angles around the nitrogen–hydrogen bond (Figure 6–15A) places the hydrogen off the line of centers between the nitrogen and the oxygen and bends the bond.

The angles of the hydrogen bond relative to the carbon–oxygen bond of the acceptor (Figure 6–15C–G) vary over a greater latitude. In keeping with the rigidity of α helices and flexibility of β structure, the angles around the acyl oxygens in β structure are much more variable (Figure 6–15F,G) than those around the acyl oxygens in α helices (Figure 6–15D). In none of these regular structures, however, is there any tendency for the values of the angles around the acyl oxygen to cluster at $\beta = 0^\circ$ and $\gamma = \pm 60^\circ$, the positions at which the nitrogen–hydrogen bond would point directly at one or the other of the lone pairs on the acyl oxygen (Figure 5–10). It has, however, already been noted that, even in crystallographic molecular models of small, unconstrained molecules, the preference for these angles is not remarkable (Figure 5–11), and there seems to be little energetic cost in pivoting the donor over the surface of the acyl oxygen distal to the acyl carbon (Figure 5–10D). Therefore, in regular structures such as an α helix or β structure, it is the steric requirements of these structures themselves that easily take precedence.

Even in refined molecular models from data sets of narrow Bragg spacing, the identification of a hydrogen bond is subjective. It is often based on the fact that two heteroatoms are simply within a certain distance of each other. The dimensions of unquestionable hydrogen bonds in regular structures, however, suggest a more objective definition of a hydrogen bond.²² It has been proposed that a hydrogen bond is an arrangement in which the heteroatoms of the donor and the acceptor are less than 0.34 nm from each other; the angle A–H–B, where A is the donor and B the acceptor, is between 150° and 180° (Figure 6–15B); and the distance between the theoretical position of the hydrogen and the heteroatom of the acceptor is less than 0.24 nm. When these definitions are applied to the rather featureless distribution of distances between nitrogens and oxygens in a crystallographic molecular model, that distribution can be divided into hydrogen bonds and non-hydrogen bonds (Figure 6–16).²²

The regular structures assumed by the polypeptide serve the purpose of maintaining the total concentration of hydrogen bonds in the solution. It seems highly unlikely that a protein could fold without withdrawing considerable numbers of its peptide bonds from contact with water. Were the donors and acceptors on these peptide bonds withdrawn from the solvent without subsequently participating in hydrogen bonds in the inte-

Figure 6–14: β Turn of type I from the crystallographic molecular model (Bragg spacing ≥ 0.089 nm) of crambin from *Crambe abyssinica*.⁹⁴ The β turn contains a hydrogen bond between the acyl oxygen of Arginine 17 and the amido nitrogen–hydrogen of Glycine 20 in the amino acid sequence of the protein. Leucine 18 and Proline 19 occupy the two central positions. The molecular model was from a data set gathered to such narrow Bragg spacing and at such a low temperature (130 K) that the electron density for hydrogen atoms could be readily discerned, and those on the amides are included in the drawing. The C γ -endo pucker of Proline 19 was also clearly defined. This drawing was produced with MolScript.⁵⁷³

rior of the protein, there would be an unavoidable loss of standard enthalpy (Figure 5–18). This loss is cancelled when they find new partners (Table 5–2). α Helices and β structure are simply efficient mechanisms for accomplishing this energetic imperative.

Stereochemistry of the Side Chains

It was pointed out in a discussion of the crystallographic molecular model of chymotrypsin, which was one of the first refined crystallographic molecular models,¹⁷ that certain **rotational conformations** of the side chains of the amino acids seemed to be preferred. As more highly refined crystallographic molecular models of proteins built from data sets of narrower Bragg spacing have become available, it has become clear that most of the side chains of the amino acids in the interior of these models assume only one of the several rotational conformations available to them,^{114,115} a remarkable fact that illustrates the confinement exercised by the efficient packing in the interior of a protein.

In maps of electron density calculated from data sets to narrow Bragg spacing, side chains displaying **alternative conformations** (Figure 4-25) are infrequent (12 of 478 side chains in human glutathione reductase;¹¹⁶

35 of 584 side chains in human β_4 hemoglobin^{117,118}) and most of those are side chains found at or near the surface of the molecule of protein, such as lysines, serines, threonines, glutamates, aspartates, and asparagines.^{74,116,118} The valine of Figure 4-25 in the interior of ribonuclease T₁ is an example of an exception to the preference of buried side chains for only one conformation.¹¹⁵ When side chains do assume two alternative conformations, each of them is usually at one of the normal minima of rotational energy,¹¹⁹ as are the unique, fixed conformations of most of the side chains.

Consequently, most of the observed rotational conformations are **staggered** rather than eclipsed, a fact that is reflected in the strong tendency (Figure 6-17)⁹⁸ for dihedral angles along carbon–carbon bonds between saturated carbons and other atoms that are hybridized sp^3 to assume values near 60°, 180°, and 300° (–60°). In extensive tabulations^{120–122} of the dihedral angles for all of the side chains in sets of refined crystallographic molecular models from data sets of narrow Bragg spacing, most of the values for the dihedral angles of carbon–carbon bonds connecting atoms that are hybridized sp^3 are clustered within 10° of one of these three values.

It has been pointed out, however, that a significant fraction of the amino acid side chains have at least one dihedral angle that falls more than 20° (5–30% depending on the side chain)¹²¹ or even more than 30° (1–19% depending on the side chain)¹²² away from the mean. If these are real **deviations**, conformations of side chains exist in which substituents are partially or fully eclipsed,¹²² situations in which considerable steric strain (15–40 kJ mol^{–1}) must be accommodated. Most of these unexpected and sterically strained dihedral angles in these crystallographic molecular models, however, are probably artifactual,¹²³ arising from unresolved alternative conformations,¹²⁴ the inaccuracy of the crystallographic molecular model, incorrect insertion into the map of electron density, and errors accumulated during refinement. Again it must be remembered that a crystallographic molecular model is not the actual structure of the molecule of protein. Nevertheless, some of these deviations may reflect the actual adjustments of some of the side chains to the impossibility of packing as complicated a molecule as a polypeptide into a compact globular structure.

The dihedral angle along the bond between C α and C β in an amino acid is designated χ_1 . It is the dihedral angle between the bond to the amido nitrogen, the most massive of the three atoms around C α , and the bond to the atom attached to C β that has the highest priority in the Cahn–Ingold–Prelog system (Figure 6-18). The sign of **dihedral angle** χ_1 is determined by the right-hand rule. The stereochemistry about this bond between C α and C β is dominated by the polypeptide rather than the rest of the side chain.

Valine is the logical place to begin the discussion of this stereochemistry because its two methyl groups can

Figure 6-17: Histograms and scatter plots of the distributions of the values for the dihedral angles χ_1 and χ_2 for the first two carbon-carbon bonds of the side chains of amino acids in the crystallographic molecular models of five proteins: penicillopepsin, streptogrisin A from *Streptomyces griseus*, streptogrisin B from *S. griseus*, the third domain of the ovomucoid inhibitor, and α -lytic endopeptidase from *Lysobacter enzymogenes*.⁹⁸ The abbreviation of each side chain appears in the upper left-hand corner of the panel. Serine, threonine, and valine had no observable dihedral angles χ_2 , so in these instances frequency is plotted as a function of the only value of the dihedral angle χ_1 . Leucine, isoleucine, asparagine, and glutamine had observable dihedral angles χ_1 and χ_2 , and in these cases each mark (γ for leucine, $+$ for isoleucine, γ for asparagine, and $+$ for glutamine) represents the value of these two angles for one of these side chains in these molecular models. Because of symmetry, the values for χ_2 for the aromatic amino acids tyrosine, phenylalanine, and tryptophan (listed together as aromatics) fall only between 0° and 180° . Reprinted with permission from ref 98. Copyright 1983 Academic Press.

assess the steric bulk of the three substituents on the α carbon because in each of the three staggered conformations (two of which are displayed in Figure 6-18), one of these three substituents must reside between the two methyl groups, a most hindered location. Because the smallest functional group should occupy this position most frequently, the distribution of the dihedral angles χ_1 of the valines in molecular models (Figure 6-17) states that the hydrogen on the α carbon is smaller (73% of χ_1 are within 30° of 175°)* than the nitrogen of the preceding amide (20% are within 30° of -64°), which is smaller

than the acyl carbon of the following amide (6% are within 30° of 63°). This behavior is completely consistent with the assessment of steric bulk based on preferences of various substituents on cyclohexane for equatorial over axial locations. The increase in free energy¹²⁵ for placing an acetoxy group in an axial location rather than an equatorial location is 2.9 kJ mol^{-1} , but the increase in free energy for placing a methoxycarbonyl group in an axial location rather than an equatorial location is 5.4 kJ mol^{-1} .

Isoleucine (Figure 6-18) reinforces these preferences by showing a similar distribution¹²⁶ of analogous stereochemical conformations (76% within 30° of -64° , 14% within 30° of 61° , and 10% within 30° of -173° , respectively). It has been suggested that isoleucine ($+$ in Figure 6-17) has different preferences from leucine (γ in Figure 6-17) for the dihedral angles χ_1 and χ_2 because these two geometric isomers should be able to satisfy in turn different steric requirements.¹²⁷

Threonine is isosteric with valine, but the designation of the dihedral angle χ_1 of threonine is 240° out of phase with that of the dihedral angle χ_1 of valine because of the precedence of the (S)-oxygen over the (R)-methyl group (Figure 6-18). The conformation of threonine (χ_1 within 30° of 59° , 49% of all threonines) in which the two substituents on $C\beta$ surround the nitrogen of the preceding amide (Figure 6-18) is about 4 times more frequent than the analogous conformation of valine (χ_1 within 30° of -64° , 20% of all valines) relative to the respective conformations (43% and 73%) in which hydrogen is surrounded. The most likely explanation for this difference is the fact that a hydroxyl group is significantly smaller than a methyl group. Another possibility, however, is that

* Values of dihedral angles χ_1 designated as within 30° of the angle at the maximum of the distribution are from the tabulation derived from an analysis of 240 crystallographic molecular models built from data sets all to Bragg spacing less than or equal to 0.17 nm .¹²²

Figure 6-18: Definition of the dihedral angle χ_1 for the carbon-carbon bond between the α carbon and the β carbon of an amino acid in a polypeptide. All dihedral angles follow the right-hand rule. For valine, angle χ_1 is the dihedral angle between the carbon-nitrogen bond and the bond to the *pro-R* methyl group. For isoleucine and threonine, angle χ_1 is the dihedral angle between the carbon-nitrogen bond and the bond to the substituent of higher priority, namely, the ethyl group or the hydroxyl group, respectively. For all other relevant amino acids, the dihedral angle χ_1 is the angle between the carbon-nitrogen bond and the bond to the remainder of the side chain.

a dihedral angle χ_1 within 30° of 59° places the hydroxyl of threonine in the proper position to form either a hydrogen-bonded ring with its own acyl oxygen or a hydrogen-bonded ring with the acyl oxygen of the amino acid that precedes it in the sequence.¹²⁸ Such hydrogen-bonded rings would explain why **serines** show such a high percentage of dihedral angles χ_1 within 30° of 64° (48%), in contrast to all other amino acids with only one substituent on the β carbon, which have a low percentage of dihedral angles χ_1 near 60° (11% of all side chains with one and only one substituent on $C\beta$).^{120,121,126}

The amino acids, other than serine, with one and only one substituent on $C\beta$ have a preference (55%)^{120,126} for dihedral angles χ_1 of $-65^\circ \pm 10^\circ$.¹²⁶ This preference⁶ is understandable because an angle χ_1 of -65° places the single substituent on the β carbon between the two least bulky substituents around the α carbon (Figure 6-18). The other two maxima occur at $-177^\circ \pm 10^\circ$ and $66^\circ \pm 8^\circ$. The bias in the direction of the α hydrogen is reflected in

the values of -65° and -177° . Of this group of side chains, those with a methylene at the γ position have dihedral angles χ_1 within 20° of 66° ,¹²¹ which would put the methylene between the two bulkiest substituents (Figure 6-18), only 7% of the time, but the side chains with an aromatic ring at the γ position, which is less bulky than a methylene, have dihedral angles χ_1 within 20° of 66° 16% of the time.¹²¹

Because the preference for a certain value for the dihedral angle χ_1 usually depends on a choice among three staggered conformers (Figure 6-18), the energies of which differ by only a few kilojoules mole⁻¹, it comes as no surprise that this choice depends on the structure of the immediate surroundings. In particular, the dihedral angles ψ and ϕ of the amino acid can affect the choice of its dihedral angle χ_1 . As might be expected, valine displays the most dramatic effects of the backbone on the dihedral angle χ_1 . For valines within either α helices or β sheets, values of dihedral angle ψ more positive than the respective ideal values cause χ_1 to switch from a value of exclusively $175^\circ \pm 8^\circ$ to a value of exclusively $-64^\circ \pm 7^\circ$.¹²³

The **dihedral angle χ_2** is assigned to the bond between $C\beta$ and $C\gamma$ in an amino acid. In **linear amino acids** such as glutamine, glutamic acid, lysine, arginine, and methionine, the majority (70%) of the dihedral angles χ_2

are clustered⁶ at $176^\circ \pm 11^\circ$, which is the angle expected for a *trans* conformation at this carbon-carbon bond.^{120,126} The remainder of the dihedral angles χ_2 for these amino acids are split equally between the two *gauche* conformations at dihedral angles χ_2 near 60° and -60° .

For the **aromatic amino acids** phenylalanine, tyrosine, histidine, and tryptophan (Figure 6-17), the conformations with dihedral angles χ_2 within 30° of 90° or -89° , where the plane of the ring is approximately perpendicular to the bond between the α carbon and the β carbon

are preferred (71% of these side chains).¹²¹ This orientation (Figure 6-21) places the polypeptide most distant from the two *ortho* substituents of the rings and also avoids eclipse. A significant fraction (29%) of these side chains, however, have values for χ_2 outside of these ranges. The aromatic rings are large, bulky substituents and each of these outliers is pushed out of the ideal range by unavoidable steric clashes with atoms from the backbone or other side chains.¹²¹ In spite of their bulk, however, the symmetric rings of tyrosine and phenylalanine have been observed to flip over slowly and continuously.¹²⁹

It has also been observed in refined maps of neutron scattering density from crystallography by neutron diffraction that the hydrogens on all methyl groups are staggered.¹³⁰ Although this seems to be the expected result because **methyl groups** in proteins should be free to rotate and assume freely a staggered conformation, there are indications that packing in the interior of a protein is so tight that even methyl groups are confined¹³¹

The dihedral angles χ_2 for the **hydroxyl groups** of serines and threonines

although they define the position only of a hydrogen, can also be observed by neutron diffraction.¹³² There is a strong tendency for the hydroxyl to be staggered (χ_2 near 60° , 180° , and -60°) with the *trans* conformation (χ_2 near 180°) slightly preferred over either *gauche* conformation. The location of an acceptor forming a hydrogen bond with the proton often seems to dictate the dihedral angle assumed by the hydroxyl. Because of conjugation, the oxygen-hydrogen bond of the hydroxyl of tyrosine is within the plane of the ring (2-23).

The distribution of the values of the dihedral angle χ_2 for **asparagine**

has two maxima at -21° and $+32^\circ$ (82% within 30° of these two maxima) that define two respective classes,^{122,133} the membership of which is determined by

the value of the dihedral angle χ_1 for that asparagine, the type of secondary structure to which it belongs, and the type of hydrogen bond formed between it and the backbone. Asparagine 34 in Figure 6-7B serves as an example of one of these choices. **Aspartate** shows the same preference for values of the dihedral angle χ_2 . The majority (82%) of the dihedral angles χ_2 for aspartates are within 60° of 0° .¹²²

Only glutamine, glutamate, methionine, lysine, and arginine have carbon-carbon bonds with **dihedral angles χ_3** . Both **glutamine** and **glutamate** show the same preferences for dihedral angles χ_3 near 0° that are shown by asparagine and aspartate for the analogous dihedral angle χ_2 .¹²² The *trans* conformation with dihedral angle χ_3 within 30° of 180° is the preferred (66%) conformation for lysine, as expected.¹²²

Methionines are usually buried and confined to one or two overall conformations in crystallographic molecular models, so the dihedral angles χ_1 ($C\alpha-C\beta$), χ_2 ($C\beta-C\gamma$), and χ_3 ($C\gamma-S$) are usually fixed. The normal preferences for dihedral angles χ_1 (59% within 30° of -67°) and χ_2 (55% within 30° of 178°)¹²² are observed, but the value for angle χ_3

has a significantly higher frequency for the two *gauche* conformers (39% within 30° of -72° and 32% within 30° of 75°).^{122,131} It has been pointed out that because the two carbon-sulfur bonds (0.18 nm) are longer than two carbon-carbon bonds (0.15 nm), the steric clashes within methionine in such *gauche* conformations should be less severe and the dihedral angles χ_3 should be less confined.¹³⁴ It seems that this unexpected preference for the *gauche* conformations arises from the fact that when methionine assumes this conformation, it is more compact.

Because the amido nitrogen is planar, it occupies a position in the puckered cyclopentyl ring of a **proline** (Equation 6-1) at which eclipse would occur if it were occupied by a methylene. As a result, only the C^γ -*exo* and C^γ -*endo* conformations of proline

can be significantly populated,¹³⁵ but it is difficult to distinguish crystallographically between these two conformations.

mations even with a data set gathered to narrow Bragg spacing (< 0.17 nm). Nevertheless, decisions can often be made either directly (Figure 6–14) or indirectly¹³¹ as to the proper conformation, and sometimes a map of electron density shows that both conformations are present in equilibrium with each other.¹³⁶

Cystine is an amino acid under peculiar steric constraints (Figure 6–19).^{137,138} The distribution of the two dihedral angles χ_1 of cystine^{26,121} shows the same order and frequencies of preferences (56% within 20° of -65° , 24% within 20° of -175° , and 12% within 20° of 64°)¹²¹ as those of any other amino acid with only one uncomplicated substituent on the β carbon. The disulfide itself, because it is a dithioperoxide, is electronically required to have a dihedral angle χ_3 along the sulfur–sulfur bond similar to the dihedral angle of hydrogen peroxide, which is 94° or -94° . If the dihedral angle χ_3 in a cystine were exactly 90° or -90° , the four lone pairs, two on each sulfur, would be as far from being parallel to each other as is possible, and this orientation would be the most stable electronically.¹³⁹

The angles observed for the dihedral angles of cystines in crystallographic molecular models are $97^\circ \pm 15^\circ$ and $-86^\circ \pm 11^\circ$ (indistinguishable from $+90^\circ$ and -90°), with little preference for the positive over the negative.¹⁴⁰ There are instances in which these two discrete, alternative conformations are both populated significantly by the same cystine (Figure 6–40B).^{141,142} The dihedral angle χ_3 of 97° or -86° in a cystine is peculiar enough to attract attention (Figure 6–19).

The bonds between the β carbons and the sulfurs in a cystine might be expected to have a preference for dihedral angles χ_2

equal to 180° as with most other amino acids, but in crystallographic molecular models, values around broad maxima of 60° and -60° (Figure 6–19) are heavily preferred.^{103,143} Each of the two bonds between the β carbons and the sulfurs should be fairly long and not severely confined by the adjacent sulfur or the lone pairs on the immediate sulfur itself, and they are probably the

Figure 6–19: A pair of cystines, Cystine 224/233 and Cystine 217/240, in the amino acid sequence of the crystallographic molecular model (Bragg spacing ≥ 0.26 nm) of carboxypeptidase C from *Saccharomyces cerevisiae*.^{137,138} The two cystines cross-link two α helices in an antiparallel coiled coil. The drawing is aligned to permit the dihedral angles χ_2 of Cystines 217 and 224 to be viewed effectively. The dihedral angles χ_3 for these cystines are both close to $+90^\circ$.

most compliant of the bonds in the cystine. Because a cystine connects two strands of polypeptide engaged in many other interactions, it probably sustains considerable torque. Presumably it is the dihedral angles χ_2 that must accommodate this torque. Because of the electronic requirements, the dihedral angle of the disulfide itself must always be near 97° or -86° , and it is only the two dihedral angles χ_2 that can adjust to allow the entire cystine to fit the distance required to be spanned between the two otherwise fixed α carbons of a cystine in a protein. For example, in Figure 6–19, if the two α helices connected by the two cystines had to move farther apart from each other or closer together, their relative movement could be accommodated by increasing

or decreasing, respectively, the dihedral angles χ_2 of Cysteines 217 and 224 or Cysteines 233 and 240 or all of them together.

If both of the dihedral angles χ_2 were 180° , the angle preferred by other amino acids with a single substituent on the β carbon, then the two α carbons in a cysteine would be about 0.9 nm apart, a rather distant connection. Because the distances between the two α carbons of cysteines in native proteins fall between 0.45 and 0.7 nm,¹⁰³ the dihedral angles χ_2 assume many other values, and rarely 180° .

So far, the dihedral angles χ have been considered independently. Usually, however, the individual rotamers of a side chain are tabulated.^{121,122} A **rotamer** is a rotational conformation of a side chain in which each carbon-carbon bond assumes a dihedral angle χ within a particular range. The range is within a certain number of degrees, for example, within 20° ¹²¹ or within 30° ,¹²² of one of the maxima for the distribution, which are usually close to the staggered dihedral angles of 60° (gauche⁺), 180° (trans), or -60° (gauche⁻). For example there are nine rotamers of isoleucine, which are, in order of their frequency, g^-t , g^-g^- , g^+t , tt , tg^+ , g^-g^+ , g^+g^+ , g^+g^- , and tg^- . Such tabulations of rotamers emphasize the dependence of one dihedral angle on the adjacent dihedral angles. There is, however, no agreement as to the statistical method that should be used to determine rotamers, their variances, or their distributions.

All of the stereochemical observations discussed so far are either consistent with the behavior of small molecules or otherwise make sense. Some of this agreement is probably illusory. During refinement, **constraints on dihedral angles** are imposed either advertently or inadvertently, and the fact that they are near ideal values in the final crystallographic molecular model may not reflect reality. Careful corrections using properly calculated **omit maps** should eliminate this bias, and crystallographic molecular models derived from data sets gathered to narrow Bragg spacing, for which few constraints need to be imposed during refinement, can avoid this problem entirely.

If there are only a few conformations that are preferred for each side chain, then there is far less flexibility involved in the folding of a protein than there seems to be at first glance. Conformations of the folded protein that demand dihedral angles to assume values other than those of lowest energy, which are normally the conformations most heavily populated in the unfolded polypeptide, require that extra energy be spent to occupy those conformations. It turns out that there is not much extra energy to go around.

Problem 6–2: Turn the alanine into a valine in your space-filling molecular model from Problem 6–1 by replacing two of the hydrogens on the β carbon with methyl groups. Rotate around the appropriate bonds until the dihedral angles ϕ and ψ have the mean values for an amino acid in parallel β structure.

- What atoms run into the two methyl groups on the side chain of the valine as rotation occurs around the bond between the α and β carbons? Use the numbering system of Figure 6–2.
- What is the value for the dihedral angle χ_1 that has the most sterically favorable disposition of the side chain in β structure?

Rotate around the appropriate bonds until the dihedral angles ϕ and ψ in your model have the mean values for a right-handed α helix.

- What atoms run into the two methyl groups on the side chain of the valine as you rotate around the bond between the α and β carbons? Again, use the numbering system of Figure 6–2.
- What is the value for the dihedral angle χ_1 that has the most sterically favorable disposition of the side chain in a right-handed α helix?

The theoretical values for the dihedral angles ϕ and ψ for a left-handed α helix should be 65° and 40° , respectively. Rotate around the appropriate bonds until the dihedral angles ϕ and ψ in your model have these values.

- What atoms run into the two methyl groups on the side chain of the valine as you rotate around the bond between the α and β carbons?
- What is the value for the dihedral angle χ_1 that has the most sterically favorable disposition of the valine side chain in a left-handed α helix?
- On the basis of these observations, why is a left-handed α helix unstable relative to a right-handed α helix?

Problem 6–3: Draw Newman projections to explain why the dihedral angles χ_2 for leucine and isoleucine display such a strong preference for 180° (Figure 6–17).

Hydropathy of the Side Chains

There is an obvious bias in the distribution of its constituent amino acids between the **surface** of a molecule of protein, which remains in contact with the water, and

its **interior**, which is more or less withdrawn from the water. This bias reflects their hydrophathy.

The **accessible surface area** of a molecule of protein can be estimated by asking a digital computer to perform a calculation equivalent to rolling a sphere of a particular size, the probe, over the surface of a space-filling crystallographic molecular model (Figure 4-17E) of that protein.¹⁴⁴ The center of the spherical probe will trace a surface, and the area of that surface, removed from that of the surface of the protein by a distance equal to the radius of the sphere, is defined to be the surface area of the protein accessible to the probe. Each portion of the irregular surface defined by the center of the probe can be assigned to a particular atom in the crystallographic molecular model by noting with which atom the probe was in contact when that portion was being created.

The surface of a molecule of protein is not smooth, but highly **irregular**, covered with cracks, crevasses, cavities, and ridges (Figure 4-17E).^{144,145} One way to demonstrate this fact is to vary the radius of the probe (Figure 6-20). When the probe is large (≥ 1.5 nm in the example chosen) the crystallographic molecular model is indistinguishable from a hard sphere (a sphere of radius 4.55 nm in the example chosen), but as the radius of the probe is decreased, much more surface area becomes accessible (the difference between the points and the curve in Figure 6-20) as the probe becomes small enough to enter the irregularities of the surface. The radius usually chosen for the probe,¹⁴⁴ in an attempt to mimic a molecule of water, is 0.15 nm (the arrow in Figure 6-20). The

Figure 6-20: Irregularity of the surface of a protein. The radius of the probe used to determine accessible surface area¹⁴⁴ was assigned a particular length (nanometers) and the accessible surface area (nanometers²) of the crystallographic molecular model (Bragg spacing ≥ 0.18 nm) of glyceraldehyde-3-phosphate dehydrogenase from *Bacillus stearothermophilus*⁵⁷⁰ was computed (points on graph). The smooth curve on the graph is the accessible surface area that a sphere of radius 4.55 nm would give as a function of the radius of the probe rolled over its surface. The arrow is at a radius for the probe of 0.15 nm. The program used in the calculations was adapted from that of Lee and Richards¹⁴⁴ by Dr Ilya Shindyalov of the Protein Data Bank.

choice is arbitrary, especially because locations to which only a single molecule of water can gain access experience diminished effects of the solvation arising from the bulk properties of water.

Usually a particular amino acid in a crystallographic molecular model is designated as **buried** if less than a certain amount of its surface area is accessible. It has been shown¹⁴⁵ that when the radius of the probe is set at 0.15 nm

$$n^{1/3} - n_B^{1/3} = \kappa \quad (6-3)$$

where n is the total number of amino acids in a protein, n_B is the number designated as buried by a particular rule, for example, every amino acid with an accessible surface area less than 0.2 nm^2 , and κ is a constant. This equation states that, in a globular protein, the amino acids defined by a rule as buried are found within a roughly spherical solid of radius r_B that is smaller than the roughly spherical solid of radius r containing all of the amino acids.¹⁴⁵

6-11

The spherical shell of width d between these two roughly spherical solids contains all of the amino acids ($n - n_B$) that are accessible by the **rule** that has been chosen. This shell can be considered to be the depth of penetration of the probe, which represents water, into the interior of the protein owing to its irregular surface. If buried amino acids are defined as only those completely inaccessible to a probe of radius 0.15 nm, d is fairly large (1.0 nm) and the buried amino acids are deep in the interior. This rule would require that in a small protein (100 aa) almost no amino acid would be completely inaccessible. If the rule, however, is that any amino acids having accessible surface area of less than 0.2 nm^2 are defined as buried, then d is only 0.5 nm and far more of them are considered to be buried.

Accessible surface areas of the amino acids in crystallographic molecular models of proteins have been calculated by use of a radius for the probe of 0.15 nm, and for each type of amino acid, the **fraction scored as buried** by at least three different rules has been separately tabulated (Table 6-2). When the most stringent rule is used, namely, that a buried amino acid in the molecular model of the protein must have no accessible surface area, the frequencies with which most of the

amino acids are buried is very low and the statistics become unreliable. When the rule is relaxed, more amino acids are scored as buried, and discriminations become more dependable.

Half of the amino acids, when they are in an unfolded polypeptide and freely accessible to a probe of 0.15 nm, have total accessible surface areas between 1.5 and 2.0 nm² and therefore are of similar **size** (Figure 4-14). Small amino acids such as alanine are probably buried more often simply because they are easier to surround, and large amino acids such as tryptophan are harder to surround completely and bury, especially in the smaller proteins. These stereochemical problems must contribute to the observed distributions.

Nevertheless, it has already been noted that the frequencies with which the various amino acids are buried are correlated¹⁴⁹ with the **free energies of transfer** for their model compounds from water to the gas phase (Table 5-9) and also with many of the other scales of hydrophathy (Figure 5-24). This correlation is actually established by the three main groups of side chains (Table 6-2): those that are hydrophobic, those that are apathetic, and those that are hydrophilic (note the three clusters in Figure 5-24). Within each of these groups, however, there is no significant correlation between extent of burial and any **scale of hydrophathy** derived from free energies of transfer. Presumably, the reason for the lack of correlation within the main groups is that

stereochemically and energetically protein folding is not a transfer between solvents. With this in mind, it still can be stated that if an amino acid is hydrophobic, it is more likely to be buried, and if it is hydrophilic, it is more likely to remain in contact with the water in the folded polypeptide.

The results of the hydrophobic effect are most readily appreciated by examining the internal **core of a crystallographic molecular model** (Figure 6-21).¹⁵⁰ This region is enriched in definitively hydrophobic amino acids such as leucine, isoleucine, valine, and phenylalanine. An even more dramatic example of a hydrophobic core is the center of a β helix, which is completely walled off from the water by the backbone of the helix and which is composed exclusively of aliphatic side chains.¹⁵¹

Each of the **hydrogen-carbon bonds** on the side chains that are removed from water provided favorable **hydrophobic free energy** to drive the folding of the polypeptide. This fact can be verified by performing site-directed mutation. So that no adverse steric effects are encountered, either an isoleucine found in the core of a crystallographic molecular model of the protein is shortened by converting it to a valine or an alanine, a leucine or a valine in the core is shortened by converting it to an alanine,¹⁵²⁻¹⁵⁶ or a position in the core next to a cavity is chosen and the mutants designed so that they expand into the cavity.¹⁵⁷ The change in the standard free energy of folding produced by the various mutations is then

measured. In such studies, it has been found that whether hydrogen-carbon bonds are added to or removed from the core relative to the number present in the core of the native protein, each one contributes between -1 and -5 kJ (mol of hydrogen-carbon bond) $^{-1}$ to the standard free energy of folding, with most of the values clustered^{155,156,158-161} between -2.5 and -3.5 kJ (mol of hydrogen-carbon bond) $^{-1}$. These values encompass* and are indistinguishable from the value of -2.8 kJ (mol of hydrogen-carbon bond) $^{-1}$ for the transfer of hydrocarbon from water to liquid hydrocarbon (Figure 5-21).¹⁵⁴ The interior of a protein is enriched in hydrophobic amino acids because this is the only way to obtain the free energy necessary to drive its folding.

When a **hydrophilic amino acid** such as lysine or glutamate is introduced into the interior of a molecule of protein by site-directed mutation, the protein becomes significantly less stable. For example, when Methionine 102 and Leucine 133 in lysozyme from bacteriophage T4, which are both buried in its interior, were replaced in turn with a lysine and an aspartate, respectively, the protein became less stable by 29 and 24 kJ mol $^{-1}$. The region surrounding the new lysine at position 102 became much more mobile to permit limited access of the lysine to the solvent, and its pK_a was found to be 6.5, a shift indicating that the neutral conjugate base had become more stable than it would have been if it were fully exposed to the water.¹⁶³ When Valine 16 of ribonuclease T₁ from *Aspergillus oryzae* is replaced with its isostere threonine, the stability of the protein decreases by 15 kJ mol $^{-1}$, and the side chain of the threonine has rotated 120° relative to that of the valine around the C α -C β bond to direct the hydroxyl group toward the solvent rather than toward the interior as the -CH₃ group of the valine was directed.¹⁶⁴ Often, however, when valine is replaced by threonine or alanine is replaced by serine in the interior of a protein, the hydroxyl group finds a nearby acceptor for its hydrogen bond, and the change in stability is small (<4 kJ mol $^{-1}$).¹⁶⁵

When a hydrophobic amino acid ends up fully exposed on the surface, this exposure is neither energetically unfavorable nor favorable because it was fully exposed before the polypeptide folded. When a phenylalanine was placed in turn by site-directed mutation at a number of fully accessible sites on the surface of micrococcal nuclease, the stability of the protein decreased on

* The broad range of these values¹⁵⁶ may be due to the fact that each of these hydrophobic chains that has been mutated in the respective experiments is located in its own particular surroundings within the native structure, and each of those surroundings produces its own particular steric effects and standard free energy of solvation.¹⁶² It has been shown that the magnitude of the change in standard free energy of folding produced by removing hydrogen-carbon bonds by mutation is directly proportional to the number of other hydrogen-carbon bonds surrounding the point of the mutation in the crystallographic molecular model of the protein.¹⁵³

Figure 6-21: Hydrophobic core in the crystallographic molecular model (Bragg spacing ≥ 0.17 nm) of a type I cohesin domain from the cellulosomal scaffolding protein A of *Clostridium thermocellum*.¹⁵⁰ The backbone (thinner lines) of the entire domain, except for the first five amino acids that were missing from the map of electron density, is presented. Only the side chains (thicker lines) of the amino acids in the core of the molecule are drawn. Note the different rotamers of isoleucine and the fact that dihedral angles χ_2 for the phenylalanines and tyrosines are almost all near 90°. The numbers are those for the amino acid sequence of the intact cellulosomal scaffolding protein. This drawing was produced with MolScript.⁵⁷³

average for each of these single substitutions by only 2 kJ mol $^{-1}$, and at least half of that decrease in stability resulted from steric effects.¹⁶⁶ No consistent changes in stability were observed when several different hydrophobic amino acids were substituted by site-directed mutation for amino acids on the surface of lysozyme from bacteriophage T4.¹⁶⁷

Clusters of **aromatic amino acids**, such as the one in the type I cohesin domain (Figure 6-21), are often found in the hydrophobic core of a crystallographic molecular model. The tendency for aromatic amino acids, cystines, and arginines to cluster has been explained in terms of favorable overlaps of their π mole-

cular orbitals,¹⁶⁸ but just as often aromatic and aliphatic amino acids intermingle. One interesting aspect of the cluster of aromatic amino acids in type I cohesin domain (Figure 6–21) is that it illustrates the tendency of two phenyl rings, in isolation from water, to form a complex in which the planes of the two rings are at around 90° to each other.¹⁶⁹ This orientation is commonly observed in the crystallographic molecular models of proteins, and theoretical calculations for benzene dimers in the gas phase suggest that it is the energetically favored arrangement.¹⁷⁰

One of the most notable features of the accessibilities of the amino acids in the native structure of a protein is that, in the folded polypeptide, the accessible surface areas of all types are less than they were in the unfolded polypeptide (Table 6–2). The accessible surface areas tabulated are for the entire amino acid in a polypeptide, both side-chain and backbone segments. Usually, the backbone is buried before the side chain, so a significant portion of the mean fraction of surface buried for each type of amino acid is accounted for by this fragment common to all of the amino acids. This backbone portion, however, cannot account for more than 0.6–0.7 nm² of buried surface area because the accessible surface area of glycine in a polypeptide¹⁴⁸ is only 0.75 nm². Therefore even the most accessible side chains, arginine, lysine, and glutamine (with a mean buried surface of 1.2 nm²), have more than 0.5, 0.55, and 0.45 nm² of the surface area of their side chains buried, respectively. The regions of each of these hydrophilic side chains that are buried are usually their hydrogen–carbon bonds. For example, in the crystallographic molecular model of the complex between the *Ha-ras* oncogene product p21 and its substrate, the amino group of Lysine 117 is engaged in several hydrogen bonds, but its butyl group is fully buried just as would be the side chain of a leucine.¹⁷¹

There should be a normal hydrophobic effect associated with the removal of the butyl group of lysine, the propyl group of arginine, and the ethyl groups of glutamine and glutamate from exposure to water even though these side chains in their entirety are among the most hydrophilic on all of the scales of hydrophathy. To assess the hydrophobic effect that was contributed by burying these portions of each of these amino acids, as well as all of the others, the **contribution of each atom** in an amino acid to its overall hydrophathy should be extracted. From these atomic parameters, the free energy of transfer for only those portions of each amino acid that are actually buried could be calculated. It was noted¹⁷² that free energies of transfer for individual solutes between water and the gas could be dissected into the individual contributions of each covalent bond that they contained. A similar dissection has since been performed upon the set of free energies of transfer for the *N*-acetyl- α -amides of the amino acids between water and 1-octanol.¹⁷³ In this latter dissection, a series of parameters based on individ-

ual atoms, rather than covalent bonds, has been presented that can reproduce the original scale of hydrophathy with acceptable precision. Presumably every scale of hydrophathy presently in use can be so dissected.

Free energies of transfer for model compounds of **tryptophan** or **tyrosine** between water and a solvent such as 1-octanol (Figure 5–24)¹⁷⁴ or ethanol,¹⁷⁵ as opposed to free energies of transfer between water and the gas phase (Table 5–9), have always suggested that tryptophan and tyrosine should be more hydrophobic than they seem to be when they are found in a protein (Table 6–2). The explanation for this is probably that solvents such as ethanol and 1-octanol are able to form hydrogen bonds with the one donor on the indole and the donor and acceptor on the phenol, making them more soluble in these solvents than they would be in a hydrocarbon and making them seem more hydrophobic than they are. This would be consistent with the observation that it is the hydroxyl on tyrosine that usually remains in contact with the water in crystallographic molecular models.¹⁷ Because of the requirement that the nitrogen–hydrogen bond in the indole of tryptophan also be hydrogen-bonded, the portion of the side chain containing this bond is also usually in contact with the water. But indole is large and the rest of it is usually buried. As a result, it is only in the last column of Table 6–2 that the hydrophobicity of tryptophan is manifest.

The neutral, but hydrophilic, amino acids **glutamine** and **asparagine** are straightforward examples of the effect of the hydrogen bonds formed with water in the unfolded polypeptide on the location of that amino acid in the folded polypeptide. Complete withdrawal of the two hydrogen-bond donors on glutamine or asparagine from water during folding would result in a net disappearance of two hydrogen bonds from the solution. The difficulty of simultaneously regaining both of these lost hydrogen bonds in the interior of the protein seems to be great enough that the primary amides in the side chains of most of the glutamines and asparagines in a protein end up in the folded polypeptide fully exposed to the aqueous phase.¹²⁶

It might be supposed that **buried hydrogen bonds** between side chains on different segments of secondary structure would be important factors because these would be capable of organizing significant regions of the protein.¹⁴⁸ Of the rarely buried hydrogen bonds between side chains,⁴⁰ however, only about 20% are the type that connect different segments of secondary structure; the other 80% connect donors and acceptors within the same α helix, β sheet, or β turn.¹⁴⁸ The steric requirements of packing the secondary structures efficiently and avoiding empty space are far more important than hydrogen bonds in positioning the segments of secondary structure and organizing the overall structure of the protein, and the few buried hydrogen bonds that do occur between segments of secondary structure are probably adventitious. It is the interdigitation of the side

chains protruding from β sheets and α helices that orient these secondary structures.

Packing of the Side Chains

Although there often are flexible loops, sometimes quite a long one,¹⁷⁶ bulging out from a globular protein and occasionally there is a tunnel passing through its interior that is required for its function,^{177,178} most of its mass is formed by compactly layering secondary structures one against the other. In the crystallographic molecular model of a protein, the space between these layered α helices, β sheets, and random meander is filled completely by the side chains of the amino acids that protrude from the polypeptide at each α carbon. The arrangement of these side chains is organized in such a way that the amino acids in the interior of the protein are **packed with admirable efficiency**. This tight packing is illustrated by the fact that space-filling crystallographic molecular models of proteins rarely contain empty spaces large enough to accommodate even a molecule of water.

A **space-filling crystallographic molecular model** is constructed by placing spheres of the appropriate van der Waals radii (Table 6–3) at the positions of the centers of atoms in the model. The **van der Waals radius** of an atom is the radius that produces a sphere the surface of which is coincident with the boundary of that atom to penetration by the boundary to penetration of another atom.¹⁷⁹ These van der Waals radii are significantly greater than the covalent radii of the various atoms.

It is difficult to obtain reliable values for van der Waals radii, so those tabulated are averages of values estimated in several different ways. Because the van der Waals radii define the **boundaries of impenetrability**, when matter is packed together in a condensed phase, the centers of no two atoms can approach closer than the

sum of their van der Waals radii, and examining the details of the packing of side chains in the interior of a crystallographic molecular model of a protein is one way to estimate values for van der Waals radii.¹⁸³ The spheres defined by the van der Waals radii define the **van der Waals surface** of a molecule.*

which is distinct from either the **molecular surface** or the **accessible surface**.

When atoms in the interiors of a set of crystallographic molecular models, from data sets each of which is to Bragg spacings of 0.17 nm or less, are assigned their respective van der Waals radii and hydrogens added at their van der Waals radii, one discovers these atoms almost always approach each other as closely as possible and do so in such a way that there is almost **no empty space** among them.¹³¹ The packing is often so tight that methyl groups are confined in equilaterally triangular spaces clamping their hydrogens. Consequently, it is not surprising that the alkyl groups in the center of a molecule of protein are confined to specific conformations rather than being free to rotate as they would be in a liquid. One result of this tight packing is that at some locations there is not enough space for a side chain. Such locations are occupied by glycines. Even in these instances, the fit is often so tight that it is steric interactions with the hydrogens of the glycine that position the α carbon and determine the values for dihedral angles ψ

Table 6–3: van der Waals Radii

atom	van der Waals ^a radius (nm)
H _{aliphatic}	0.115
H _{aromatic}	0.100
C	0.175
N	0.160
O	0.150
S	0.180
P	0.180

^aValues are averaged from various tabulations^{179–183} and expressed to nearest 5 pm, which may overstate their accuracy.¹⁷⁹

and ϕ .¹³¹ Even though it might seem to be the case from an examination of Figure 6-4B, not all of the glycines in a protein, however, are handling unavoidable steric problems because many can be replaced with larger amino acids by site-directed mutation without affecting the function of the protein.¹⁸⁵

Another consequence of the economy in arranging the side chains of the amino acids is that the **volume of a molecule** of protein is quite small relative to its molecular mass. The volume occupied by the atoms in a molecule of protein can be calculated by summing all of its individual atomic volumes defined by the van der Waals surface, and the actual volume of the molecule can be calculated from its partial specific volume and its molecular weight. From this calculation it is learned that 75% of the volume of a molecule of protein is occupied by atoms.^{180,184,186} By comparison, in most organic liquids only about 45% of the volume is occupied by atoms and in water only 36%, but in a solid of hexagonally packed spheres 75% of the volume would be filled by atoms.¹⁸⁶ In anhydrous crystals of small organic molecules, 70–80% of the volume is filled by atoms.¹⁸⁰

The high density of the packing in the interior of a molecule of protein is also reflected in its **compressibility**. The compressibility of the interior of a molecule of protein has been estimated from two different interpretations of the available experimental measurements^{184,187} to be about 20 Gbar⁻¹. This value is intermediate between those for liquids (CCl₄, 100 Gbar⁻¹; C₁₀H₂₂, 105 Gbar⁻¹; H₂O 46 Gbar⁻¹) and solids (ice Ih, 12 Gbar⁻¹; quartz, 2.7 Gbar⁻¹; NaCl, 4 Gbar⁻¹).

At first glance, all of these results seem incompatible with the observation that the partial specific volume of a protein (usually 0.72–0.75 mL g⁻¹) can be calculated* quite accurately from the sum of the molar volumes of its constituents^{188,189} because each protein has a unique structure. The accuracy of this calculation suggests that each structure, although it is unique, incorporates the requirement that its volume be as small as possible. The **minimization of molecular volume** is an important noncovalent force in the folding of a molecule of protein, and it dictates many of the features of the structure. This

* This calculation does not treat the constituents as independent solutes in free solution. In fact, if each side chain were an independent solute, each of their partial molar volumes would include a covolume,¹⁹⁰ which is a volume that arises simply because a particular constellation of atoms is an independent molecule dissolved in a given solvent. These covolumes are substantial. For water¹⁸⁹ the covolume of a solute is 14 cm³ mol⁻¹, and for organic solvents¹⁹⁰ it is 25 cm³ mol⁻¹. Therefore, the sum of the partial molar volumes of the components of a protein, were they each separate molecules in solution, would be significantly greater than its actual partial molar volume. To the extent that its covolume arises from the fact that a solute is in free solution in a given solvent, the fact that the partial molar volume of a protein is the sum of the atomic volumes of its substituents with no added covolume states that those substituents are not in free solution. This of course is true; they are economically packed into a solid.

noncovalent force minimizing the empty space within a molecule of protein can be considered to be a consequence of the hydrophobic effect, if the hydrophobic effect is defined as the tendency of water to minimize the volume of the cavity occupied by any solute.

Although there are a few proteins in which the folded polypeptide forms a knot,^{191,192} the packing of every other protein appears to result from the **consecutive layering** of one element of secondary structure upon another, much as one would fold a cloth or a hinged rod. α Helices pack upon α helices, β sheets pack upon β sheets, and α helices pack upon β sheets. In all of these situations the secondary structures take up orientations with respect to each other that permit the side chains that protrude from each of them to interdigitate (Figure 6-22).^{193,194} This **interdigitation** is the reason that there is very little vacant space in the interior of a molecule of a protein. If it can be assumed that the configuration of minimum volume is the preferred configuration in the condensed phase, then these interdigitations promote the achievement of such a minimum volume. In order to form as many interdigitations as possible, the individual segments of secondary structure are required to assume preferred orientations with respect to each other. Viewed in this perspective, packing is a structural force just as the formation of hydrogen bonds between buried donors and acceptors on the side chains of the amino acids would be a structural force, but packing is more important.

The **orientation** between two α helices, two sheets of β structure, or an α helix and a sheet of β structure can be assigned an **angle Ω** .^{195,196} The angle Ω between two α helices is the angle between their two axes (Figure 6-23).¹⁹⁷ The sign on Ω is given by the right-hand rule. Consequently, the angle Ω in Figure 6-23 has a negative sign. Because the pattern in which the amino acids protrude from an α helix has a 2-fold rotational axis of pseudosymmetry at each position in the α helix (focus on position i at the right of Figure 6-23), the axis of the α helix has no direction associated with it and a value of $\Omega = -50^\circ$ is equivalent to a value of $\Omega = +130^\circ$. The angle Ω between two sheets of β structure is the angle between the direction of the parallel or antiparallel strands in one sheet and the direction of the strands in the other sheet (Figure 6-24).¹⁹⁵ The right-hand rule determines the sign of angle Ω , and the angle Ω in Figure 6-24B is, therefore, negative. No distinction is made between parallel and antiparallel relationships of the strands or the amino- and carboxy-terminal ends of a given strand of β structure because all combinations of these distinct stereochemistries produce almost the same pattern in which the side chains are distributed across the face of the sheet (Figure 4-16B,C). The angle Ω between an α helix and a sheet of β structure is the angle between the axis of the α helix and the direction of the β strands (Figure 6-25D).¹⁹⁵

The most frequently observed angle Ω between two

α helices¹⁹⁷ is around -50° , the angle used to construct Figure 6-23. One-third of all adjacent α helices in molecular models of globular proteins are inclined with respect to each other by an angle Ω between -60° and -40° . There is a steric explanation for this preference. When an α helix is observed from one side (Figure 6-26),¹⁹⁷ it can be seen that the side chains are arranged in sets of parallel ridges and grooves. For example, side chains 8 and 4; 19, 15, and 11; and 22 and 18 in Figure 6-26 form a set of ridges and grooves, but so do side chains 4 and 1, 11 and 8, 18 and 15, and 22 and 19. If one α helix is opposed to another, the first set of these ridges will fit into the second set of these grooves, and conversely when the angle between the two helices is -50° (Figure 6-23). An example of the interdigitation that occurs in such situations is found between two adjacent α helices in the molecular model of bovine carboxypeptidase A (Figure 6-27).¹⁹⁷

There are a number of other values for the angle Ω between two α helices that promote less favorable interdigitations of the side chains, and examples of all of them have been observed.¹⁹⁷ Because several possibilities exist and because α helices can tighten or loosen to **accommodate different angles** close to the ideal values, the distribution of angle Ω between -90° and $+90^\circ$ is fairly uniform¹⁹⁷ with the exception of the striking and sharp peak at -50° . For example, in the crystallographic molecular model of cytidine deaminase, two α helices in the interior cross at an angle Ω of 90° , but the side chains protruding from them at the interface do not pack together well.¹⁹⁸ In the distribution of angles Ω , however, there is another preferred angle represented by a broad maximum in the distribution at $+20^\circ$.¹⁹⁹ This angle Ω defines the orientation of two α helices in a coiled coil.

Suppose that the amino acids emerged from a right-handed α helix at successive angles of precisely $102\frac{1}{2}^\circ$ instead of about 99° . Every seven amino acids ($7 \times 102\frac{1}{2} = 720$) in such an α helix, the angular dispositions of the side chains would repeat precisely. Two such tightened α helices could be placed next to each other, with their axes parallel, in such a way that their side chains would interdigitate regularly along the interface (Figure 6-28).^{50,200} Every seventh side chain in one helix would sit to one side of every seventh side chain of the other, and every side chain four amino acids to the carboxy-terminal side of every seventh side chain in one polypeptide would sit to the other side of every side chain four positions to the carboxy-terminal side of every seventh side chain in the other. As a result of these interdigitations, the two α helices could comfortably fit together side by side for an indefinite length because the topography of the interface would repeat precisely every seven amino acids.

α Helices, however, do not have angles between successive side chains of $102\frac{1}{2}^\circ$ but less than that. Crick²⁰¹ pointed out that such an interface, permitting the advantageous interdigitation and repeat every seven

Figure 6-22: Interdigitation of the side chains in the core of the crystallographic molecular model (Bragg spacing ≥ 0.14 nm) of human HLA class I histocompatibility antigen A-2.^{193,194} The three segments of polypeptide to the left of the figure are from three strands of an antiparallel β sheet and together form one of its pleats. The segment to the right is a β turn of type I the side chains of which interdigitate with the side chains on the two edges of the pleat. The donors for hydrogen bonds on the side chain of Glutamine 96 find acceptors on the acyl oxygen of Tryptophan 60' and the aromatic π system of Phenylalanine 56', and the donor on the side chain of Threonine 10 finds an acceptor on a buried molecule of water. Although not shown, the donor on the side chain of Tryptophan 60' finds an acceptor on the side chain of Aspartate 122. The pleated β sheet is from the α subunit of the protein, numbered (unprimed) according to its amino acid sequence, and the β turn is from the β subunit of the protein, numbered (primed) according to its sequence. This drawing was produced with MolScript.⁵⁷³

side chains, nevertheless could be retained if the two α helices, instead of being parallel to each other, twisted around each other in a left-handed coiled coil such that the twist of the coiled coil exactly compensated for the difference between the actual angle between successive amino acids in the α helix and $102\frac{1}{2}^\circ$. If the actual angle between successive amino acids in a right-handed α helix is 99° ,^{8,22} the two α helices would have to twist around each other in a left-handed sense at $-3\frac{1}{2}^\circ$ for

Figure 6-23: Use of superimposed helical nets¹⁹⁶ to describe the contacts at an interface between two α helices.¹⁹⁷ (Top) The angle between two adjacent α helices, i and j , is defined as the angle Ω between the two axes; its sign is determined by the right-hand rule. (Right) α Helix i in a vertical orientation is numbered out from its center. The central amino acid is given the designation i ; those below are designated by negative integers, and those above, by positive integers. The relative orientations in which amino acids $i-7$, $i-4$, $i-3$, i , $i+3$, $i+4$, and $i+7$ are distributed can be projected onto a plane tangential to the position of amino acid i . These seven projected points define a unique lattice, or helical net. For α helix i the lattice is face-up, in the orientation of the original α helix. (Left) α Helix j also defines the same lattice as that defined by α helix i , but, because α helix j is to be opposed to α helix i , face to face, the helical net for α helix j is flipped over, face-down. (Bottom) The two helical nets, the one for α helix i face-up and the one for α helix j face-down, are then opposed and rotated with respect to each other until maximum interdigitation of the lattice points is achieved. The angles at which maximum interdigitation occurs in the helical nets will be the angles at which maximum interdigitation occurs between the amino acids of the two α helices. every position in one of the sequences. Although the actual twist of a coiled coil should reflect a tradeoff between energy required to tighten the α helix and energy required to bend the α helix into the supercoil, in the coiled coil of tropomyosin the twist is -3.4° to -3.9° for each position in the sequence,^{50,202,203} and in the one from general control protein GCN4 (Figure 6-29)²⁰⁴⁻²⁰⁶ it is -3.6° to -3.9° , values that seem almost too close to the expected one.

The original **coiled coil of α helices** predicted from these geometric arguments contained two parallel α helices. The coiled coils formed by tropomyosin and general control protein GCN4 are coiled coils of two parallel α helices of identical sequence. There are, however, examples of coiled coils of two parallel α helices of nonidentical sequence,²⁰⁷ two antiparallel α helices of nonidentical

sequence,²⁰⁸ three parallel α helices of identical sequence,²⁰⁹ three parallel α helices of nonidentical sequence,^{200,210} three antiparallel α helices of identical sequence,²¹¹ three antiparallel α helices of nonidentical sequence,²¹² four parallel α helices of identical sequence,^{205,213,214} four antiparallel α helices of nonidentical sequence,^{215,216} five parallel α helices of identical sequence,²¹⁷ five antiparallel α helices of nonidentical sequence,²¹⁸ and 12 antiparallel α helices of nonidentical sequence producing a cylinder with a hollow center.²¹⁹ There is even an example of a coiled coil of four antiparallel α helices that coils around another copy of itself to form a coiled coil of coiled coils (Figure 6-30).²²⁰

That both **parallel and antiparallel** arrangements are observed must follow from the two facts that an α helix has a **pseudo-2-fold axis of symmetry** with

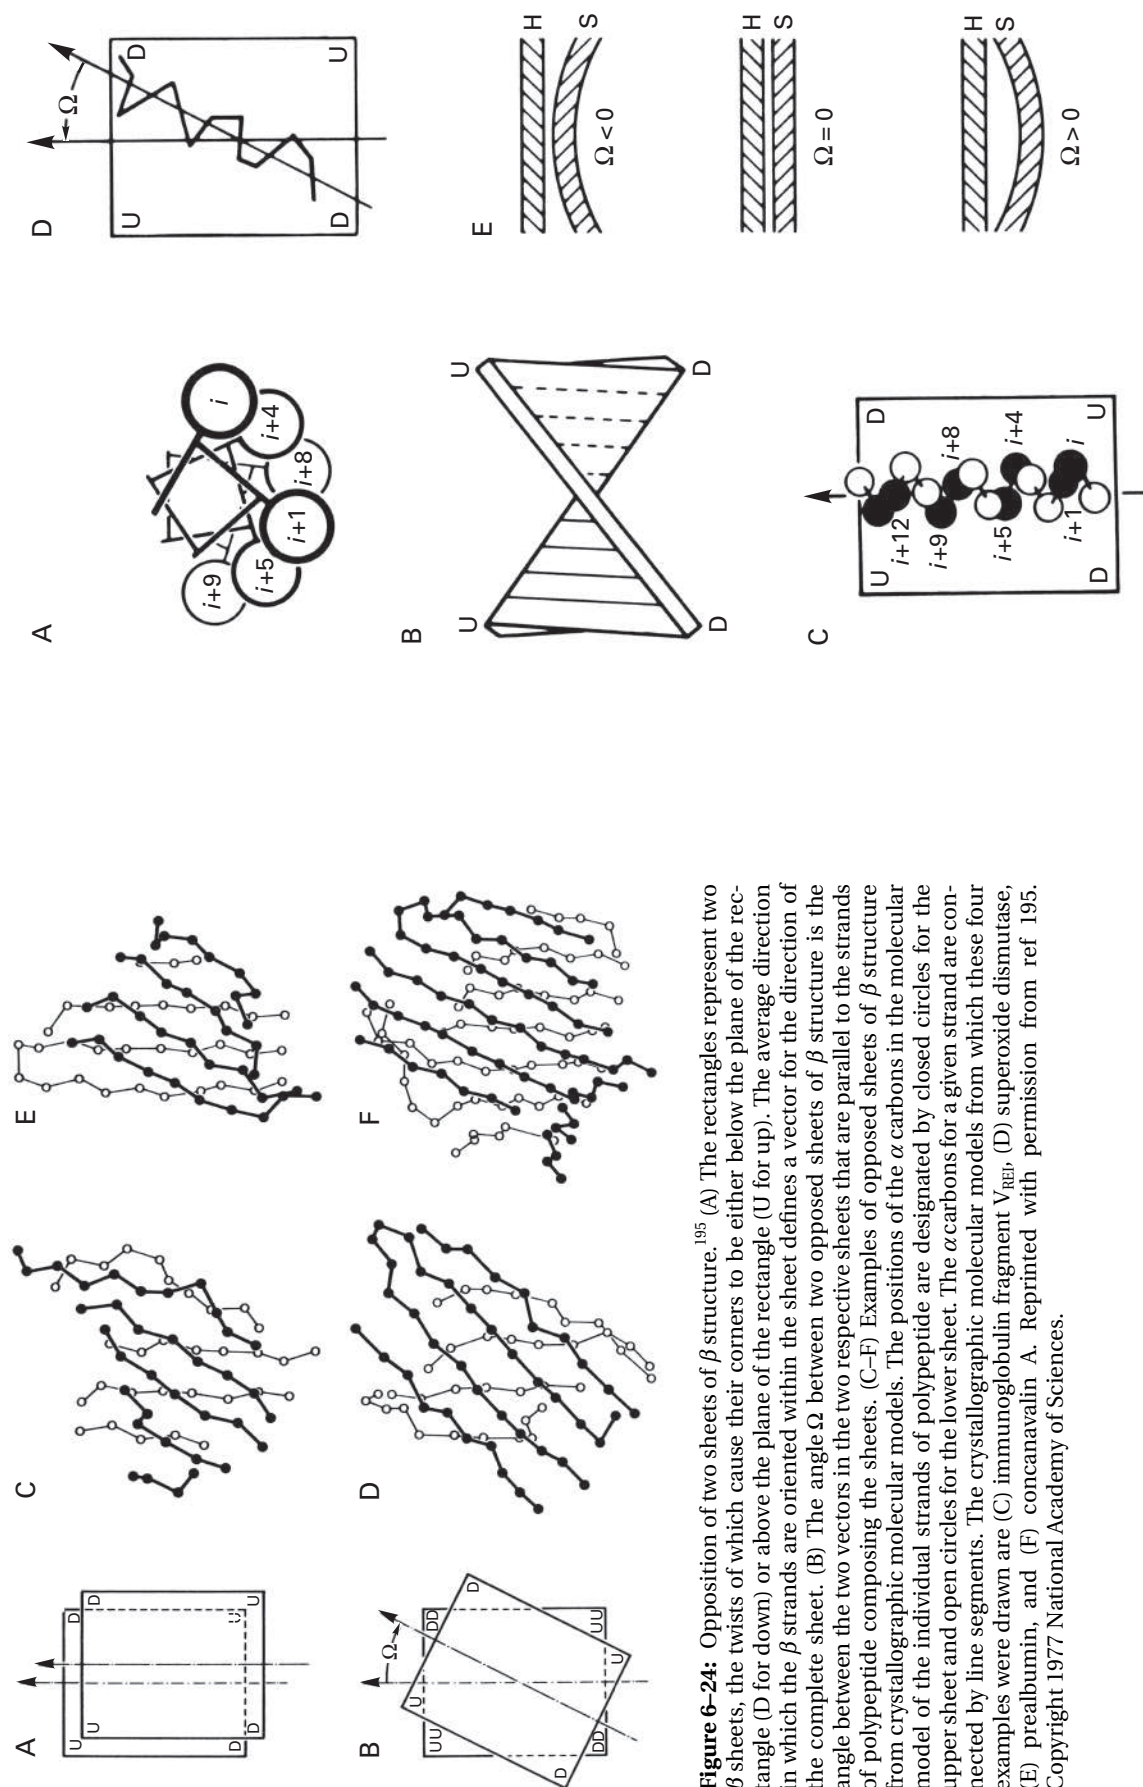

Figure 6-24: Opposition of two sheets of β structure.¹⁹⁵ (A) The rectangles represent two β sheets, the twists of which cause their corners to be either below the plane of the rectangle (D for down) or above the plane of the rectangle (U for up). The average direction in which the β strands are oriented within the sheet defines a vector for the direction of the complete sheet. (B) The angle Ω between two opposed sheets of β structure is the angle between the two vectors in the two respective sheets that are parallel to the strands of polypeptide composing the sheets. (C–F) Examples of opposed sheets of β structure from crystallographic molecular models. The positions of the α carbons in the molecular model of the individual strands of polypeptide are designated by closed circles for the upper sheet and open circles for the lower sheet. The α carbons for a given strand are connected by line segments. (B) A topographic map of the front face of an α helix of polyalanine. The contours are at intervals of 0.05 nm and the topmost contour, that surrounding the numbers 4, 15, and 22, is at 0.475 nm from the axis of the α helix. The numbers are on the methyl carbons of the appropriate alanine. Reprinted with permission from ref 197. Copyright 1981 Academic Press.

respect to the emergence of its side chains and that the packing of these side chains governs the existence of a coiled coil. The twist in a coiled coil of three α helices is -3.0° to -4.0° for each position in the sequence of one if its α helices; that in one of four α helices, -1.9° to -3.0° ; and that in one of five α helices, -2.6° ,^{209,210,213,214,217} but the situation seems to be much less constrained for those with four and five α helices, for which there are examples of coiled coils with right-handed supercoiling.²²¹

Crick calculated the **diffraction pattern** of X-radiation expected from a macroscopic fiber constructed of aligned coiled coils of α helices and was able to explain why the meridional reflection in the pattern that would normally arise from the pitch of 0.54 nm for an untwisted α helix should shorten to a pitch of 0.51 nm when the α helix becomes twisted into a coiled coil. A prominent

Figure 6-27: Packing of two opposed α helices in the crystallographic molecular model of bovine carboxypeptidase A.¹⁹⁷ An α helix in the molecular model comprising amino acids 72–90 is tightly opposed to an α helix comprising amino acids 285–307. The molecular model was converted into a space-filling representation and only the amino acid side chains along these two α helices were displayed. A set of three parallel planes was cut through the interface between the two helices and superposed to create a topographic map through the interface. The planes were approximately parallel to the two helical axes and at intervals of 0.1 nm. The contours of the side chains in the lower α helix are solid; those in the upper are broken. Each amino acid in the map is designated by its number in the amino acid sequence, and lines designating the axes of the two α helices are included. The angle Ω between these two helices¹⁹⁷ is -56° . Reprinted with permission from ref 197. Copyright 1981 Academic Press.

meridional reflection, representing a repeat of 0.51 nm, had been observed previously²²² in the diffraction patterns of fibers of keratin, myosin, and fibrinogen, and it is now known that such a reflection is indicative of the coiled coils of α helices in these proteins. The infrared spectra of coiled coils of α helices are also characteristic.²²³

The sequence of the polypeptides in any coiled coil of α helices can be divided into successive units, or **heptads**, each seven amino acids in length. The first and fourth amino acid in each heptad (positions *a* and *d* in Figure 6-28) are the most deeply buried amino acids in the interface between the two or more α helices in the coiled coil (Figure 6-29). These most deeply buried locations are isolated from the water surrounding the coiled coil, and the side chains sequestered there are usually

Figure 6-28: Interaction between α helices in a coiled coil.^{50,200}

(Top) Alignment of two tightened α helices with 3.5 amino acids for each turn rather than 3.6. Amino acids from amino-terminal to carboxy-terminal are designated as *a, b, c, d, e, f*, and *g*; the view is end-on looking from amino-terminal to carboxy-terminal amino acid. Every seven amino acids the orientations would repeat, and this would place the amino acid after amino acid *g* precisely below amino acid *a* and so forth. (Middle) The two α helices in the top panel are cut along two respective lines normal to the plane of the page and passing through amino acids *f* and *f'* and then flattened, one against the other. The two resulting planes are then turned together -90° about a vertical axis so that the gray positions end up above the white. This view illustrates the interdigitations of amino acids *a* and *d*. (Bottom) Three tightened α helices running parallel to each other. In this arrangement also, amino acids *a* and *d* can interdigitate.

Figure 6-29: Drawing of the crystallographic molecular model (Bragg spacing ≥ 0.18 nm) of a coiled coil of α helices.²⁰⁴ A peptide 31 amino acids long with the amino acid sequence from Arginine 249 to Glycine 279 of general control protein GCN4 from *S. cerevisiae* was synthesized. In solution two copies of this peptide spontaneously form a coiled coil of α helices, which is the native structure of this portion of the full-length protein. The coiled coil was crystallized, and a crystallographic molecular model was built from a map of electron density calculated from a data set gathered from these crystals. The numbering in the figure is that of the amino acid sequence of the full-length transcription factor, only a segment of which is represented by the synthetic peptides. Only the side chains of the amino acids in the *a, d, e, g, a', d', e', g'* positions of the coiled coil (Figure 6-28) are included in the figure to emphasize the interface between the two α helices.⁵⁷³ This drawing was produced with MolScript.

hydrophobic amino acids such as leucine, valine, isoleucine, alanine, phenylalanine, tyrosine, and methionine.⁵⁰ The hydrophobic amino acid can also be a cystine as in the antiparallel coiled coil of α helices in carboxypeptidase C from *Saccharomyces cerevisiae* (Figure 6-19).¹³⁸ An α helix that has a heptad repeat of hydrophobic amino acids is an amphipathic α helix (Figure 6-8). There are a few interesting exceptions to the rule that coiled coils are formed from amphipathic α helices, such as the chloride ion chelated by five symmetrically arrayed glutamines in the center of the coiled coil of five parallel α helices in extracellular matrix protein COMP.²¹⁷

Figure 6-30: Coiled coil of two parallel coiled coils of four antiparallel α helices comprising the complete crystallographic molecular model (Bragg spacing ≥ 0.20 nm) of the ligand binding portion of the methyl-accepting chemotaxis protein II from *Salmonella typhimurium*.²²⁰ The complete protein is built from two copies of a folded polypeptide 553 amino acids long. The portion of the protein containing the two identical segments of polypeptide between Glycine 26 and Arginine 188 was expressed as a fragment, purified, and crystallized. The drawing is of the crystallographic molecular model of this fragment of the entire protein. The numbering is for that of the complete protein. Each of the two polypeptides forms a structure built around a coiled coil of four antiparallel α helices. These two coiled coils are in turn coiled around each other in parallel.

Each of the amino acids in the **core of the coiled coil** (amino acids *a* and *d* in Figure 6-28) on one α helix is sandwiched between its partner on the opposite coiled coil (*a'* and *d'*) and the amino acid to the amino-terminal (*g*) or carboxy-terminal (*e*) side, respectively, of its partner (Figure 6-28, middle panel). For example, Leucine 253 in one of the α helices in the coiled coil of general control protein GCN4 (Figure 6-29)²⁰⁴ is sandwiched between Leucine 253 and Glutamate 254 on the other; Valine 257, between Lysine 256 and Valine 257 on the other; Leucine 260, between Leucine 260 and Leucine 261 on the other; Leucine 267, between Leucine 267 and Glutamate 268 on the other; and so forth. The side chains of the amino acids on the flanking positions (*g* and *e*, respectively) are often ones that are hydrophobic distally

and hydrophilic peripherally, such as glutamate, lysine, arginine, and glutamine,²⁰⁸ that can provide hydrogen-carbon bonds to cover the hydrophobic side chains in the core before they enter the water fully.

In the crystallographic molecular model of the coiled coil from transcription factor GNC4, the hydrophobic amino acids of the heptad repeats interdigitate along the interface between the two α helices to form the hydrophobic core of the structure and to produce the supercoil. They and those that flank them pack so closely together and so efficiently that there is almost no vacant space in the core of the structure. The two identical α helices are parallel to each other and packed in precise register so that each central hydrophobic side chain packs against its twin from the other α helix. The asparagines at position 16 pack side by side in the core of the coiled coil, and because the hydrogen bond between them lies upon the axis of symmetry of the coiled coil, the two possible hydrogen bonds between the respective amido protons and acyl oxygens are present in the map of electron density as alternative conformations.

Because a coiled coil has such a regular structure, it is possible to design **synthetic peptides** that assume a coiled coil of α helices spontaneously^{211,224} by incorporating heptad repeats into their sequences. Almost any amphipathic α helix has the potential to form a coiled coil. It is not possible, however, to predict what type of coiled coil they will form²¹¹ because this decision seems to be made on the basis of the details of the packing in the hydrophobic core between the two α helices. For example, the packing in the interior of a coiled coil of three α helices is so tight that the inability of the three equivalent leucines to adopt the proper angles χ_1 in a parallel arrangement causes the three copies of one of these synthetic peptides to form a coiled coil of antiparallel α helices instead.²¹¹ Likewise, when mutations were made to hydrophobic amino acids in the heptad repeat of the portion of general control protein GCN4 that normally forms a symmetric coiled coil of two parallel α helices (Figure 6-29), the mutant peptides unexpectedly formed coiled coils of three and four parallel α helices.²⁰⁵ Interactions among the amino acids facing the water also influence the type of coiled coil formed.²²⁵ All of these results suggest that the different types of coiled coils have similar structural requirements.

Although there are exceptions in which a coiled coil has a right-handed twist,^{221,226} the left-handed twist of most coiled coils causes the angle Ω between any two of the α helices to be $+18^\circ$ to $+24^\circ$ (Figures 6-29 and 6-30).^{209,210,217} Such structures contribute to the broad maximum at 20° in the distribution of angle Ω between two α helices. As the number of α helices bundled together becomes larger and as the constraints of the overall tertiary structure of the protein are exerted, the regular packing of the coiled coil breaks down. Nevertheless, in a bundle of α helices stacked next to each other at angles Ω around $+20^\circ$, such as the one in

protein R2 from ribonucleoside-diphosphate reductase of *E. coli*²²⁷ and the one in δ -endotoxin CryIIIA(a) from *Bacillus thuringiensis* subspecies *tenebrionis*,²²⁸ there are hints of coiled coils.

Although there are examples of β sheets fully exposed on both faces to solvent,^{229–232} almost all β sheets are found packed against other β sheets or sandwiched between layers of α helices, usually in the most buried regions of a molecule of protein. When β sheets pack against each other, there are only two orientations observed with significant frequency. In a sheet of β structure, the side chains of the amino acids along a given strand alternate in protruding above the sheet and below the sheet (Figure 4–16B,C). On a given side of the sheet, the protrusions form an approximately square array aligned with the β strands (Figure 6–31).²³³ There are two ways for two square arrays to interdigitate if they are flat, one with angle $\Omega = 0^\circ$ and the other with angle $\Omega = 90^\circ$.

There are examples of two β sheets packing against each other with an angle Ω of 0° , each strand of the one sheet running almost exactly between two of the strands of the other,²³⁴ as the closed fingers of one hand fit into the grooves of the closed fingers of another, but because β sheets twist (Figure 6–9) and because the array is not exactly square (Figure 6–31), sheets of β structure usually pack at angles Ω of $-30^\circ \pm 15^\circ$ (Figure 6–24).^{195,233,235} Were two twisted β sheets to be **packed in parallel** to each other with angle Ω equal to 0° , their two (indicated by U and D in Figure 6–24A,B) twists would match. The twist, however, causes the side chains protruding from the bottom of the top sheet to lean one way and those protruding from the top of the bottom sheet to lean the other,^{233,235} and when the side chains interdigitate the sheets cannot be parallel to each other but are forced to assume an angle Ω around -30° . Even at an angle Ω of -30° , however, the twists of the two β sheets fit together effectively.⁸¹ The associations between the two parallel β sheets in prealbumin illustrate the stereochemistry at such an interface between two twisted sheets (Figures 6–24E and 6–32).²³⁵ The preference for an angle Ω of -30° , however, is not a strong one because local disruptions in the β strands can cause the angle to shift to positive values.²³⁶ Even β sheets as narrow as two β strands in an antiparallel β hairpin will stack against each other with the strands parallel.²³⁷

An angle Ω equal to 90° , the other value predicted for the stacking of two square arrays, is also a preferred orientation observed for two stacked β sheets.²³⁸ When two sheets of β structure are aligned at 90° to each other, the twists instead of fitting together oppose one another, and one pair of diagonal corners is closer together than the other pair of diagonal corners (Figure 6–33).²³⁸ It is usually at the close corners that the polypeptide connects one sheet to the other.^{238,239} The interdigitations of the amino acids in the three **layered orthogonal β sheets** of penicillopepsin illustrates the packing observed between orthogonal β sheets (Figure 6–34).²³⁸

Figure 6–31: Distribution of side chains on one side of a β sheet.²³³ The representation is that of a four-stranded antiparallel β sheet in the crystallographic molecular model of the light constant domain from γ globulin (λ) New. The four strands of polypeptide of the β sheet in the crystallographic molecular model were placed in the plane of the page, and the α carbons were connected with line segments. The α carbon of each amino acid the side chain of which protruded below the plane of the page was marked with a dark dot. The side chains protruding below the page from these positions were displayed in space-filling format, and their projections on the plane of the page were traced. Each projection is labeled with the name of the particular amino acid. The amino acids in one column, valine, isoleucine, alanine, and proline and threonine, were assigned letters determined by the order in which their strands occur in the amino acid sequence. Proline d and Threonine d, which are adjacent in the amino acid sequence, were treated as the same amino acid to retain the pattern. The other amino acids were numbered in the direction in which the particular strand ran across the page. The view is from above and of the amino acids hanging down from the sheet. Lines indicate a lattice on which the α carbons of these amino acids lie. Reprinted with permission from ref 233. Copyright 1981 Academic Press.

Regardless of whether the angle Ω between β sheets is -30° or 90° , the side chains between the two sheets are **well buried**, are usually hydrophobic (Figures 6–32 and 6–34), and fit together tightly with a minimum of empty space. An interesting exception to these rules is found in a family of small proteins that use the interior of an orthogonal sandwich of two β sheets to bind a fatty acid. In such proteins, space is made within the interface into which fits the hydrophobically compatible fatty acid.²⁴⁰

The packing in the center of a **β barrel** (Figure 6–11) can be considered to be a special case of the packing of β sheets. The alternate amino acids along each β strand that enter the core of the β barrel occur in layers roughly perpendicular to the axis of the hyperboloid.⁷⁷ In a β barrel of eight strands, the four members of each of these layers come from alternate strands (Isoleucine 51, Leucine 112, Leucine 161, and Isoleucine 212; Serine 85, Leucine 135, Glycine 182, and Leucine 234; and Glutamate 53, Lysine 114, Glutamate 163, and Glutamate 214 in Figure 6–11). Within each layer of this cylindrical cake, the four side chains pack against each other and each successive layer packs against the layer below it (the

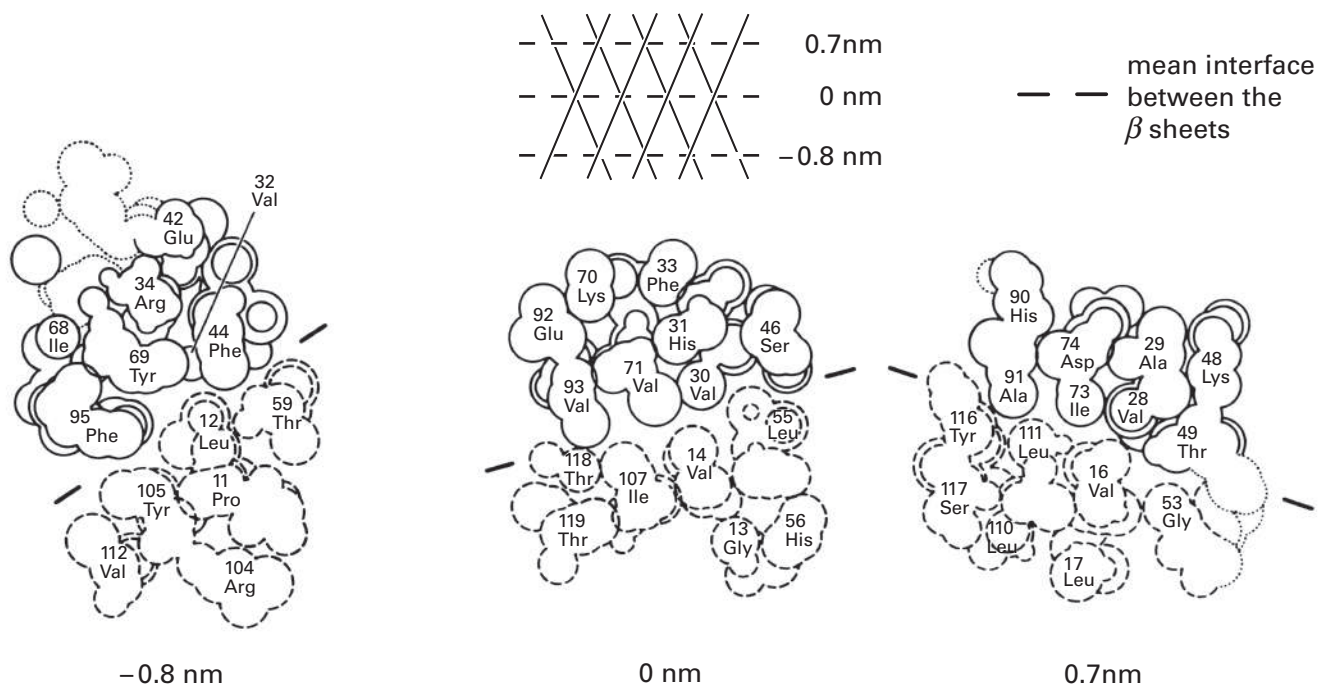

Figure 6–32: Packing of the amino acids at the interface between two opposed β sheets in the crystallographic molecular model of prealbumin.²³⁵ A tracing of the α carbons of the strands in this structure is presented in Figure 6–24E. This is represented diagrammatically in the upper inset, where the locations of the horizontal sections through the structure are designated by their positions in nanometers relative to the central section. The sections are normal to the two β sheets, and the strands run approximately normal to the planes of the sections. The amino acids in the upper sheet (in which the four strands run parallel, antiparallel, parallel, antiparallel) are enclosed in solid lines; those in the lower sheet (in which the four strands run parallel, antiparallel, antiparallel, parallel) are enclosed in broken lines. The straight lines indicate the orientation of the interface, which twists in a right-handed sense as the sections proceed through the structure. Reprinted with permission from ref 235. Copyright 1981 National Academy of Sciences.

layer of 85, 135, 182, and 234 is sandwiched between that of 51, 112, 161, and 212 and that of 53, 114, 163, and 214 in Figure 6–11). In the top layer of the β barrel in Figure 6–11, the hydrophobic portions of the side chains pack against the layer below, and the four hydrophilic atoms, the nitrogen and the three oxygens, are pointed upward out of the end of the barrel.

In β barrels of five or six strands, the radii of the hyperboloids are small enough that the cylinder can

remain circular while the side chains tightly fill the central cavity, but in β barrels of eight strands, the hyperboloid is usually **flattened** into an ellipse to pack the side chains in each layer as tightly together as possible.⁷⁷ In ribonucleoside-diphosphate reductase from *E. coli*, a β sheet of five parallel strands antiparallel to a second β sheet of five parallel strands together form a β barrel of ten strands, but it is flattened so that the two respective sheets are opposed to each other across the minor axis of the ellipse.⁹⁰ This structure is drifting in the direction of a sandwich of two β sheets at an angle Ω equal to 90° . Again, an interesting set of exceptions is that of β barrels in which a cavity is

Figure 6-33: Abstract representation of the orientation of two orthogonal β sheets packed against each other that incorporates the left-handed twist usually associated with such structures.²³⁸ The front view illustrates the orthogonal disposition of the strands of the two respective sheets. The top view illustrates the twist, the fact that the strands can join at the two corners (A and B) that are brought together by the separate twists, and the fact that two of the corners are splayed by the twist. The view of the opened structure demonstrates how the stack can be produced by folding over two coplanar parallel sheets of β structure to produce an arrangement joined at the two corners by two continuous strands. A typical example of such a close corner occurs in murine adipocyte lipid-binding protein.²³⁹ The bottom two sheets of β structure in the three-layered sandwich of penicillopepsin (Figure 6-34) also have this arrangement. They are connected at two diagonal corners and splayed at the other two. Reprinted with permission from ref 238. Copyright 1982 American Chemical Society.

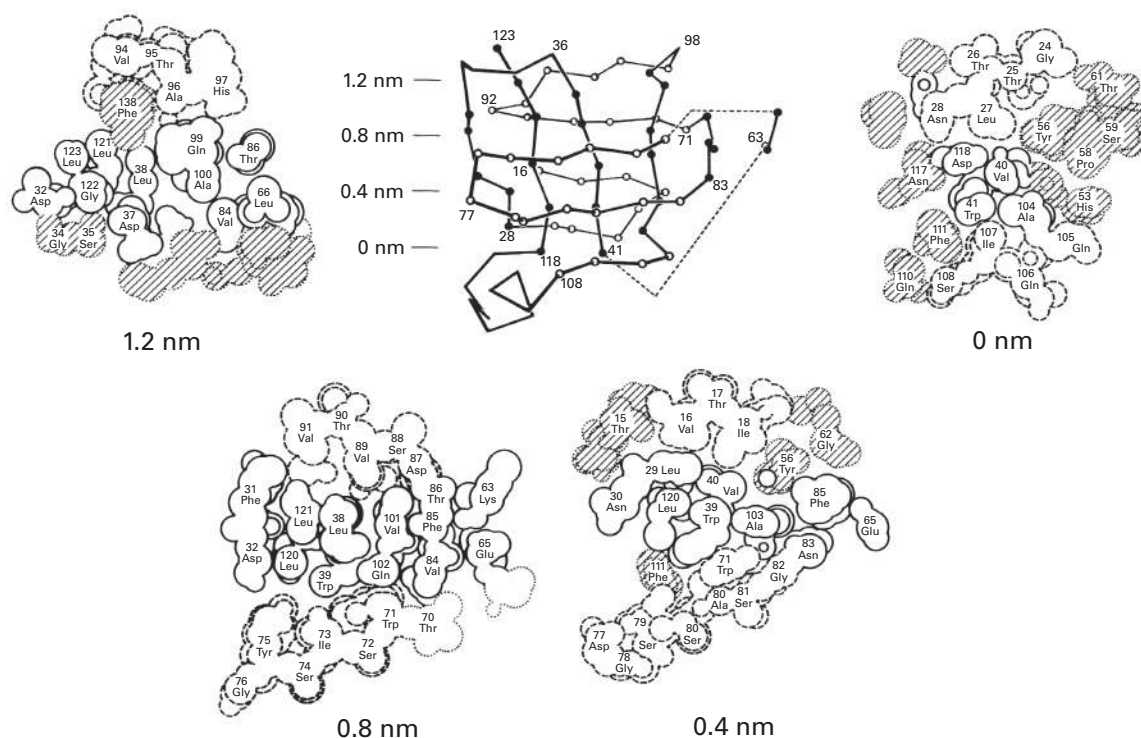

Figure 6-34: Packing of amino acids at the interface between three alternately orthogonal sheets of β structure in the crystallographic molecular model of penicillopepsin.²³⁸ In the center of the figure, the α carbon atoms of the molecular model between amino acids 16 and 123 are connected by line segments to provide a tracing of the polypeptide. The three-layered sandwich is viewed from above and consists of a three-stranded sheet of β structure (parallel, antiparallel, parallel) on top of a four-stranded sheet of β structure (parallel, parallel, antiparallel, antiparallel) on top of a second four-stranded sheet of β structure (parallel, antiparallel, parallel, antiparallel). The indicated sections 0.4 nm apart were cut through the three-layered sandwich in a space-filling representation of the molecular model. The planes of the sections were horizontal and normal to the page as indicated. The packing between the sheets can be viewed in respective cross sections arrayed in counterclockwise order from top to bottom. Amino acids are numbered, and all amino acids in a given pleated sheet are in either solid outline or broken outline. Amino acids in hatched outline are not in the sheets of β structure. In the cross sections, the strands of the sheets at the top and the bottom run parallel to the page while the sheet in the middle runs perpendicular to the page. Reprinted with permission from ref 238. Copyright 1982 American Chemical Society.

required for the function of the protein, such as the cavity in the middle of the β barrel of retinol-binding protein in which the retinol is bound.²⁴¹ In this β barrel, the ligand provides enough extra hydrophobic mass that the barrel can remain circular even though it has eight strands. The β barrel of red fluorescent protein from *Discosoma* is circular even though it is composed of 11 strands because there is an α helix running through its center.²⁴²

An α helix lying upon a sheet of β structure usually has its axis almost parallel to the strands of the sheet because the α helix is straight, the sheet is twisted, and a straight rod can contact a twisted surface only when it is either parallel or perpendicular to the axis of the twist (Figure 6-25).¹⁹⁵ The angle Ω observed²⁴³ between α helices and adjacent sheets of β structure is usually around 0° , and almost all values fall between -20° and $+10^\circ$. The exceptions are usually instances in which the angle Ω is close to 90° .^{244,245} In one of these instances, a long β sheet of four strands wraps around an α helix²⁴⁵ as one's four fingers would wrap around a cylindrical rod 3–4 cm in diameter. This grip is yet another example of the elasticity of β structure.

The interface (Figure 6-35)²⁴³ between three of the α helices and one of the β sheets in lactate dehydrogenase illustrates the fit between an α helix and a twisted β sheet in a parallel orientation. Note that the side chains from the α helices lie upon the gaps between the side chains in the sheet of β structure. Because a sheet of β structure twists appropriately, the α helices lying across its surface parallel to its strands are aligned next to each other with angles Ω of about -40° between adjacent pairs even when they cleave tightly to the surface of the sheet.²⁴³ This value for angle Ω is sufficiently close to the -50° that produces the most frequently observed type of interdigitation between two α helices. Therefore, both the interfaces between the α helices and the sheet of β structure and the interfaces among the α helices themselves can exist simultaneously in almost optimum orientations. It is also possible, however, that the twist of such a sheet of β structure arises from the requirement that the α helices upon it be positioned at the proper angles to maximize the interdigitation of their amino acids. For all of these reasons, a **twisted β sheet sandwiched between two layers of**

Figure 6-35: Schematic formation of the interface between three α helices and a sheet of β structure found in the crystallographic molecular model of L-lactate dehydrogenase.²⁴³ The sheet of β structure is presented in the bottom left of the figure with its strands running vertically in the y direction and the axis of the right-handed twist parallel to the x -axis. Side chains of the amino acids on the upper face of the sheet are identified and numbered by the amino acid sequence of the protein. The three α helices that will form the interface with the sheet of β structure are presented in the upper left of the figure with the face that will participate in the final interface directed upward. The axes of the three helices (αG , αB , and αC) are almost parallel to the vertical y -axis. Side chains that will participate in the interface are identified and numbered. When the three α helices are rotated 180° around the x -axis and placed upon the sheet of β structure as they are in the molecular model, the interface is produced by the interdigitation of the highlighted amino acids from the sheet and the highlighted amino acids from three α helices, respectively. It is these interdigitations that position the three α helices upon the sheet of β structure. Adapted with permission from ref 243. Copyright 1980 Academic Press.

parallel α helices is one of the most common tertiary structures.

This arrangement is also the one assumed by the **coating on a β barrel**. The most common type of β barrel is one in which all of the strands run consecutively and in parallel (Figure 6-11), and usually within the polypeptide connecting the amino-terminal end of one strand to the carboxy-terminal end of the next (for example, the connection between Cysteine 54 and Alanine 83 in Figure 6-11) there will be an α helix running along the outer surface of the β barrel parallel to the β strands of the β barrel. Consequently, the strands occur consecutively around the barrel, and the underlying repeating pattern

is β strand, α helix, β strand, α helix and so forth with extraneous segments of other secondary structure thrown in at random. Even in the hybrid β barrel in ribonucleoside-diphosphate reductase, the five parallel β strands in each of the two antiparallel β sheets forming the barrel occur consecutively and are each connected to the next by a segment of polypeptide containing an α helix running across the outside of the barrel.²⁴⁶ There is a peculiar variant of this α -helically wrapped β barrel in which each of the strands of β structure in the central barrel is replaced by an α helix to form an α -helically wrapped α -helical barrel.²⁴⁷

It is useful to imagine the interior of a molecule of

protein created by all of these arrangements as a three-dimensional **jigsaw puzzle** because this is an image that emphasizes the interdigitations among the side chains of the amino acids driving the various orientations of the secondary structures. The pieces of this puzzle, however, are neither inelastic nor invariant,²⁴⁸ and there can be flaws in its mosaic.

The **elasticity of the packing** of the amino acids in the interior of a protein is most readily demonstrated by performing site-directed mutation. When Alanine 129 in lysozyme from bacteriophage T4 is replaced with leucine, the stability of the protein decreases²⁴⁹ by 6 kJ mol⁻¹, but its structure is affected only in the vicinity of the mutation. There it expands, most notably at Leucine 121, in response to the increase in the size of the side chain at position 129 (Figure 6-36).²⁵⁰ When Valine 30, located between two β sheets in the core of human transthyretin is replaced with methionine, the β sheets move apart by 0.1 nm to accommodate the consequent steric effect.²⁵¹ The usual response to mutations such as these that increase the volume of matter in the hydrophobic core of a protein is that the structure expands in response to the local increases in volume and the stability of the protein decreases,²⁵² occasionally catastrophically.²⁵³ The strain of the increase in size can also be accommodated by a conformational change of an adjacent side chain to a significantly different rotamer.²⁴⁹

There is **never only one invariant arrangement** of side chains that can solve the problem of filling the space between segments of secondary structure in the hydrophobic core of a protein. For example, in the plastocyanin from *Enteromorpha prolifera* the surface of one β sheet uses Isoleucine 19, Isoleucine 96, and Valine 82 to conform to the surface of a neighboring β sheet that is formed from Valine 3, Phenylalanine 29, and Isoleucine 39, while the plastocyanin from *Populus nigra* uses Phenylalanine 19, Valine 96, and Phenylalanine 82 to conform to the same surface composed of Valine 3, Phenylalanine 29, and Isoleucine 39.²⁵⁴ Leucines 84, 91, 99, 118, 121, and 133 and Phenylalanine 153 of lysozyme from bacteriophage T4 can all be replaced simultaneously with methionines, and although the mutant is 21 kJ mol⁻¹ less stable than the wild type, it has the same overall structure with the exception that the hydrophobic cluster formed by these seven side chains of almost equal volume to the cluster that it replaced is now a different puzzle, just as compact as the first.²⁴⁸

Many proteins in their native states have **cavities** of various sizes* in their hydrophobic cores that are flaws in

the mosaic of the puzzle,²⁵⁷ some large enough to bind random hydrophobic ligands.²⁵⁸ When larger amino acids are replaced by smaller ones through a site-directed mutation, an unnatural cavity is formed, and the contraction of the structure surrounding the artificially created cavity^{256,259-261} again illustrates the elasticity of the puzzle. Although this contraction is usually incomplete, leaving a definite cavity where one was not present before, when Isoleucine 29 in lysozyme from bacterio-

Figure 6-36: Elastic expansion within the hydrophobic core of the crystallographic molecular models (Bragg spacing ≥ 0.19 nm) of lysozyme from bacteriophage T4.^{250,571} Alanine 29 in the wild-type protein was replaced with a leucine by site-directed mutation. When the crystallographic molecular model of the portion of the mutant protein surrounding the mutation (black bonds) is superposed on the crystallographic molecular model of the same portion of the wild-type protein (white bonds), the details of the expansion of the molecule in the vicinity of the mutation are readily observed. The greatest displacement is that of Leucine 121, but Leucine 133 also moves outward as well as the entire α helix containing Leucine 129 and Leucine 133. Phenylalanine 114 is forced to assume a less advantageous rotamer (see 6-5 and Figure 6-21). This drawing was produced with MolScript.⁵⁷³

* The calculation of the volume and extent of cavities inside crystallographic molecular models is not straightforward.^{255,256} The volume accessible to a spherical probe is usually calculated, and the radius chosen for the probe has a dramatic effect on what is regarded as a cavity, what is regarded as its volume, and what is regarded as its dimensions because the smaller the probe, the more easily it slips between the atoms.

phage T4 is replaced with alanine, the structure surrounding the site of the mutation collapses to such a degree that no discernible cavity remains.²⁵⁶ When an unnatural cavity is formed by site-directed mutation, the stability of the protein usually decreases.^{252,259} It has been proposed that this instability produced upon the mutation of a larger amino acid to a smaller suggests that naturally occurring cavities in proteins destabilize their structure,¹²⁷ but it is not possible to extrapolate from the effects resulting from artificial changes performed by site-directed mutation to the effects of changes produced by natural selection.

It has been argued that because the ability of a particular polypeptide to form a particular tertiary structure is not drastically affected by extensive replacement of amino acids in its core by site-directed mutation^{248,262} and because the volume in the interior of a molecule of protein can be filled with a number of different arrangements of the normally available hydrophobic side chains,²⁶³ the packing of the amino acids cannot dictate the tertiary structure that results when the polypeptide folds. Such arguments, however, ignore the fact that it is the **overall pattern in which the side chains emerge** from the secondary structures, not the identity of those side chains, that dictates the values of the angles Ω and hence the tertiary structure. The fact that the details of the packing beyond these dictations display such tolerance is not remarkable because it has long been known that evolution by natural selection frequently performs similar replacements. From a consideration of the logic of the interdigitations that are observed in naturally occurring proteins, it can be concluded that it is such interactions among the side chains that produce the relative orientations assumed by the secondary structures and that these orientations are crucial to creating the tertiary structure of a protein.

D A E L S Q M Q T

- (A) Write out this sequence in the same format⁵⁰ as the following diagram of a portion of the amino acid sequence from the coiled coil of α -tropomyosin:

In your diagram place the appropriate amino acids from the sequence of human epidermal keratin along the center line as was done in the diagram of the sequence of α -tropomyosin.

- (B) What is the role of the amino acids placed along the center line?
- (C) Circle the two amino acids in your diagram that do not seem to fit this role.
- (D) How may they be excused?

Problem 6–5: In the coiled coil of α helices shown in Figure 6–29, why do Lysine 263 and Glutamate 268 and Lysine 275 and Glutamate 270 form hydrogen bonds?

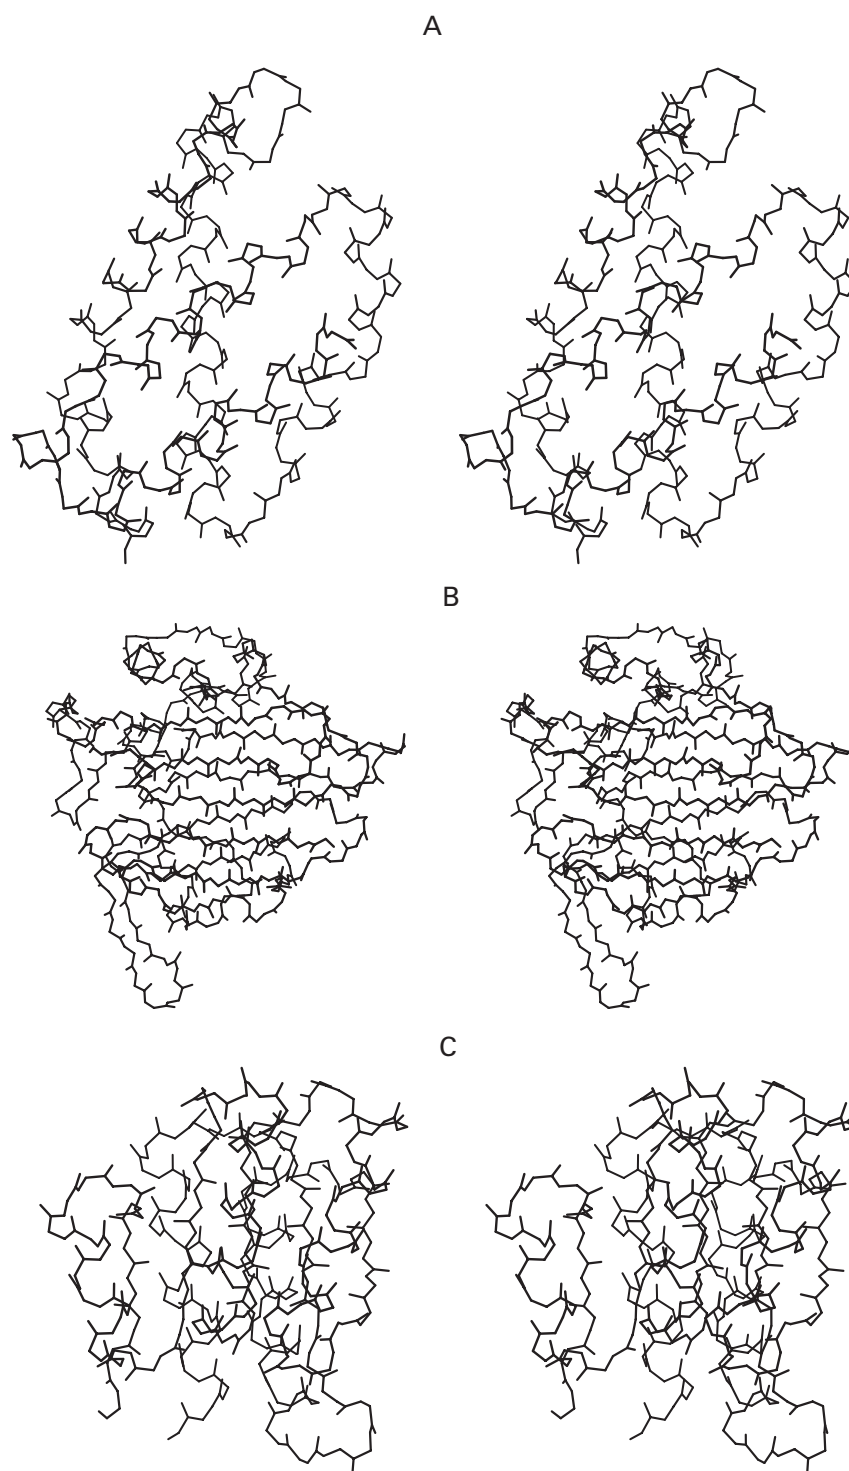

Problem 6–6: The drawings on the next page of three crystallographic molecular models^{265–267} illustrate aspects of the packing between segments of secondary structure. These drawings were produced with MolScript.⁵⁷³ Discuss each molecular model separately and describe the points illustrated by each in turn.

Water

About 40–70% of the volume of a crystal of protein is occupied by water.²⁶⁸ It fills the **large vacant spaces** among the folded polypeptides. The majority of the molecules of water in a crystal of protein are **liquid and disordered** over the time required to collect a data set. Regardless of the degree of refinement or the minimum Bragg spacing, the regions containing this disordered water remain featureless and have a mean electron density similar to that of liquid water.²⁶⁹ These regions of the unit cell are treated as solids of uniform electron density that have the shape of the disordered regions peculiar to the particular crystal. These irregular solids can be used for refining phases by solvent flattening and are always incorporated as such into the molecular model of the unit cell from the first cycle of the refinement because when these water-filled lacunas are added explicitly to the molecular model, the *R*-factor decreases significantly.²⁶⁹

During a refinement, maps of difference electron density are frequently calculated. In addition to the large

Problem 6-6

spaces filled with disordered water, small **discrete peaks of positive electron density** become regularly recurring features of these maps. Because no reasonable rearrangement of the atoms of the molecular model of the protein is able to erase these features and because they are unaccompanied by adjacent peaks of negative electron density indicative of a misalignment of the molecular model, these peaks are assumed to represent either individual molecules of water or individual molecules of solutes from the solution in which the crystals

were formed, which is usually a concentrated solution of ammonium sulfate, poly(ethylene glycol), or a smaller glycol. Sulfate is an ion with a large number of electrons, and any peaks of electron density representing sulfate can usually be recognized with little difficulty.³⁰ Molecules of glycols or other polyols are also easily recognized. The ammonium cation, however, is indistinguishable in its electron density from a molecule of water, but proteins at neutral pH rarely bind many cations so it is usually assumed that the smaller isolated

Figure 6-37: Molecules of water buried in the interior of crystallographic molecular models of proteins. (A) A single peak of positive electron density (designated by the cross) assigned to the location for a molecule of water, unconnected to any other peak of positive density, within the interior of the crystallographic molecular model (Bragg spacing ≥ 0.20 nm) of deoxyribonuclease I.⁸ The map of difference electron density is for $(2F_o - F_c)$ with α_c , so the peak is prominent. The molecular skeleton is the refined molecular model itself. The molecule of water is hydrogen-bonded to the amido nitrogen-hydrogens of Isoleucine 193 and Isoleucine 211 and the acyl oxygens of the same two amino acids. Reprinted with permission from ref 8. Copyright 1986 Academic Press. (B) Three peaks of positive electron density buried deeply within the crystallographic molecular model (Bragg spacing ≥ 0.18 nm) of ribonuclease U₂ from *Usilago sphagnetorum*.²⁷⁰ The peaks were assigned as locations for molecules of water at an early cycle in the refinement, but the electron density presented is an omit map. The three molecules of water were omitted from the final molecular model, which after the omission was submitted to five additional cycles of refinement. The map of difference electron density is for $F_o - F_c$ with F_c and α_c calculated from the model produced by these five cycles. These three locations for molecules of water are completely cut off from the bulk water by the protein and participate in hydrogen bonds only with the backbone and side chains of the surrounding amino acids.

peaks of electron density are locations at which molecules of water are situated.

A **location for a molecule of water** in the crystallographic molecular model of a protein is a positive peak of electron density (Figure 6-37)^{8,270} that persists in its location in maps of difference electron density as the refinement progresses and that has a magnitude 0.2–1.0 times the magnitude expected for a stationary molecule of water. The reason for the generous range is that the magnitude of the peak of electron density arising from a more or less fixed molecule of water decays to less than 20% that of a stationary molecule of water when its vibrational amplitude is only 0.06 nm.²⁷¹ For example, the magnitudes of the peaks of electron density in Figure 6-37B vary significantly even though these locations are heavily chelated. The sometimes vague peaks of electron density present in a difference map at the moment when the decision is made by the crystallographer that they represent molecules of water should be distinguished from the more solid peaks of electron density that appear at the same positions in the map of electron density calculated with F_o and α_c after the contributions of these molecules of water have been included in α_c . These more solid peaks are only there because waters have been added to the model, not because the peaks have become more well defined. There is an additional drawback of this strategy for identifying fixed locations occupied by molecules of water. Such a peak of positive electron density sometimes is the result of the alternative conformation of a side chain, and what was assumed to be water at low resolution turns out to be protein atoms from minor conformations at higher resolution.

A portion of the peaks of electron density assigned

as representing molecules of water in a map are observed in the same locations in maps of electron density for the same protein in different crystals or for the same protein from a different species, and such locations are considered to be **conserved**.²⁷² It is assumed that a conserved location is occupied consistently, in particular, when the protein is in solution rather than in the crystal. Molecules of water in the map that are not conserved are assumed to be peculiar to that protein in that crystal, and such locations may or may not be occupied to a significant extent when the protein is free in solution.

There are different **degrees of conservation**. Peaks representing molecules of water may be found at the same locations in two different molecules of the protein in the same unit cell. For example, 25 positions in thioredoxin from *E. coli*,²⁷³ 46 positions in cytochrome *b*₅₆₂ from *E. coli*,⁹⁹ and 26 positions in β -lactamase from *E. coli*²⁷⁴ are occupied by molecules of water in both of the crystallographic molecular models of the respective protein in the same unit cell. Peaks representing molecules of water may be found at the same locations in the same molecule of protein in different crystals. For example, 30 positions for molecules of water in ribonuclease T₁ are conserved in four different crystals of the protein.²⁷⁵ They may be found at the same locations in crystallographic molecular models of the same protein from different species. For example, a string of five molecules of water is found at the same locations in the interiors of crystallographic molecular models of both cytochrome *f* from *Phormidium laminosum* and cytochrome *f* from *Brassica rapa*.²⁷⁶ They may even be found at the same locations in different but related proteins. For example, two positions for molecules of water are found at the same locations in crystallographic molecular models of ferredoxin-NADP⁺ reductase, phthalate-dioxygenase reductase and a fragment of nitrate reductase (NADH).²⁷⁷

The molecules of ordered water included in the final refined molecular model surround the molecule of protein, fill deep clefts in its surface, and are found in its interior (Figure 6–38).⁹⁸ They represent locations in the actual molecule of protein in the crystal that are consistently occupied by a molecule of water. Each **location is fixed and static** because it is observed in the map of electron density, but the actual molecules of water at those locations on the surface of the molecule of a protein change sites and exchange with molecules of water in the disordered regions of the unit cell as rapidly as **molecules of water change positions** in the hydrogen-bonded lattice of liquid water itself. A lower limit of 1 ns⁻¹ for the rate constant for the exchange of molecules of water at such locations on the surface has been established experimentally,²⁷⁸ and the rate constant for their rotation has been observed²⁷⁹ to be about 50 ns⁻¹. The latter rate constant is indistinguishable from that for a molecule of water in the bulk phase. It is the locations for the molecules of water that remain fixed relative to the molecule

of protein, not the molecules of water themselves. There are also locations for molecules of water on flexible portions of the protein that change their conformations so widely that the locations for those molecules of water cannot appear in the map of electron density.

One of the more unexpected observations has been the discovery of molecules of **water buried in the interior** of proteins with no direct contact with the solvent. These occur as single forlorn molecules (Figures 6–37A and 6–39),^{8,280} or as small clusters of two or more mole-

Figure 6–38: Locations for molecules of water in the crystallographic molecular model (Bragg spacing ≥ 0.18 nm) of penicillopepsin.⁹⁸ At various cycles of the refinement of this crystallographic molecular model, it was decided that certain members of the array of as yet unassigned peaks of positive density in the map of difference electron density were locations for molecules of water, and a molecule of water was placed at each of these positions in the model. The 319 unique locations for molecules of water so positioned are designated in the figure with open circles (oxygen atoms) relative to the polypeptide backbone without the side chains. The drawing of the crystallographic molecular model is presented in the same orientation as that in Figure 4–17. This drawing was produced with MolScript.⁵⁷³

Figure 6-39: Structures surrounding Tryptophan 36 in the crystallographic molecular model (Bragg spacing ≥ 0.16 nm) of human Bence-Jones protein Rhe.²⁸⁰ This protein is a compact globular structure formed from a folded polypeptide 114 amino acids in length. Tryptophan 36 lies in the center of the molecule, well sandwiched between two antiparallel β -pleated sheets (above and below Tryptophan 36 in the figure). Segments from Isoleucine 20 to Cysteine 22, Valine 34 to Tyrosine 37, Leucine 48 to Aspartate 53, Serine 64 to Lysine 67, Alanine 72 to Leucine 74, and Tyrosine 87 to Cysteine 89 are included in the figure. Together their side chains and backbone completely surround Tryptophan 36 with mostly hydrogen-carbon bonds, making this an example of a well-buried side chain. The cysteine is also hydrophobic. A position for a molecule of water, represented by an unattached oxygen, is buried with the tryptophan and forms a hydrogen bond to the nitrogen-hydrogen of the indole. Its two donors in turn form hydrogen bonds with the acyl oxygens of the backbone at positions 52 and 62. This drawing was produced with MolScript.⁵⁷³

cules (Figure 6-37B)²⁷⁰ surrounded by donors and acceptors of hydrogen bonds from the protein itself. For example, in the crystallographic molecular model of equine hepatic alcohol dehydrogenase ($n_{aa} = 374$), 12 molecules of water making no contact with the solvent have been located in the interior of the protein,²⁸¹ three as a triplet, two as a doublet, and seven as singlets; in the model of α -lytic endopeptidase ($n_{aa} = 198$), nine molecules of water making no contact with the solvent have been located, three as a triplet, four as two doublets, and two

as singlets;⁹⁷ in the model of fatty-acid-binding protein from *Manduca sexta* ($n_{aa} = 131$), nine molecules of water making no contact with solvent have been located, four as a quartet, two as a doublet, and three as singlets;²⁸² and a string of five molecules of water making no contact with solvent have been located in the model of cytochrome *f* from *Phormidium laminosum*.²⁷⁶ A pair of water molecules is located in the center of the β barrel in the middle of the crystallographic molecular model of chitinase B from *Serratia marcescens*, deeply buried in the core of the protein.²⁸³

Even such locations occupied by molecules of water buried within the structure of the protein exchange rapidly with water in the bulk phase, presumably as the result of breathing movements in the folded polypeptide. For example, a molecule of water at one of the buried locations in bovine pancreatic trypsin inhibitor exchanges with water in the bulk phase at a rate constant²⁸⁴ of 6 ms^{-1} .

Molecules of water are also buried in **cracks and fissures** connected to the solvent. For example, in penicillopepsin a finger of five water molecules extends from the surface into the interior (Figure 6-40A).⁹⁸ In the crystallographic molecular model of unoccupied chloramphenicol *O*-acetyltransferase, there is a channel 2.5 nm in length filled with a continuous chain of water molecules extending from one side of the molecule of protein to the other.²⁸⁵ A more common situation, however, is for a fairly broad fissure to be filled with an extended cluster of water (Figure 6-40B).^{286,287}

Some proteins have **sizeable cavities** in their interiors. Although there is electron density in the cavity in the crystallographic molecular model of human interleukin 1 β , it is featureless.²⁸⁸ Nuclear Overhauser effects in nuclear magnetic resonance spectra on the absorptions of protons in the side chains lining this cavity demonstrate that it contains molecules of water.²⁸⁹ Because the electron density is featureless, the two or three molecules of water in the cavity must be mobile, which would make sense because it is lined with the side chains of valines, leucines, and phenylalanines that provide no donors or acceptors to pin the molecules of water. The 22 molecules of water in the large internal cavity of unoccupied rat fatty-acid-binding protein, however, are all represented by peaks of electron density in the map and together form a large hydrogen-bonded cluster pinned by the donors and acceptors of tyrosines and glutamates lining the cavity.⁷⁴

Often, a particular role can be assigned to a molecule of water observed in a map of electron density. For example, in the crystallographic molecular model of the triacylglycerol lipase from *Geotrichum candidum*, 17 of the molecules of water at fixed positions donate hydrogen bonds to the vacant acyl oxygens at the carboxy-terminal ends of α helices (Figure 6-6), and 14 of the molecules of water at fixed positions accept hydrogen bonds from the vacant nitrogen-hydrogens at the amino-terminal ends of α helices.²⁹⁰ In the crystallo-

Figure 6-40: Molecules of water penetrating the interior of the molecule of protein but remaining in direct connection with the bulk water. (A) A cluster of four peaks of positive electron density (the four arranged vertically one above the other) assigned as the locations for four molecules of water in the interior of the crystallographic molecular model (Bragg spacing ≥ 0.18 nm) of penicillopepsin.⁹⁶ These four locations are well-defined and the molecules of water occupying them are held in an extensive array of hydrogen bonds with donors and acceptors in the interior of the model. The molecule of water at the bottom of the stack, however, forms one hydrogen bond with a molecule of water at a location to the left that is poorly occupied and in full contact with the bulk water. As such, this structure is a finger of water passing into the interior. This drawing was produced with MolScript.⁵⁷³ (B) Locations for molecules of water in a fissure in the surface of the crystallographic molecular model (Bragg spacing ≥ 0.13 nm) of toxin II from *Androctonus australis*.^{286,287} The fissure is formed from three segments of the polypeptide in which each of the amino acids is numbered by its position in the sequence of the protein. The fissure is in contact with the bulk water (situated to the right) over all of its length, and many of the hydrogen bonds are between molecules of water, but the entire cluster is held in place by hydrogen bonds to donors and acceptors on the protein that surrounds it. Cystine 12/63 assumes two alternative conformations in which the disulfide is the right-handed and left-handed rotamer, respectively. This drawing was produced with MolScript.⁵⁷³

A

graphic molecular model of cholesterol oxidase from *Brevibacterium sterolicum*, a number of water molecules are involved in linking one segment of β structure to another.¹⁵ Usually, however, the molecules of water at fixed positions are chelated at random by the donors and acceptors of the protein.

The ordered water found covering the open surface of a crystallographic molecular model (Figure 6-38) is held in its discrete locations by **hydrogen bonds** to donors and acceptors on the surface. This pinning is accomplished by particular asparagines, glutamines, lysines, aspartates, arginines, and glutamates distributed over the surface of the individual molecules of protein. These donors and acceptors hold the molecules of water in extended, fixed hydrogen-bonded networks.²⁹¹ It is the donors and acceptors on the protein that anchor these networks in the unit cell. At their peripheries the networks contain molecules of water attached only to other molecules of water, and at the far edges the networks fade into the disorder of the bulk solvent in the crystal. The number of water molecules included as individuals in the refined molecular model is probably a function more of the minimum Bragg spacing of the data set, the peculiarities of the refinement, and the subjective decisions of the crystallographer than of any discrete distinction between ordered and disordered water in the actual crystal, if any such distinction can ever be made.

Networks resembling clathrates are rarely^{292,293} found around hydrophobic functional groups on the surface of crystallographic molecular models,²⁷ and those networks that are found usually do not seem to be the

B

result of the fact that they surround a hydrophobic side chain.²⁹¹ If such networks around hydrophobic amino acids are present in the crystal but are not pinned to the same locations in each unit cell or if they are rearranging continuously while the data set is being gathered, they would not be seen in the crystallographic molecular model. If the charged functional groups on the surface of a protein are surrounded by spheres or semispheres of hydration, as the paradigm associated with the hydration of spherical ions suggests (Figure 5–9), the molecules of water in these shells of hydration are not pinned, because no indication of their presence is seen in the maps of difference electron density. Charged functional groups on the side chains of the amino acids, however, often have one or two molecules of water forming hydrogen bonds to their donors and acceptors. All of these points reemphasize the fact that only specific locations occupied by molecules of water for long periods of time appear as distinct features in maps of electron density.

Of the water molecules that are attached directly to the molecule of protein in a refined crystallographic molecular model, about two-thirds make only one hydrogen bond to the protein^{269,294} and one-third make two or more hydrogen bonds. The **mean number of hydrogen bonds** between molecules of water in this first layer of hydration and the protein is 1.7.⁹⁸ The average distance between one of these waters and a donor nitrogen is 0.29 ± 0.02 nm and between one of these waters and an acceptor oxygen is 0.29 ± 0.02 nm.^{98,269} Of these water molecules directly bound to protein, 42% act as donors to acyl oxygens of the polypeptide backbone, 16% act as acceptors from nitrogen–hydrogen bonds of the polypeptide backbone, and 42% are in hydrogen bonds to donors and acceptors on the side chains.^{8,98,269} In the crystallographic molecular model of lysozyme,²⁶⁹ of the waters bound to functional groups of side chains on the surface of the protein, 24% were donors to carboxylates, 13% were donors to primary amides, 13% were acceptors for primary amides, 14% were acceptors for primary alkyl ammoniums, 14% were acceptors for guanidiniums, 14% were hydrogen-bonded to alkyl hydroxyls, and 6% were hydrogen-bonded to phenolic hydroxyls.

The **disordered side chains** in a crystallographic molecular model are usually at its surface in the most accessible locations. Because they are at the surface, they are usually hydrophilic and are probably even more hydrated than the ordered side chains. Any molecules of water bound to these disordered side chains are never seen in the crystallographic molecular model. Therefore, the mean number of waters bound to each side chain is probably an underestimate of the actual values. Nevertheless, of the side chains to which bound water can be assigned in lysozyme,²⁶⁹ aspartic acids have a mean of 2.0 waters; lysines, a mean of 1.8 waters; asparagines, a mean of 1.6 waters; glutamic acids, a mean of 1.5 waters; threonines, a mean of 1.2 waters; tyrosines, a mean of 1.0 water; serines, a mean of 0.7

water; and glutamines, a mean of 0.7 water bound to their side chains. More than 50% of the arginines are disordered, but those that can be observed have 1.5 waters bound.

When a set of 16 crystallographic molecular models from data sets gathered to Bragg spacings of 0.17 nm or less were examined,²⁹⁵ side chains that had two or three heteroatoms that can participate in hydrogen bonds (aspartate, arginine, glutamate, histidine, and glutamine) frequently (>70%)²⁹⁵ had one or more waters bound to them, while those with only one (tyrosine, tryptophan, threonine, and lysine) less frequently had water bound to them (60–70%). Asparagine (61%) and serine (51%) fall out of these ranges, probably because they are often hydrogen-bonded to the backbone.

It is the molecules of water hydrogen-bonded to the donors and acceptors of these side chains that produce the sharp maximum at around 0.29 nm in the solvent distribution function around a molecule of protein.²⁹⁶ The hydrophobic side chains (methionine, alanine, phenylalanine, isoleucine, leucine, and valine) much less frequently (10–30%) have fixed locations for molecules of water adjacent to them, but these side chains are usually buried in the interior of the protein. Those hydrophobic groups that do have fixed locations for molecules of water adjacent to them are surrounded by a layer of water in which the centers of the oxygen atoms are about 0.4 nm from the centers of the carbon atoms of the side chains,²⁹⁶ as expected from their van der Waals radii (Table 6–3).

There are a number of **physical measurements** which register the fact that each molecule of protein in solution has water bound to it in an irregular network creating a **shell of hydration**. The molecules of water in this shell of hydration differ from the molecules of water in the bulk of the solution away from the molecule of protein in several of their physical properties. For example, neutron scattering has revealed that the layer of hydration immediately adjacent to the surface of a molecule of protein has a density about 10% greater than that of the bulk water.²⁹⁷ From a dissection of the compressibility of this layer of hydration, it has been concluded that it contains extensive hydrogen-bonded networks¹⁸⁴ similar to those observed in crystallographic molecular models.^{286,291} While it is unable to distinguish the water in this layer from water in bulk solution because its rate of relaxation is too fast, nuclear magnetic resonance is able to detect the buried waters in a molecule of protein because their rates of relaxation are so much slower.²⁹⁸

Each of the molecules of water surrounding a molecule of protein at a given instant is in a different situation (Figure 6–38), and the relationship between each one of these molecules of water and the molecule of protein depends upon the respective situation. It is the contribution of each one of these molecules of water to the statistical behavior that produces the value of the physical property measuring the **hydration** of the protein, $\delta_{\text{H}_2\text{O}}$

[grams of H₂O (gram of protein)⁻¹]. Each contribution will be a unique function of the situation of the respective molecule of water, and the physical measurement will be only an average over all of these contributions. Mathematically, this heterogeneity in the situations of the waters participating in the shell of hydration can be expressed as a **weighted mean**:²⁹⁹

$$\delta_{\text{H}_2\text{O}} = \frac{M_{\text{H}_2\text{O}}}{M_p} \sum_{i=1}^n w_i \quad (6-4)$$

where $M_{\text{H}_2\text{O}}$ is the molar mass of water (18.0 g mol⁻¹), M_p is the molar mass of the protein, and the sum is over a set of statistical weights w_i .

There are two ways to think of the meaning of the **statistical weights** w_i . It can be assumed that there are n sites for the binding of water molecules around the protein, the positions of which move through the solution in lock step with the protein. The statistical weight w_i for a given site is then the occupancy of that site, which is the fraction of the time that the site is occupied by a molecule of water.²⁹⁹ It is also possible to consider all n molecules of water in the vicinity of the protein at a given instant. The statistical weight w_i in this case expresses the degree of influence the molecule of protein has over the behavior of water molecule i . When $w_i = 1$, the location occupied by water molecule i is fixed, as if covalently, to the molecule of protein. When $w_i = 0$, the water molecule i is uninfluenced in its behavior by the presence of the molecule of protein.

Under no circumstances should the layer of hydration surrounding a molecule of protein be pictured as a uniform layer clearly distinguished from the water in the bulk of the solution by some discontinuous boundary. Rather, the layer of hydration gradually fades from fixed defined locations for molecules of water adjacent to the surface of the molecule of protein to molecules of water distant from the surface that are only marginally affected by its presence.

It is almost always the case that physical measurements of hydration yield a simple number, $\delta_{\text{H}_2\text{O}}$, the **grams of water bound for every gram of protein** (Table 6-4). It is not surprising that this number varies with the method used to obtain it, as more or less of the molecules of water surrounding the protein differ more or less from the water in the bulk solvent in the particular behavior measured by the particular procedure.

The **self-diffusion of water** decreases when protein is added to the solution,³¹⁰ and this decrease can be explained if it is assumed that the water of hydration, being less mobile than the water in the bulk phase, does not participate significantly in self-diffusion. With this assumption, the amount of water bound to the protein can be calculated.

The relative permittivity of a solution of protein decreases discontinuously when the frequency of the

alternating electric field used to measure that relative permittivity becomes greater than the ability of the molecules of protein to reorient in response to its alterations,³¹¹ and another discontinuous decrease is observed when the frequency becomes greater than the ability of the water in the bulk solvent to reorient. Between these two extremes, there is a third **dielectric relaxation** that is assigned³⁰¹ to the waters of hydration bound to the protein. These waters have dielectric relaxations 10–100-fold slower than the waters in the bulk solution. From the spectrum of these dielectric relaxations, the concentration of these relatively immobilized molecules of water and hence the amount of water bound to the protein can be calculated. These molecules of water, however, are not fixed to the protein, or they would be required to rotate with it, and their dielectric relaxation would be indistinguishable from that of the protein itself.

Solid **powders of dry protein** always have water incorporated in them and the amount of this water of hydration can be chemically determined. A more systematic approach is to equilibrate the dry powder, either as a precipitate, as a microcrystalline solid, or as visible crystals, with air of a certain relative humidity. It has been proposed that air at 90% relative humidity is the appropriate choice.³⁰³ Below this value the powders tend to become glasses,³⁰³ and above this value they become hygroscopic. The amount of water bound by a solid powder of a given protein at 90% relative humidity can be taken as its hydration.

If it is assumed that the water hydrating a protein is entirely unable to dissolve salting-out solutes that are otherwise freely soluble in water,³⁰⁴ the negative of the **preferential solvation** of a particular protein in a particular solution (Equation 1-57) can be multiplied by the molarity of the water in that solution and the molar mass of water to obtain a value for the grams of H₂O (gram of protein)⁻¹ in the layer of hydration. To perform measurements of preferential solvation, a solution of the protein is usually brought into equilibrium with a solution containing only water and the salting-out solute, for example, glucose,³⁰⁴ lactose,³⁰⁴ or sucrose³⁰⁵ (Table 6-4). It is also possible to equilibrate crystals of a protein with solutions of salting-out solutes and from the dependence of the density of the crystal on the density of the solution to determine the amount of water in the crystal that excludes the solute.^{299,302,306}

When a solution of protein is frozen, the water of hydration freezes below the freezing point of the water in the bulk solution. Not until the temperature is lowered to below 180 K does it all become frozen.³¹² For example, at -3 °C, 0.51 g of water (g of protein)⁻¹; at -5 °C, 0.46 g of water (g of protein)⁻¹; and at -7 °C, 0.41 g of water (g of protein)⁻¹ remained unfrozen in a solution of ovalbumin.³¹³ **Unfrozen water** is more mobile than frozen water, and the two can be distinguished by nuclear magnetic resonance.^{307,312} The amount of unfrozen water in a

^aAll units are grams of water (gram of protein)⁻¹.

frozen solution of protein at 238 K (-35°C) has been designated as water of hydration.

Upper limits on the amount of water that migrates with a molecule of protein through the solution can be calculated from the **frictional coefficient**.³⁰⁸ The radius of a hard sphere the same volume as a molecule of protein can be calculated from its molar mass and partial specific volume, and the radius of the sphere that would have the same frictional coefficient as the molecule of protein can be calculated with Equation 1-66. The latter sphere is always larger than the former. If it is assumed that the entire difference in volume is water forced to move with the molecule of protein, an upper limit to the amount of bound water can be calculated (Table 6-4). It is an upper limit because molecules of protein are not spheres and a particle with the same volume as a given sphere but a different shape will always have a larger frictional coefficient than that sphere. How much of the difference between the two radii is due to hydration and how much to differences in shape has never been ascertained unambiguously for any protein. The numbers tabulated are not intended to be estimates of hydration, but upper limits of the hydration.

It is also possible to estimate the hydration of a protein from the **scattering at small angles** of X-radiation from a solution of that protein as a function of the angle of that scattered radiation.³⁰⁹

There are several remarkable features of this tabulation (Table 6-4). The values for bound water are all similar, and each technique produces values that, although they do not agree, are in the same range (**0.2–0.4 g g⁻¹**), which is about 2 mol of water (mol of amino acid)⁻¹. There seems to be no significant difference in the amount of bound water for every gram of protein over a 5-fold range in size of the proteins, between ribonuclease ($n_{\text{aa}} = 124$) and serum albumin ($n_{\text{aa}} = 581$). For a small protein such as lysozyme ($n_{\text{aa}} = 129$) or dihydrofolate reductase ($n_{\text{aa}} = 162$), these results indicate that there should be 200–300 molecules of bound water for every molecule of protein. In a crystal of lysozyme, 140 molecules of water had locations that were sufficiently distinct to be incorporated into the refined molecular model.²⁶⁹ In a crystal of dihydrofolate reductase, 264 molecules of ordered water had sufficiently distinct locations to be incorporated in the refined molecular model.²⁷ Whether these ordered molecules of water bear any relation to the bound water detected by the physical measurements is uncertain.

There is a highly significant correlation between the **accessible surface area** of a crystallographic molecular model of a protein and the total number of amino acids it contains, regardless of whether it is a monomer or an oligomer.³¹⁴ As a result of this correlation, the mean accessible surface area for each amino acid falls gradually and monotonically from 0.53 nm^2 (amino acid)⁻¹ when the protein contains 100 amino acids to 0.30 nm^2 (amino acid)⁻¹ when the protein contains 2000 amino

acids. From the definition of accessible surface area (6-12) it follows that a molecule of water, held by hydrogen bonds at 0.28 nm from its nearest neighbors, can cover about 0.07 nm^2 of accessible surface area if waters are assumed to pack in hexagonal array or 0.09 nm^2 if they are in a tetrahedral lattice (Figure 5-2). This means that there are about 7 waters (amino acid)⁻¹ immediately adjacent to the surface of a protein containing 100 amino acids and 4 waters (amino acid)⁻¹ immediately adjacent to the surface of a protein containing 2000 amino acids. These limits would be equivalent to 1.2 and 0.7 g of water (g of protein)⁻¹, respectively. For the proteins gathered in Table 6-4, which all contain less than 600 amino acids, the span would be 1.2–0.9 g of water (g of protein)⁻¹. Therefore, the water of hydration determined by physical measurements is considerably less than the amount of water required to cover the surface of a molecule of protein with a continuous rigidly fixed layer.

Part of the reason for this discrepancy may be that, as with the networks of water covering the surface of a molecule of protein in a crystallographic molecular model, the layer of hydration is patchy and discontinuous^{286,291} but the **heterogeneity** that must exist among the waters of hydration is probably most of the reason. Some waters at the surface are held tightly ($w_i \cong 1.0$), but most are only loosely influenced by the protein ($w_i < 1$) and contribute only partially to the weighted mean (Equation 6-4). Therefore it is not surprising that the weighted mean is less than the limit calculated by simply counting every immediately adjacent molecule of water and presuming it to be fixed to the protein. The range over which the amount of immediately adjacent molecules of water ($0.9\text{--}1.2 \text{ g g}^{-1}$) varies among the proteins of the size of those contributing to Table 6-4 is narrow, and this fact explains why all of the proteins seem to have about the same degree of hydration, within the variation of the measurements.

The molar concentration, and hence the thermodynamic activity, of the water in the bulk phase of a solution of protein can be changed without changing its concentration in the layer of hydration by adding a salting-out solute such as sucrose, triethylene glycol, dioxane, stachyose, or poly(ethylene glycol) that is excluded from the layer of hydration.^{315–317} Because the water in the layer of hydration is in rapid equilibrium with the water in the bulk phase, changing the activity of the water in the bulk phase changes its activity in the layer of hydration, and this change affects any chemical reaction in which the amount of hydration of the protein changes. As one might expect, the binding of substrates to an enzyme,^{316,318} the binding of a protein to DNA,³¹⁵ a large conformational change of a protein,^{317,318} or the binding of one protein to another causes significant changes in hydration. From the magnitude of the effect of changing the concentration of water on the dissociation constant for these reactions, the number of molecules of water removed from or added to the layer of hydration during

the reaction can be estimated. These range from 9 molecules of water for binding of a substrate to a hydrated active site³¹⁶ to 60 molecules of water for a significant conformational change.^{317,318} In the latter transformation, a portion of the water detected as leaving the shell of hydration is thought to be molecules beyond the first layer.

Problem 6–7: Assign the hydrogens to donors and acceptors in Figures 6–37B and 6–40A,B.

Ionic Interactions

Almost all of the charged amino acids—glutamate, aspartate, histidinium, lysinium, and arginine—are found on the surface of the crystallographic molecular model of a protein, so that they retain their hydration. Aside from the few that have roles as acids and bases in the function of the protein, the reason that these charged amino acids are present on the surface of a protein is to permit it to dissolve in water at high concentrations. For example, the concentration of hemoglobin in an erythrocyte is 0.3 g mL^{−1}.

The **distribution of these elementary charges** on the surface of a molecule of protein seems to be random with little regard for the signs of the elementary charges and no attempt to compensate the charges. Patches of positive charge and patches of negative charge are as common as regions where the charges are evenly divided. Changing these distributions seems to have little effect on the stability of the protein.³¹⁹ The lysozyme from bacteriophage T4 has an excess of nine elementary positive charges over elementary negative charges at neutral pH. When lysines on its surface were changed to glutamates by site-directed mutation to produce a number of single, double, triple, and quadruple mutants in which the net charge number decreased from +9 to +7, +5, +3, and +1, respectively, the mean change in the free energy of folding of the protein was $+3.3 \pm 2.9$ kJ mol^{−1}.³²⁰ Consequently, the protein decreased slightly in stability rather than increasing in stability as its excess charge was neutralized, and the magnitudes of the individual decreases in stability showed no correlation with the magnitude of the decrease in charge. Increases in stability of the same magnitude (−4 to −8 kJ mol^{−1}), however, have been observed upon neutralizing imbalances of charge on the surfaces of ubiquitin³²¹ and the subunit-binding domain of dihydrolipoyllysine-residue acetyltransferase from *Bacillus stearothermophilus*.³²² All of these experiments were performed at an ionic strength of 0.05 M, so the differences in stability observed would

probably have been even smaller at the physiological ionic strength of 0.15 M.

There are experimental results suggesting that the charge of the amino acids on the surface of a protein may electrostatically increase the rate of association^{323,324} or increase the equilibrium constant for association^{325–328} of ligands that bear an opposite charge. These effects, however, are rarely more than a factor of 2 (−1.7 kJ mol^{−1}) at physiological ionic strengths, and often the ionic strength of the solution must be lowered to observe them at all,³²⁶ so they can be of little consequence biologically.

The **acid dissociation constants** of the individual acid–bases of the side chains on the surface of a protein are shifted by the elementary charges on the amino acids in their vicinity. For example, it has been shown that the pK_a of Histidine 64 in subtilisin BPN' decreases by 0.26 unit when Aspartate 99 is mutated to a serine³²⁹ because when the elementary negative charge of Aspartate 99 is no longer in its vicinity, the stability of the histidinium ion decreases relative to that of the neutral histidine. All such pairwise interactions are tautomeric because if one side chain shifts the pK_a of another, then the other side chain must shift the pK_a of the first. If the negative charge of Aspartate 99 shifts the pK_a of Histidine 64, the positive charge of Histidine 64 must shift the pK_a of Aspartate 99. A large constellation of such **tautomeric interactions** determines the individual acid titrations of the side chains on the surface of a protein.

The acid–base **titration curve** of a native protein (Figure 1–11) is the summation of the individual titrations of the accessible acid–bases on its surface. For every 100 amino acids, a normal protein contains about five aspartic acids, six glutamic acids, two histidines, three tyrosines, and six lysines.³³⁰ The aspartic acids ($pK_a = 4.0$) and glutamic acids ($pK_a = 4.4$) account for most of the dissociation of protons between pH 2 and 5.5. The lysines ($pK_a = 10.4$) and tyrosines ($pK_a = 9.8$) account for most of the dissociation of protons between pH 8 and 12. These are the two major features of the titration curve of a protein because these four amino acids account for the majority (90%) of the acid–bases present in the protein. The histidines account for most of the small amount of dissociation that occurs between pH 5.5 and 8.

As the pH is decreased below the isoelectric point, a protein gains net positive charge number as each proton associates, and as the pH is increased above the isoelectric point, the protein gains net negative charge number as each proton dissociates. This change of net charge number with decreases and increases of pH causes the addition of each successive proton or the removal of each successive proton, respectively, to be more difficult. The reason for this is that the gathering of net charge number on a molecule, even one as large as a protein, is an unfavorable reaction relative to dispersing those elementary charges evenly throughout the solution. Because tautomeric interactions are themselves electrostatic, the effect of the resulting charge on the

overall acid dissociation of the molecule of protein is simply the summation of all the tautomeric interactions among all the side chains, the individual titrations of which produce the complete titration curve.

That the **electrostatic work** of creating this charge shifts the observed titration curve is easily demonstrated by changing the ionic strength (Figure 1-11). An increase in ionic strength shrinks the layer of counterions around each individual, charged amino acid in the protein (Equation 1-71) and causes them to exert a decreased effective electrostatic charge in their influence on neighboring acid-bases undergoing titration. This in turn decreases the electrostatic work that must be performed to create charge on the neighboring acid-bases and shifts the titration curve closer to the curve that would have been seen if each acid-base titrated only according to its intrinsic pK_a . This electrostatic shielding due to increased ionic strength produces a steepening of the titration curve for the protein both below and above its isoelectric point (Figure 1-11).

It is possible to correct roughly³³¹ for the electrostatic work involved in creating charge on the molecule of protein by assuming that in a given region of the titration curve, for example, between pH 2 and 5.5, only one type of acid-base is titrating and all of the members of this set have the same intrinsic pK_a , $pK_{a,int}$. Then it is assumed that the charge on the molecule of protein, Q_i , is proportional to the mean net proton charge number, $\bar{Z}_{H,i}$, and that $pK_{a,int}$, which is proportional to a free energy, is shifted arithmetically by the electrostatic work, which is a free energy and which should be proportional to $\bar{Z}_{H,i}$.

The values of the **intrinsic acid dissociation constants** obtained by these corrections for electrostatic work agree with expectation (Table 2-2) to a certain extent. The value of $pK_{a,int}$ for the carboxyl groups in several proteins the titration curves of which between pH 2 and 5.5 have been analyzed in this way³³¹ are between 4.0 and 4.8. The titration of tyrosine side chains in a native protein can be followed independently by using the large difference in ultraviolet absorbance between the phenol and the phenolate anion to calculate f_A and f_{HA} .³³² The values of $pK_{a,int}$, corrected for electrostatic work, for tyrosines in several proteins³³¹ are between 9.4 and 10.8. The contribution of tyrosine to the titration curve between pH 8 and 12 can then be deducted from the overall curve, and values of $pK_{a,int}$ for the lysines in these same proteins can be calculated. They lie between 9.8 and 10.4.

The titration curves of proteins usually fail to meet expectations in one key aspect. There are usually too few acid-bases contributing to the titration.³³¹ The **deficit** is most easily noticed in the case of histidine and tyrosine. The number of moles of protons dissociating from a mole of protein between pH 5.5 and 8 is often less than the moles of histidine in a mole of that protein. This deficit can be explained by assuming that the values of pK_a for one or more of the histidines have been lowered and that their titrations have become buried in those of

the large number of carboxylates. The moles of tyrosine the ultraviolet absorption of which displays the expected shift between pH 9 and 11 upon formation of the phenolate anion is often less than the total moles of tyrosine present in a mole of the protein. For example, only four of the six tyrosines in ribonuclease can be titrated^{331,333} and only two of the four tyrosine side chains of chymotrypsinogen can be titrated³³¹ within accessible ranges of pH. With most proteins, values of pH greater than 11 are inaccessible, so it can be said only that each of these missing tyrosines has a pK_a greater than 11.

Both the decreases in the values of pK_a for the histidines and the increases in the values of pK_a for the tyrosines implied or demonstrated by these results are reasonable. If these shifts in pK_a are due to burying the side chains in the interior of the protein, even though they remain accessible to the solvent and capable of acid-base reactions, their neutral forms should become more stable relative to their charged forms. In most cases, the missing acid-bases in a titration curve are assumed to be buried in the interior of the folded polypeptide. Such **buried acid-bases** can be seen in the crystallographic molecular models of proteins. For example, in the crystallographic molecular model of ribonuclease, Tyrosine 25 is almost completely buried (the solvent accessibility of its phenolic oxygen is only 0.02) and Tyrosine 97 is completely buried.³³⁴ It has been assumed that these are the two tyrosines in the native protein that do not participate in acid-base titrations.

These examples of buried tyrosines or histidines are special cases of the fact that polar amino acids are found in the interior of a protein, even ones that are normally charged. For example, Arginine 30 in the crystallographic molecular model of xylose isomerase from *Anthrobacter* strain B3728 is completely surrounded by both the backbone and mostly carbon-hydrogens of other side chains (Figure 6-41).¹¹² It does not form an ion pair with any anionic side chain. Instead, its five donors form hydrogen bonds with four acyl oxygens from the backbone and a molecule of water. Because one of the hydrogen bonds is to a molecule of water, it cannot be determined whether or not the guanidino group is positively charged. Aspartate 76 is buried in the interior of ribonuclease T₁ of *A. oryzae*³³⁵ and a cluster of three glutamates, two histidines, and an aspartate is buried in the interior of the iron free form of the R2 protein of ribonucleoside-diphosphate reductase.³³⁶

The amino acids that are charged at neutral pH are either the anionic conjugate bases of neutral acids, for example, carboxylates, or the cationic conjugate acids of neutral bases, for example, ammonium cations. It may be the case that when such an amino acid is buried, it is buried as the **neutral acid or the neutral base**, respectively. This conclusion follows from the fact that the farther the pK_a of a normally charged amino acid is from 7.0, the less likely it is to be buried (Table 6-2). Such a buried amino acid usually participates in a set of hydrogen

Figure 6-41: Arginine buried in the crystallographic molecular model (Bragg spacing ≥ 0.23 nm) of xylose isomerase from *Anthrobacter* strain B3728.¹¹² The unattached oxygen (open circle) is a fixed location for a molecule of water. Two segments of the folded polypeptide, Threonine 16 to Alanine 31 and Proline 295 to Tryptophan 305, are displayed. This drawing was produced with MolScript.⁵⁷³

bonds that fit its donors or its acceptors (Figure 6-41), so it is neither surprising nor informative that replacing it by site-directed mutation with an amino acid that is isosteric but has a different pattern of donors and acceptors, such as an asparagine for an aspartate, usually produces a less stable protein.³³⁵ From examining closely the constellation of donors and acceptors around such a buried amino acid, however (see Problem 6-8), one often comes to the conclusion that it is buried in its charged form. If this is the case, the protein itself must somehow replace most of the enthalpy of hydration that is lost upon removing the charge from the water. In such situations, it is the large number of complementary donors and acceptors of hydrogen bonds that seems to accomplish this feat in the absence of any compensation of charge.³³⁷ Most of the time, however, when a charged amino acid is found in a crystallographic molecular model at a location removed from the water, it is found as a partner in an ion pair.

Ion pairs are actually ionized hydrogen bonds. An **ionized hydrogen bond** is a hydrogen bond between a positively charged donor and a negatively charged acceptor. An example would be the hydrogen bonds between an argininium cation and an aspartate anion (Figure 6-42) or an argininium cation and a glutamate anion (Figure 6-58).^{338,339} That almost all ion pairs are ionized hydrogen bonds follows from the fact that the distance between the two heteroatoms, one from the cation and one from the anion, that make the closest contact in an ion pair is usually that of a hydrogen bond (0.3 nm),^{15,24,72,340} the fact that the angles at this point of contact are usually those expected of a hydrogen bond; and the fact that a deuteron can be found between these two heteroatoms in crystallographic molecular models from neutron diffraction of deuterated proteins.³⁴⁰

Although occasionally an ion pair will be as ideal as the one illustrated in Figure 6-42,^{30,97,341} in which the two acceptors of the carboxylate are respectively occupied by two of the donors of the guanidinium ion to form a six-

Figure 6-42: An ionized hydrogen bond between Aspartate 193 and Arginine 13 in the crystallographic molecular model (Bragg spacing ≥ 0.175 nm) of chloramphenicol *O*-acetyltransferase.^{338,339} The hydrogen bonds between donors and acceptors on other side chains, but not those between acyl oxygens and amido nitrogen-hydrogens of the backbone, are drawn. The one apparently unoccupied donor on Arginine 13 is pointing toward the π system of the side chain of Tryptophan 11 and presumably forms a hydrogen bond with it. The segments from one subunit of the protein, Phenylalanine 11 to Phenylalanine 17 and Histidine 189 to Alanine 198, and one segment from an adjacent identical subunit of the protein, Phenylalanine 90' to Phenylalanine 97', are displayed. This drawing was produced with MolScript.⁵⁷³

membered ring, usually it is more peculiar because molecules of protein are the products of evolution by natural selection. For example, a positive side chain and a negative side chain will not be directly hydrogen-bonded to each other but linked through an intermediate, as Arginine 102 and Aspartate 142 are linked by Threonine 107 in α -lytic endopeptidase (Figure 6–43).⁹⁷ As if to illustrate the **irrelevance of placing positive next to negative**, Arginine 8 and Arginine 366 in pepsinogen, albeit each hydrogen-bonded to carboxylates, are nevertheless stacked on top of each other, their π molecular orbital systems parallel to each other, within a buried hydrogen-bonded cluster.³⁴²

Whether the hydrogen bond between a carboxylate anion on the one hand and a histidinium, ammonium, or guanidinium cation on the other is ionized or not depends formally on whether the proton is on the stronger base, in which case the bond is ionized, or on the weaker base, in which case it is neutral. In almost every instance in which a potentially ionized hydrogen bond is found in a crystallographic molecular model, it is unknown on which atom the proton resides. An estimate of the **effect of the relative permittivity** on the location of the proton in an ionized hydrogen bond has been made,³⁴³ and it was concluded that the relative permittivity of the surroundings would have to be less than that of CCl_4 ($\epsilon_r = 2.2$) before the shift of the proton from an ammonium cation to a carboxylate anion in the ionized hydrogen bond between them

would be favored. If this is the case, such ionized hydrogen bonds are probably ionized even when surrounded by protein because the relative permittivity of protein is thought to be between 3 and 6.³⁴⁴ Certainly, in the crystallographic studies of proteins by neutron diffraction, in which the location of the proton has been observed directly, it usually forms a normal σ bond with the stronger base.

The energy required to transfer an ionized hydrogen bond from water to a region of low relative permittivity is almost as large as the energy required to transfer a monovalent ion,³⁴⁵ so a **buried ion pair** is only marginally less unstable than a buried, uncompensated arginine, lysine, aspartate, or glutamate. Consequently, when one member of an ion pair is replaced by site-directed mutation, the protein becomes less stable, but only by 10–15 kJ mol^{-1} .³⁴⁶ Such observations are, however, ambiguous because the amino acids in the vicinity of the mutation can rearrange to take advantage of alternative compensations. For example, when Aspartate 193 represented in Figure 6–42 is mutated to an asparagine, this

Figure 6–43: Hydrogen-bonded network involving Arginine 102 and Aspartate 142 in the crystallographic molecular model (Bragg spacing ≥ 0.17 nm) of α -lytic endopeptidase from *L. enzymogenes*.⁹⁷ Two strands of polypeptide, from Arginine 102 to Tyrosine 109 and Cysteine 137 to Serine 143, from the interior of the protein are displayed as well as a molecule of water (open circle). The interaction between the two oppositely charged side chains, the arginine and the aspartate, is mediated by their respective hydrogen bonds to Threonine 107. This drawing was produced with MolScript.⁵⁷³

asparagine swings away to form hydrogen bonds with the backbone amido nitrogen–hydrogen of Histidine 196 and the backbone acyl oxygen of Glutamate 95', and Arginine 13 swings away to form a new ionized hydrogen bond with the side chain of Glutamate 95' as well as a hydrogen bond with the acyl oxygen of Threonine 94'.³³⁸

A buried ionized hydrogen bond is less stable than a buried neutral hydrogen bond³⁴⁷ and certainly less stable than an isochoric pair of hydrophobic side chains. When the partially buried ionized hydrogen bonds

among Arginine 31, Glutamate 36, and Arginine 40 in the Arc repressor were replaced with hydrophobic interactions among a methionine, a tyrosine, and a leucine, respectively, the mutant that resulted was -16 kJ mol^{-1} more stable than the wild-type protein.³⁴⁸ Why buried ionized hydrogen bonds uninvolved in the function of the protein have not been eliminated in this way by evolution by natural selection is unknown. Buried, ionized hydrogen bonds, however, are rare; most ionized hydrogen bonds are found on the surfaces of crystallographic molecular models of proteins where they can be stabilized by the solvation of the water. Even then they represent a minority of the ionized hydrogen bonds that potentially could form. Most of the fortuitously juxtaposed, oppositely charged side chains on the surface of a crystallographic molecular model do not participate in hydrogen bonds³¹⁹ “even though in most cases there is no steric reason why they cannot.”³⁴⁹ It is the competition of the donors and acceptors of the water that prevents it.

The **frequency** with which ionized hydrogen bonds are observed in crystallographic molecular models (Table 6–5) is no greater than the probability that they would occur at random. Only hydrogen bonds between two side chains are considered in the tabulation, and the probability that a certain hydrogen bond will form at random is calculated from the frequency with which the amino

acids occur in the usual protein and the number of equivalent donors or equivalent acceptors present on each amino acid. If anything, ionized hydrogen bonds are observed less frequently than predicted by this calculation of probability. This may be due to the fact that both charged donors and charged acceptors will tend to be more exposed to the water and less likely to form hydrogen bonds. A reciprocal argument could be invoked to explain the fact that hydrogen bonds between hydroxyl groups are more frequent than expected (Table 6–5), because amino acids bearing hydroxyl groups are often buried (Table 6–2). Nevertheless, with few exceptions, the frequencies with which each of the particular hydrogen bonds are observed are about those expected from the probability that the respective donor and acceptor would encounter each other at random, regardless of charge.

An example of the interchangeability of charged and uncharged donors and acceptors of hydrogen bonds occurs in phycobiliproteins, where an ionized hydrogen bond between an arginine and an aspartic acid in one species is replaced isochorically by hydrogen bonds between two glutamines in another:³⁵²

This, however, may not be very common because the amino acids surrounding an ionized hydrogen bond have been selected for their ability to solvate the charges and such a tailored environment should resist the neutralization of the bond.³⁵³ Nevertheless, all of these considerations suggest that an ionized hydrogen bond is no different from an un-ionized hydrogen bond except that it should be less stable when exposed to solvent and present greater problems of solvation when it is buried.

^aFrom tables in refs 8, 22, 97, and 98. ^bProbability that the hydrogen bond would occur at random, calculated only from frequencies of functional groups^{350,351} in proteins and their respective number of donors or acceptors, assuming no preferences for type of hydrogen bond. ^cProbability on the same scale as the others but not included for normalization.

- (A) The side chain of which of the 20 amino acids descends from the top left of the figure into its center?
- (B) Draw the structures of all of the hydrogen bonds made by the donors and acceptors on this side chain. In your drawing include the σ lone pairs of the acceptors and the hydrogens of the donors as in the drawings in Table 6-5. Indicate clearly the chemical identity of each donor and acceptor in your drawing by including enough of its structure that there is no doubt as to what functional group it is and by labeling it.
- (C) Is the side chain charged or neutral? How can you be sure?

- (D) In a solution of protein, are there an excess of donors or acceptors for hydrogen bonds? On the basis of this consideration, why should all donors of hydrogen bonds find a partner? Do all of the donors on the amino acid side chain in the center of the figure find acceptors?
- (E) Because the figure is for a region of electron density from the center of the molecule of protein, what is the most unexpected feature of the arrangement? What seems to permit this unexpected arrangement?

Hydrogen Bonds

Although they are less frequent than the hydrogen bonds between the amido nitrogen–hydrogens and the acyl oxygens of the backbone producing the secondary structure of a protein, hydrogen bonds between the **donors and acceptors on the side chains** of the amino acids are common features of crystallographic molecular models. The **stereochemistry** of such hydrogen bonds is as expected.³⁵⁴ The various acceptors to the nitrogen–hydrogen bonds that are donors on the side chains of glutamine, asparagine, arginine, histidine, and tryptophan are located preferentially at positions to which the sp^2 nitrogen–hydrogen bonds of the donors are pointed. The donors to the oxygens that are acceptors on glutamate, aspartate, asparagine, and glutamine show some preference for the positions at 120° to the carbon–oxygen double bond to which the sp^2 lone pairs of electrons on the oxygens are pointed, but there is much more flexibility to their locations as they pivot around these lone pairs (Figure 5–10D). The distribution of hydrogen-bond donors and acceptors around the hydroxyl oxygens of serines and threonines is even more flexible, but there are noticeable preferences for the two positions at dihedral angles χ_2 of 80° and 280° . The donors and acceptors to the phenolic oxygen of tyrosine, however, have a strong preference to be in the plane of the ring at angles of 120° to the carbon–oxygen bond, as expected from the sp^2 hybridization of the oxygen. The three nitrogen–hydrogen bonds on lysine are almost always occupied by three respective acceptors arranged around the ammonium ion at angles near the 109° expected from its sp^3 hybridization^{15,355,356} but not located at any preferred dihedral angles χ_4 .³⁵⁴

It is fairly common (17% of the tryptophans, 9% of the tyrosines, 6% of the phenylalanines, and 1% of the histidines in crystallographic molecular models from data sets with minimum Bragg spacings less than 0.17 nm) for a nitrogen–hydrogen, an oxygen–hydrogen, or a sulfur–hydrogen bond to be directed towards the **π cloud of an aromatic side chain** with its hydrogen close enough (< 0.3 nm) to conclude that a hydrogen bond has been formed.³⁵⁷ Most frequently, these hydro-

gen bonds are between the π clouds of tyrosine and tryptophan acting as acceptors and the ammonium nitrogen–hydrogens of lysines.^{358,359} When the nitrogen–hydrogen bonds are themselves attached to a π system, however, as with glutamine, asparagine, arginine, and histidine, their π cloud is often stacked on the π cloud of the aromatic side chain. In such instances, the nitrogen–hydrogen bonds point away from the aromatic ring,^{359,360} and none can form a hydrogen bond with it. There are exceptions, however, such as Glutamine 96 in human HLA class I histocompatibility antigen A-2 (Figure 6–22) and Glutamine 399 in ribulose-bisphosphate carboxylase (Figure 6–44B).

As is the case with the backbone of the polypeptide, when the donors of hydrogen bonds on the side chains of the amino acids are removed from the water and stripped of their hydrogen bonds with the solvent, there would be a considerable increase of enthalpy if they did not find **new partners** in the interior of the protein. Most if not all of them do.

One of the remarkable features of the **buried hydrogen bonds** that result from this energetic imperative is that they tend to be clustered. For example, of the 54 side chains in myoglobin that form hydrogen bonds with atoms in the protein other than bound water, 16 participate in eight closed pairs and nine participate in three closed triplets, but 29 participate in larger clusters.³⁰ These clusters often incorporate buried water. Examples of such clusters occur in deoxyribonuclease I (Figure 6–44A)⁸ and in ribulose-bisphosphate carboxylase (Figure 6–44B).³⁶¹ In these clusters, charged amino acids participate as donors and acceptors of hydrogen bonds as readily as uncharged amino acids and there is no obvious balancing between positive and negative charges (Figure 6–44A).

Clusters of hydrogen bonds serve to orient functionally important amino acids. For example, a “complex network of hydrogen bonds” serves to orient the six histidines responsible for chelating the copper and the zinc in superoxide dismutase.³⁴¹ Histidine 57 in the active site of chymotrypsin is oriented by a hydrogen bond to Aspartate 102, which in turn is oriented by three other hydrogen bonds, one to each of its three remaining acceptors.¹⁷ Histidine 31 in deoxyribonuclease I is functionally important and is held in position by the cluster in which it participates (Figure 6–44A), as is Histidine 325 in ribulose-bisphosphate carboxylase (Figure 6–44B). The hydrogen bond in the case of deoxyribonuclease I forces the dihedral angle χ_2 of Histidine 31 to assume an unfavorable value when it is positioned properly. Carboxylic acids, histidines, and arginines are most susceptible to such pinning because they have donors and acceptors at two or more separate locations on their side chains, and they are rigid structures because of their π molecular orbital systems. These features make them easily immobilized.

Just as an accounting of the concentrations of all of

Figure 6-44: Examples of clusters of hydrogen bonds among side chains. (A) A large cluster of partially buried hydrogen bonds in the active site of the crystallographic molecular model (Bragg spacing ≥ 0.20 nm) of bovine deoxyribonuclease I.⁸ Segments of the folded polypeptide from Phenylalanine 6 to Arginine 9, Isoleucine 59 to Arginine 63, Tyrosine 76 to Tyrosine 80, Serine 110 to Glutamate 112, Alanine 132 to Serine 135, Methionine 166 to Phenylalanine 169, Alanine 232 to Arginine 235, and Serine 250 to Proline 254 are drawn. Only those side chains involved in the hydrogen-bonding are drawn. Locations of molecules of water are drawn as unbonded oxygen atoms (open circles). This drawing was produced with MolScript.⁵⁷³ (B) Completely buried string of hydrogen bonds in the center of the β barrel of parallel consecutive strands in the crystallographic molecular model (Bragg spacing ≥ 0.16 nm) of ribulose-bisphosphate carboxylase.^{361,572} The β barrel has eight β strands and each inserts two amino acids, i and $i + 2$, into the core. The drawing presents the eight consecutively arranged strands of the β barrel from Leucine 167 to Threonine 171, Phenylalanine 197 to *N*-(Carboxy)lysine 199, Glycine 235 to Tyrosine 237, Isoleucine 262 to Aspartate 266, Leucine 288 to Histidine 292, Histidine 323 to Histidine 325, Leucine 373 to Alanine 376, and Serine 396 to Glutamine 399, as well as a segment from Valine 155 to Leucine 160 capping the barrel. Only hydrogen bonds between side chains in the core of the β barrel are drawn. These are a string from Glutamate 156 through Histidine 323 and Histidine 290 to Histidine 325 and hydrogen bonds between the two amido nitrogen-hydrogens on Glutamine 399 and the phenolic oxygen of Tyrosine 237 and the π system of Histidine 290. Consequently, all six of the hydrogen bonds together form a linked cluster. This drawing was produced with MolScript.⁵⁷³

the charged species in a solution, the charge balance, is essential to a quantification of the behavior of acids and bases, an accounting of the individual concentrations of all of the donors and acceptors of hydrogen bonds in a solution, the **hydrogen-bond balance**, is essential to a quantification of their behavior. In a solution of protein, for example, the cytoplasm of a cell, the concentration of acceptors of hydrogen bonds exceeds the concentration of donors. There are 300 acceptors but only 180 donors for every 100 amino acids in a protein.^{350,351} The presence of nucleic acid and carbohydrate only increases this disparity. When a polypeptide is unfolded, its donors and acceptors are freely accessible to the solution and participating in rapidly changing hydrogen bonds with molecules of water, but because at any given instant only one acceptor can pair with each donor, there will be, at all times, a concentration of unoccupied acceptors at least as large as the concentration of this inescapable excess of acceptors over donors. The concentration of unoccupied donors at a given instant, however, will be small if not insignificant.

Whenever the donor of a hydrogen bond is removed from water during the folding of a protein but paired with an acceptor from the protein, the **total number of hydrogen bonds in the solution** does not change. Almost every one of these new hydrogen bonds will have the same enthalpy of formation as the old hydrogen bond between that donor and water because

almost all of the acceptors within a molecule of protein have acid dissociation constants associated with their σ lone pairs of electrons that are not appreciably different from that of the lone pairs of electrons on water ($pK_a = -1.7$). Consequently, the enthalpy of formation of that hydrogen bond will be close to 0 (Equation 5-49). Because both the competition of the water for this donor (Equation 5-45) and the entropies of approximation involved in forming the regular structures of the polypeptide backbone (Figure 5-19) or a hydrogen bond between two side chains are entropic terms, they can be combined into the larger question of the change in standard entropy accompanying the folding of the polypeptide.

If upon folding, however, a **donor for a hydrogen bond**, such as the nitrogen-hydrogen of an amide or the oxygen-hydrogen of a hydroxyl group, finds itself sequestered within the structure without an acceptor, the number of hydrogen bonds in the solution decreases by one. This unsatisfactory sequestration would produce a change in standard enthalpy* of +15 to +20 kJ mol⁻¹ (Table 5-2) and would consequently squander a considerable portion of the net free energy available for folding. Consequently, such a loss must be avoided, and it is likely that every nitrogen-hydrogen bond and oxygen-hydrogen bond of a folded polypeptide participates as a donor in a hydrogen bond, either with water, with an acyl oxygen of a peptide bond, or with a lone pair of electrons on a side chain. It comes as no surprise that there are few^{6,362} if any^{113,363} unoccupied donors of hydrogen bonds in crystallographic molecular models.

If, upon folding, an acceptor such as a lone pair of electrons on the acyl oxygen of an amide or on the oxygen of a phenol or alcohol finds itself without a donor, there is not much of a penalty. For example, if as many as half of the excess of acceptors over donors in the polypeptide were to become sequestered unoccupied, the increase in the free energy of formation of the hydrogen bonds in the solution would be less than $-RT \ln 0.5$ or 1.7 kJ (mol of folded polypeptide)⁻¹. It comes as no surprise that there are quite a few unoccupied acceptors of hydrogen bonds in crystallographic molecular models. The most obvious examples of unoccupied acceptors are the second lone pairs of electrons on the acyl oxygens in a β sheet buried in the center of a molecule of protein (Figure 6-9). The fact that only a fraction of the acyl oxygens on either the backbone or on the side chains end up with two donors (Figure 6-7) is inconsequential because many acceptors were vacant before folding occurred

* This change in standard enthalpy is not to be confused with the dissociation of a hydrogen bond in the reaction described in Equation 5-22. In this situation, in which the dissociated donor and acceptor are not sequestered from the solvent, equienergetic hydrogen bonds are formed between the dissociated donor and the dissociated acceptor with surrounding molecules of water, there is no net decrease in the concentration of hydrogen bonds in the solution, and the change in standard enthalpy is 0.

anyway. All of these considerations should be kept in mind when the standard free energy of formation for a hydrogen bond is being assessed experimentally, because it is often the case that these differences in importance between donor and acceptor affect the results of the experiment.

The necessity that the donor of a hydrogen bond retain an acceptor is particularly relevant when the indole of **tryptophan** is considered. The side chain of tryptophan is remarkably soluble in ethanol,¹⁷⁵ which has twice as many acceptors of hydrogen bonds as donors. Likewise, during partition between water and 1-octanol, the side chain of tryptophan has the greatest preference for 1-octanol of all the amino acids (Figure 5-24). As the indole contains only a donor, a net of one hydrogen bond is created every time it is dissolved in ethanol. When it is transferred from water to 1-octanol, a net of one hydrogen bond is also created because a solution of indole in water has more donors than acceptors and 1-octanol has more acceptors than donors. When indole is transferred, empty donors disappear from water and empty acceptors disappear in the alcohol. Consequently, the side chain of tryptophan is significantly more hydrophilic³⁶⁴ than is indicated by its solubility in ethanol or its transfer between water and 1-octanol, two proposed measurements of its hydrophobicity.^{174,175} Because a solution of protein has, as does ethanol or 1-octanol, more acceptors than donors, similar imbalances of donors and acceptors have a major effect on the distribution of amino acids between the surface and the interior of a molecule of protein or the coupling of the donors and acceptors of hydrogen bonds withdrawn from water during the process of folding the polypeptide.

One example of the strong tendency of tryptophan to retain its hydrogen bond with water occurs in the structure of the Bence-Jones protein Rhe. A tryptophan in the center of the crystallographic molecular model of this protein, though completely buried, is engaged in a hydrogen bond with a buried molecule of water sitting next to its indole nitrogen (Figure 6-39).²⁸⁰ This molecule of water is trapped in the interior during the folding of the polypeptide, and its two donors are hydrogen-bonded in turn to two acyl oxygens from the backbone. In γ -II crystallin, two of the tryptophans are also hydrogen-bonded to buried molecules of water.¹⁶⁸ Usually, however, tryptophan retains the hydrogen bond to the nitrogen-hydrogen bond of its indole in less dramatic ways. For example, all of the donors in the indoles of the tryptophans of chymotrypsin retain hydrogen bonds with the solvent or another acceptor in the interior.¹⁷ The other two tryptophans in γ -II crystallin form hydrogen bonds with acyl oxygens.¹⁶⁸ In deoxyribonuclease I, all of the tryptophans, though mostly buried, retain contact with the solvent at their nitrogen-hydrogen bonds.⁸ The indole nitrogen-hydrogen bond of Tryptophan 21 in the lipoyl domain of dihydrolipoyllysine-residue acetyl-

transferase from *B. stearothermophilus*, which does not fully exchange with $^2\text{H}_2\text{O}$ in the solvent over 3 years, is well buried in the core of the protein but hydrogen-bonded to the acyl oxygen of Proline 61.³⁶⁵

There are also other anecdotal instances in which the **requirement that donors must be occupied** seems to be expressed. Arginine is one of the best examples. When it is partially buried, all of the five hydrogen-bond donors on the guanidinium are provided with acceptors (Figure 6–41).³⁶⁶ In the binding site on trypsin with which both arginine and lysine associate normally, there is a constellation of acceptors that can occupy in turn the five donors on the former and the three donors on the latter even though the dispositions of those donors do not overlap. Consequently, there are empty acceptors in each complex but never empty donors.³⁶⁷ When Tyrosine 385 in 4-hydroxybenzoate 3-monooxygenase is mutated to a phenylalanine, it creates an empty acceptor on Tyrosine 201 and nothing happens, but when Tyrosine 201 is mutated to phenylalanine, it creates an empty donor on Tyrosine 385 and a molecule of water is found in the crystallographic molecular model sitting where the hydroxyl of Tyrosine 201 used to be and occupying that donor.³⁶⁸ When an unoccupied hydrogen-bond donor in the complex between a peptide and penicillopepsin is replaced with a methylene group, the inhibitor binds 400 times more tightly.³⁶⁹ “The pH dependence of chromate binding and the extremely low affinity of phosphate are attributable mainly to the lack of hydrogen bond acceptors in the binding site” of sulfate-binding protein from *Salmonella typhimurium*.³⁷⁰

The difference in the importance of a donor and that of an acceptor affects the magnitude of the free energy of formation of a hydrogen bond in a protein, but so does its location in the structure. One of the unexpected observations resulting from an examination of crystallographic molecular models is the high frequency with which hydrogen bonds between donors and acceptors, each from the protein itself, occur on the surface of the folded polypeptide.¹⁶⁸ Because of the strong hydration of ions or the high relative permittivity of liquid water or both of these factors, ionized hydrogen bonds between monovalent anions such as formates or acetates and monovalent cations such as alkyl ammoniums, imidazoliums, or guanidiniums have negligible standard free energies of formation in aqueous solution.³⁷¹ Consequently, ionized hydrogen bonds on the surface of a molecule of protein should be unstable, but so should neutral hydrogen bonds because the competition for the donors and acceptors by the water surrounding them should prevent them from forming.

Many of the hydrogen bonds found on the surface of a crystallographic molecular model are **artifacts** of the constraints applied during refinement. If potential energies that favor rather than disfavor the formation of an ion pair or a hydrogen bond are incorporated advertently or inadvertently into the procedure for refinement, ionized

and un-ionized hydrogen bonds will form during the refinement rather than in the actual protein. Such fantastical hydrogen bonds on the surface of a crystallographic molecular model tend to appear and disappear as further refinement is performed and as the data set is extended to narrower Bragg spacing. For example, a set of 12 hydrogen bonds on the surface of myoglobin between pairs of amino acid side chains in which both of the partners have been conserved by natural selection throughout all myoglobin sequences had been identified in a refined molecular model of the protein.³⁰ When the Bragg spacing of the data set was decreased and the refinement significantly improved,³⁷² seven of these hydrogen bonds, four of which had been between oppositely charged side chains, were no longer present in the crystallographic molecular model.* All assignments of hydrogen bonds between two amino acid side chains on the surface of a protein should be regarded with skepticism unless properly calculated **omit maps** clearly indicate their existence.†

Nevertheless, hydrogen bonds, both ionized and un-ionized, probably do exist on the **surface of a protein**. When they do, there are probably particular reasons for their existence. **Steric effects** of neighboring amino acids and the backbone of the polypeptide can bring a donor and acceptor together in an orientation such that **entropy of approximation** sufficient to overcome solvation of ions and competition by water is realized. It is also possible that these hydrogen bonds are simply the random result of the participation of all of the donors and acceptors on the surface of the molecule of protein in the hydrogen-bonded network of the water surrounding it (Figure 6–38). In this case, these hydrogen bonds would be only the fortuitous outcome of the fact that the positions of these donors and acceptors in the larger lattice happen to be adjacent to each other. This hydrogen-bonded network of waters and donors and acceptors from the protein itself should be a rather fluid structure. The crystallographic molecular model represents only the structure of lowest energy in a constantly fluctuating environment. One observation, however, suggesting that some of these hydrogen bonds on the surface of the crystallographic molecular model are real is that they have negative standard free energies of formation.

The standard free energies of formation for hydrogen bonds seen in the crystallographic molecular models of proteins have been estimated by site-directed mutation. It is not possible to make an accurate estimate of the standard free energy of formation of such a hydrogen bond by mutating only one member of the pair.³⁷³ A single mutation will always have steric, hydrophobic, and electrostatic effects associated with it that are unrelated to the

* C. Chothia and A.M. Lesk, personal communication.

† This is yet another instance in which omit maps must be used to position atoms correctly and eliminate the artifacts inherent in the constraints applied during refinement by simulated annealing.

loss of the hydrogen bond itself but that cannot be separated from the change in standard free energy for only the loss of the hydrogen bond. To correct for these effects, a double-mutant cycle is performed.³⁷⁴ A **double-mutant cycle** is a set of three site-directed mutations: the single mutation of the donor in the hydrogen bond, the single mutation of the acceptor in the hydrogen bond, and the double mutation of both. The four standard free energies of folding of these three mutants and the unmutated wild-type protein are then measured, and they are used to create a linkage relationship:

where DA is the wild-type protein, MA is the single mutant of the donor, DM is the single mutant of the acceptor, and MM is the double mutant. The change in standard free energy $\Delta G_{\text{DA}}^{\circ}$ is the change in free energy of folding when the donor is mutated in the presence of the acceptor; $\Delta G_{\text{DM}}^{\circ}$, when the donor is mutated in the absence of the acceptor; $\Delta G_{\text{AD}}^{\circ}$, when the acceptor is mutated in the presence of the donor; and $\Delta G_{\text{AM}}^{\circ}$, when the acceptor is mutated in the absence of the donor. By definition

$$\Delta G_{\text{DA}}^{\circ} + \Delta G_{\text{AM}}^{\circ} = \Delta G_{\text{AD}}^{\circ} + \Delta G_{\text{DM}}^{\circ} \quad (6-8)$$

Each of these changes in standard free energy is the difference* in the standard free energies of folding between the two proteins connected by the respective arrows defining the mutation. A positive value for the difference states that the mutant version is less stable than the unmutated version. Conveniently, although the actual standard free energy of folding of a protein cannot be estimated accurately, differences in standard free energy of folding can.³⁷⁵

The **free energy of formation of the hydrogen bond** $\Delta G_{\text{AHB}}^{\circ}$ (Table 6-6) should be

$$\Delta G_{\text{AHB}}^{\circ} = \Delta G_{\text{DM}}^{\circ} - \Delta G_{\text{DA}}^{\circ} = \Delta G_{\text{AM}}^{\circ} - \Delta G_{\text{AD}}^{\circ} \quad (6-9)$$

For example, in the crystallographic molecular model of ribonuclease from *Bacillus amyloliquifaciens*, there is an

* As is usually the case in physical chemistry, the difference is the standard free energy of folding for the product of the mutation minus that for the unmutated protein, the reactant.

Table 6-6: Standard Free Energy of Formation of Hydrogen Bonds in Proteins Estimated from Double-Mutant Cycles^a

donor/acceptor	location ^b	$\Delta G_{\text{AHB}}^{\circ c}$ (kJ mol ⁻¹)
lysinium/glutamate ³⁷⁶	surface	-2.3
argininium/aspartate ³⁷⁷	surface	-0.9
argininium/aspartate ³⁷⁷	surface	-2.0
aspartate/argininium/aspartate ^{d 377}	surface	-3.3
amino terminus/glutamate ³⁷⁸	surface	-6.3
lysinium/glutamate ³⁷⁸	surface	0.0
serine/aspartate ³⁷⁹	buried	-5.7
lysine/threonine ³⁸⁰	buried	-6.3 ^e
arginine/glutamate ³⁸⁰	buried	-7.1 ^e
arginine/aspartate ³⁸⁰	buried	-27 ^{ef}
histidine/aspartate ³⁸⁰	buried	-20 ^e

^aWhere available, values were for measurements derived from the standard free energies of folding or standard free energies of association at an ionic strength close to that encountered in cytoplasm (0.15–0.2 M). ^bBased on a crystallographic molecular model of the protein. ^cStandard free energy of formation calculated from double-mutant cycles by Equation 6-9. ^dTriple-mutant cycle; standard free energy is for the mean of the two hydrogen bonds. ^eEstimated from free energies of association rather than free energies of folding. ^fMean of two hydrogen bonds.

ionized hydrogen bond between Arginine 110 and Aspartate 8. The difference in free energy of folding between the protein with both the arginine and the aspartate and a mutant in which Arginine 110 is replaced with alanine, $\Delta G_{\text{DA}}^{\circ}$, is -3.3 kJ mol⁻¹; that between the mutant in which Aspartate 8 is replaced with alanine and the double mutant, $\Delta G_{\text{DM}}^{\circ}$, is -4.2 kJ mol⁻¹; that between the protein with both the arginine and the aspartate and the mutant in which Aspartate 8 is replaced with alanine, $\Delta G_{\text{AD}}^{\circ}$, is +2.3 kJ mol⁻¹; and that between the mutant in which Arginine 110 is replaced with alanine and the double mutant, $\Delta G_{\text{AM}}^{\circ}$, is +1.4 kJ mol⁻¹. Therefore, the free energy of formation of the hydrogen bond³⁷⁷ is -0.9 kJ mol⁻¹. The single mutations of each member of this particular pair would have led to contradictory conclusions concerning the strength of the hydrogen bond; on the one hand that it was endergonic and on the other that it was exergonic.

As expected, the hydrogen bonds between donors and acceptors on the surface of a protein have **marginal stability** (Table 6-6) and are in the range observed for similar hydrogen bonds on an isolated α helix (Table 5-7). The standard free energies of formation for buried hydrogen bonds, however, are significantly more favorable, again as expected. Hydrogen bonds found in buried locations of a molecule of protein are removed from competition with water, found in a region of lower relative permittivity, and fixed more rigidly in their orientations than hydrogen bonds on the surface. All three of these circumstances should significantly increase their stability relative to those on the surface, so it is surprising that the differences observed are as small as they are.

Even the value for the standard free energy of for-

mation of a particular hydrogen bond in a protein obtained by a double-mutant cycle is not completely free of contributions from interactions with neighboring amino acids. When all of the amino acids in a cluster of hydrogen bonds surrounding the hydrogen bond between Arginine 218 (TEM) and Aspartate 49 (BLIP) in the complex between β -lactamase TEM-1 from *E. coli* and its inhibitor protein BLIP were mutated to alanine, the standard free energy of formation of that hydrogen bond increased from -9 to $+1$ kJ mol^{-1} .³⁸¹ Similar increases of 4 – 6 kJ mol^{-1} were observed when the amino acids surrounding three other hydrogen bonds in the same cluster were mutated to alanine. Consequently, the standard free energies of formation listed in Table 6–6 may be only **lower limits** of the value for that hydrogen bond in the absence of assistance from its surroundings.

Approximation is probably the greatest contributor to the stability of a buried hydrogen bond between two side chains. Following formation of the secondary structure and the alignment of secondary structures by packing, the donor and acceptor of a buried hydrogen bond should be efficiently aligned and a considerable amount of entropy of approximation should have been realized, yet the free energies of formation of such buried hydrogen bonds are less than -30 kJ mol^{-1} in the most advantageous circumstances (Table 6–6). The wide variability in the standard free energies of formation could reflect wide differences in the success with which donor and acceptor are aligned given all of the steric problems of the interior of a protein.

There are other experimental observations suggesting that approximation is not so successful as it should be. In a series of tight complexes (dissociation constants less than 750 nM) between thermolysin and a set of ligands that bind to its active site, when the respective nitrogen–hydrogens of the phosphoramidates in the ligands, which each form a hydrogen bond with the acyl oxygen of Alanine 113 in the crystallographic molecular model of the complex,³⁸² were replaced with methylenes, the association constants for the ligands remained the same.³⁸³ When corrected for the removal of the two hydrogen–carbon bonds of the methylene from water, the standard free energy of formation for this buried, rigidly aligned hydrogen bond is -6 kJ mol^{-1} , well within the range of those for buried hydrogen bonds in Table 6–6 but not anywhere near the value predicted from the entropy of approximation that must be realized. Even more surprising is that when the amido nitrogen–hydrogen of a hydrogen bond in the middle of an α helix of T4 lysozyme was replaced with an ester oxygen, the free energy of folding of the protein increased³⁸⁴ by 7 kJ mol^{-1} , but that increase was indistinguishable from the increase expected for the enthalpy of formation of the hydrogen bond between the acyl oxygen of the ester, relative to the acyl oxygen of the unmutated amide, and the nitrogen–hydrogen with which it forms a hydrogen bond.³⁸⁵ In other words, these latter experiments suggest that the

free energy of formation of a hydrogen bond in the middle of an α helix in a protein is indistinguishable from 0 , even though considerable entropy of approximation is realized. All of these results emphasize that it is difficult to form a hydrogen bond in an aqueous solution.

Even though there are hydrogen bonds in a molecule of protein that do have negative standard free energies of formation, it is the structure of the protein that approximates the donor and the acceptor, causing their hydrogen bond to become stable. It is this approximation that overcomes, in many cases meagerly, the otherwise overwhelming competition of the water for the donors and acceptors. The folding of the protein that approximates the donor and acceptor in such a hydrogen bond is driven entirely by the hydrophobic effect. It is only after the hydrophobic effect has collapsed the random coil, withdrawn the donors and acceptors from water, and excluded water from the interior that the hydrogen bonds of the α helices and β structure are able to form. It is only when the hydrophobic effect, expressed as the minimization of the internal volume of the protein, has locked the secondary structures into the tertiary structure, that donors and acceptors of hydrogen bonds between side chains are brought close enough together and are constrained sufficiently that they can form otherwise unfavorable hydrogen bonds. It is only after all of this prelude that the observed hydrogen bond has a lower standard free energy of formation than the hydrated, separated donor and acceptor had in the unfolded polypeptide.

It is the case that such favorable free energy of formation adds to the **stability of the protein**, but this is an illusory contribution. The amino acid sequence of the protein and hence the location and identity of each side chain in its structure is the result of evolution by natural selection. The hydrogen-bonded pair of side chains that currently occupies a particular location in the structure could have been chosen because it was the constellation of atoms that sterically filled that particular location in the structure most effectively relative to all of the other possibilities that were tried, not because it is a hydrogen bond. It has a favorable free energy of formation because the two side chains that were chosen for these other reasons, happened to end up with a donor and an acceptor adjacent to each other. The hydrogen-bonded pair is not necessarily the most energetically favorable pair of side chains that could have occupied that position. In fact, even though it was not so astute a process as evolution by natural selection that determined the choice of the replacements, it is sometimes the case that the double mutant in a double-mutant cycle or even one of the single mutants is as stable as the wild type containing the hydrogen bond.

The relationship between the strength of a hydrogen bond and the **difference in pK_a between donor and acceptor** (Figure 5–14) has been verified in the context of a molecule of protein. As the pK_a of Tyrosine 27 in micro-

coccal nuclease from *Staphylococcus aureus*, which forms a hydrogen bond with Glutamate 10, was lowered by substituting various fluorinated tyrosines, the free energy of folding of the protein, presumably reflecting the decreases in the free energy of formation of the hydrogen bond, decreased³⁸⁶ by 2.0 kJ mol⁻¹ (unit of p*K*_a)⁻¹. This value for the Brønsted coefficient is near that observed (Equation 5–37) for a hydrogen bond in CCl₄ [1.3 kJ mol⁻¹ (unit of p*K*_a)⁻¹]. This increase in strength, as the increase in the acidity of the phenolic side chain matches its p*K*_a more closely with that of the glutamate, suggests that, as in other situations, the hydrogen bond between an acid and its conjugate base should be a strong one.

In crystallographic molecular models there are examples of **hydrogen bonds between an acid and its conjugate base**. In turkey troponin C, Glutamate 57 forms a geometrically ideal hydrogen bond with Glutamate 88 in which it is unknown on which carboxylate the proton resides.²⁴ There is no experimental indication, however, that such hydrogen bonds are unusually stable. The histidinium ion in the hydrogen bond between Histidine 24 and Histidine 119 in sperm whale myoglobin has a p*K*_a of 6.0.³⁸⁷ If this were a particularly stable interaction, the p*K*_a of the acid dissociation that eliminates it should have been much higher (Table 2–2). The hydrogen bond³⁸⁸ between Lysine 206 and Lysine 296 of human transferrin, although necessarily lowering the values of p*K*_a for the lysines participating in it,³⁸⁹ has been shown to destabilize the protein.^{390–392}

No evidence has been presented that hydrogen bonds between acids and their conjugate bases in proteins display properties associated with low-barrier hydrogen bonds, but hydrogen bonds displaying one such property, a low **fractionation factor** (Equation 5–31), have been identified in proteins. The fractionation factor ϕ for a proton in a hydrogen bond in a protein is measured by following the fraction, f_{AHB} , of the hydrogen bond of interest that remains undeuterated, AH⊙B, as a function of the mole fraction $x_{\text{H}_2\text{O}}$ of undeuterated water in a series of mixtures of H₂O and D₂O

$$x_{\text{H}_2\text{O}} = \frac{[\text{H}_2\text{O}]}{[\text{H}_2\text{O}] + [\text{D}_2\text{O}]} \equiv \frac{[\text{L}_2\text{O}\odot\text{HOL}]}{[\text{L}_2\text{O}\odot\text{HOL}] + [\text{L}_2\text{O}\odot\text{DOL}]} \quad (6-10)$$

where L again stands for either H or D.

A physical property that monitors the concentration of the undeuterated hydrogen bond, such as the intensity (i_{AHB}) of the absorption of its proton in a nuclear magnetic resonance spectrum is monitored.^{393,394} Equations 5–31 and 6–10 can be combined to give³⁹⁵

$$\frac{i_{\text{AHB}}}{i_{0,\text{AHB}}} = \frac{[\text{AH}\odot\text{B}]}{[\text{AL}\odot\text{B}]} \equiv f_{\text{AHB}} \equiv \frac{x_{\text{H}_2\text{O}}}{\phi(1 - x_{\text{H}_2\text{O}}) + x_{\text{H}_2\text{O}}} \quad (6-11)$$

where [AL⊙B] is the total concentration of hydrogen bonds, both deuterated and protonated; and $i_{0,\text{AHB}}$ is the intensity of the absorption in H₂O. The normalized intensity of the absorption of the proton in the hydrogen bond as a function of $x_{\text{H}_2\text{O}}$ is fit by nonlinear least squares to Equation 6–11 to obtain ϕ .

In this way, the fractionation factors for the protons within the hydrogen bonds of the secondary structure of a protein can be measured. There are results suggesting that a significant portion of these protons have fractionation factors less than 1. For example, 13 of the 87 amino acids in the phosphocarrier protein HPr from *Bacillus subtilis*³⁹⁴ and 36 of the 231 amino acids in micrococcal nuclease from *S. aureus*³⁹³ have been reported to have amido protons with fractionation factors less than 0.80, and six of the 76 amino acids in ubiquitin have fractionation factors less than 0.90.³⁹⁶ There is some uncertainty to these measurements because it is quite difficult to equilibrate all of the protons in the hydrogen bonds of the secondary structure of a protein with deuterons in the solution,³⁴⁰ and an unequilibrated position would appear artifactually to have a low fractionation factor (Equation 5–31). In more recent studies of the fractionation factors of protons in streptococcal protein G³⁹⁷ and the SH3 domain of proto-oncogene protein-tyrosine kinase from *Gallus gallus*,³⁹⁶ none of the protons in the nitrogen–hydrogens of the backbone had fractionation factors less than 0.9. Nevertheless, it is thought to be the case that some of the protons in the hydrogen bonds of the secondary structure of many proteins have **abnormally low fractionation factors**.³⁹⁶

There also seems to be a correlation between the fractionation factor of a proton and the **length of the hydrogen bond** that it occupies in a crystallographic molecular model of a protein.³⁹⁷ In crystallographic molecular models built from data sets to Bragg spacing of less than 0.1 nm, the maps of electron density are accurate enough that the bond lengths of the hydrogen bonds are of sufficient reliability to identify those that are abnormally short,^{398–400} and there are usually a few abnormally short hydrogen bonds (0.26–0.28 nm) among those between amido nitrogen–hydrogens and acyl oxygens of the backbone.³⁹⁸ It is thought that such shortened hydrogen bonds are the ones that display low fractionation factors and therefore are low-barrier hydrogen bonds.³⁹⁷

It is not possible, however, for these short low-barrier hydrogen bonds to be strong hydrogen bonds³⁹⁶ because the difference in p*K*_a between the nitrogen–hydrogen (p*K*_a = 16) and the oxygen (p*K*_a = –0.5) is so large and any decrease in polarity would only widen the difference. Whenever a polymer as long and heterogeneous as a molecule of protein is folded into a unique conformation, it is hard to believe, in spite of evolution by natural selection, that all of the steric problems can be solved. There must be some places in the structure that are tight fits. When such a tight fit occurs at a hydrogen

bond between an amido nitrogen–hydrogen and acyl oxygen of the backbone, the hydrogen bond shortens to relieve the **strain**, much as the hydrogen bond in hydrogen maleate monoanion shortens in response to the steric compression. This shortened hydrogen bond must be weaker than the unshortened bond because there is repulsion energy in the compressed case that would be relieved on relaxation to the normal distance. This shorter but weaker hydrogen bond has a smaller fractionation factor because this property is determined only by the degree of overlap of the wells of potential energy confining the proton on the donor and the acceptor. It is a low-barrier hydrogen bond not because the strength of the bond has brought donor and acceptor together but because the contraction of the distance is imposed by the rest of the framework. It has also been concluded from studies of complexes between proteins and small ligands that there is no correlation between the length of a hydrogen bond and its strength.⁴⁰¹

Horovitz, A., Serrano, L., Avron, B., Bycroft, M., & Fersht, A. (1990) Strength and co-operativity of contributions of surface salt bridges to protein stability, *J. Mol. Biol.* 216, 1031–1044.

Problem 6–9: Aspartate 12 and Arginine 16 are located in an α helix on the surface of a mutant of the ribonuclease from *B. amyloliquifaciens*. The arginine and the aspartate do not form an ionized hydrogen bond in the crystallographic molecular model of the enzyme from the closely related species, *Bacillus intermedius*, even though they are close enough to each other to do so. Three mutants were produced in the ribonuclease from *B. amyloliquifaciens*: Arginine 16 \rightarrow threonine, Aspartate 12 \rightarrow alanine, and the corresponding double mutant. The differences in standard free energies of folding for the three mutants and the original protein were as follows:

	difference in standard free energy of folding (kJ mol ⁻¹)	
	ionic strength = 0.1 M	ionic strength = 0.55 M
ΔG°_{RD}	2.1	1.8
ΔG°_{RA}	1.7	2.0
ΔG°_{DR}	1.8	1.0
ΔG°_{DT}	1.4	1.2

where ΔG°_{RD} is for mutation of Arginine 16 in the presence of aspartate at position 12; ΔG°_{RA} , for mutation of Arginine 16 in the presence of alanine; ΔG°_{DR} , for mutation of Aspartate 12 in the presence of arginine at position 16; and ΔG°_{DT} , for mutation of Aspartate 12 in the presence of threonine.³⁷⁵

- (A) Estimate the interaction between Arginine 16 and Aspartate 12 at the two ionic strengths.

- (B) The uncertainty in your calculated values was estimated by the authors to be ± 0.2 kJ mol⁻¹. Is the electrostatic interaction significantly different from zero at physiological ionic strength? Is this surprising?
- (C) What conclusion would you have reached had only Arginine 16 been mutated?

Problem 6–10:

- (A) Write out the amino acid sequence of the protein in the drawing below of a crystallographic molecular model. This drawing was produced with MolScript.⁵⁷³
- (B) List the pairs of cysteines that participate in the cystines.
- (C) What structural feature of a cystine is illustrated by the model?
- (D) Identify the participants in a small hydrophobic cluster.
- (E) List as a pair the donor and the acceptor of each of the hydrogen bonds in the model by the letter and number of its respective amino acid and by the respective designation defined in Figure 4–14 for the atom participating in the hydrogen bond.
- (F) Which hydrogen bonds are probably artifacts of the procedure used to refine the molecular model?

Problem 6-11

Problem 6-11: The two stereo drawings to the right represent portions of the crystallographic molecular models of two proteins.^{274,366} These drawings were produced with MolScript.⁵⁷³

Each of the hydrogen bonds in each stereo drawing is numbered in the figure. Draw the chemical structure of each hydrogen bond in the two stereo drawings. Number each of your drawings with the number for the hydrogen bond assigned in the figure. There are two hydrogen bonds numbered 5 for the same acceptor. Draw all of the lone pairs and all of the hydrogens on each functional group providing the donor and on each functional group providing the acceptor. For example, the correct chemical structure of hydrogen bond number 1 is

Association of Proteins with Nucleic Acid

It is during the association of proteins with nucleic acids that the importance of packing, the existence of fixed positions for molecules of water, the irrelevance of direct compensation of charge, and the stereochemical role of hydrogen bonding are all manifest. A **double helix of DNA** (Figure 3-9)* presents to the protein designed to associate with it a regular structure that can be recognized by its peculiar shape, its pattern of hydration, its high density of negative charge, and its array of donors and acceptors of hydrogen bonds.

Along each of the two **phosphodiester backbones**, there are regularly spaced pairs of **phosphoryl oxygens** on each phosphorus in each phosphodiester linkage. Within each pair, the two oxygens share between themselves the single negative elementary charge of the phosphoryl group and are directed outward at the sp^3 angle of 109.5° , and each oxygen has the equivalent of two acceptors for hydrogen bonds.

The **pairs of bases** contain their own internal hydrogen bonds, two for the pair between adenine and thymine and three for the pair between guanine and cytosine, and these are located in the core of the structure. Although there are a small number of proteins that can induce a single base to swing out of the stack, thus exposing both itself and its interior donors and acceptors,^{402,403} this conformational change is a difficult one. Most proteins bind to DNA in its normal conformation and never see these hydrogen bonds in the core. The pairs of bases are **stacked** one upon the other, but they

* You should trace the two polynucleotide backbones (O-C-furanose-O-P-O-C-furanose-O-P-...) through the double helix.

do not overlap entirely. Consequently they are a helical staircase but one with narrow treads.

There are two helical grooves, the **major groove** and the **minor groove** (facing the viewer in the upper half and lower half, respectively of Figure 3-9), the former wider than the latter. It is in these grooves that the narrow treads of the stairs are found. Each pair of bases projects a characteristic pattern of donors and acceptors into each groove. The pair of adenine and thymine projects a methyl group, an acceptor, a donor, and an acceptor into the major groove and two acceptors into the minor groove; and the pair of guanine and cytosine projects an acceptor, an acceptor, and a donor into the major groove and an acceptor, a donor, and an acceptor into the minor groove. The order and orientation of these donors and acceptors differs between a guanine-cytosine pair (6-13) and a cytosine-guanine (6-14) pair and between an adenine-thymine pair (6-15) and a thymine-adenine pair (6-16):⁴⁰⁴

so that a sequence containing a G can be distinguished from one containing a C; and a sequence containing an A, from one containing a T.

All of these donors and acceptors of hydrogen bonds provide fixed positions for occupation by molecules of water, but not all of them are firmly occupied. Each segment of DNA has its own characteristic pattern of fixed positions for molecules of water (open circles in Figure 3-9), and it has been observed that when a molecule of protein binds to DNA, some of these positions remain occupied within the complex.⁴⁰⁵ Consequently, the donors and acceptors on these molecules of water that are incorporated into the complex, as well as those provided by the bases in the major groove and the minor

groove and those along the backbone, all provide keys for the recognition of the double-helical DNA by the protein.

There are two **levels of recognition** on which proteins operate in binding to DNA. Certain proteins are required by their function to recognize any segment of double-helical DNA regardless of its sequence. Examples of such proteins are histones that form chromatin from DNA, the RecA protein that catalyzes recombination, helicase and DNA-directed DNA polymerase that are components of the system replicating DNA, and DNA topoisomerase that passes one segment of DNA through another. These proteins recognize only the overall shape of a molecule of DNA and the acceptors along its phosphodiester backbone. Other proteins are required by their function to recognize specific sequences of double-stranded DNA and bind tightly to them. Examples of such proteins are repressors that shut off certain genes, transcription factors that initiate transcription at certain genes, and activators that increase the rates of transcription of certain genes. Many of these latter proteins are able to bind to any segment of a double helix of DNA and then run along the double helix until they reach their targets, and proteins of this type must perform both levels of recognition. Such proteins demonstrate that the ability to recognize specific sequences is a special case of the ability to recognize DNA in general.

One property of the proteins that recognize DNA is that their composition is biased against negatively charged amino acids and in favor of **positively charged amino acids**.⁴⁰⁶ On the open surfaces of these proteins that do not participate in the complexes with DNA, the density of glutamates and aspartates is the same as that on the open surface of any other protein, but in the interfaces between these proteins and DNA, the density of glutamates and aspartates is about 40% of that found in the interfaces between two molecules of protein. On the open surfaces, the density of arginine and lysine in these proteins is 30% greater than that on the open surfaces of other proteins, but at the interfaces between these proteins and DNA, the density of lysines and arginines is 2.5 times that in the interfaces between two molecules of protein. These equivalent biases against electrostatic repulsion and in favor of electrostatic attraction are reasonable responses to the high density of negative charge on the DNA to which these proteins must bind.

These overall biases, however, are distributed evenly over the interface between protein and DNA and not focused only on the **phosphodiester**s within it. Although lysines and arginines do provide donors to the acceptors on the phosphodiester backbone,⁴⁰⁷ they do so no more frequently than other amino acids. For example, in the crystallographic molecular model of the complex of DNA with rat DNA polymerase β , only one of the donors to the phosphodiester is the guanidinium of an arginine; the other nine are nitrogen-hydrogens from the polypeptide backbone and hydroxyls of a tyrosine and a threonine.⁴⁰⁸ In the crystallographic molecular model of the complex

between DNA and the regulatory protein Cro from bacteriophage 434, many of the donors to the phosphoryl oxygens are amido nitrogen–hydrogens from the polypeptide backbone,⁴⁰⁹ while in that between DNA and the regulatory protein Cro from bacteriophage λ , a tyrosine, a threonine, an asparagine, a glutamine, and two amido nitrogen–hydrogens from the backbone provide donors to phosphoryl oxygens (Figure 6–45).⁴¹⁰ In the complex between topoisomerase I and DNA, hydrogen-bond donors to the phosphoryl oxygens are provided by an

Figure 6–45: Recognition of phosphoryl oxygens on DNA by donors of hydrogen bonds from the amino acids in a protein.⁴¹⁰ The interactions depicted are from the crystallographic molecular model (Bragg spacing ≥ 0.30 nm) of the complex between regulatory protein Cro from bacteriophage λ (66 aa) and the double-helical duplex between d(ACATACACCGGGGTGATAC) and d(TGATACACCGGGGTGATAG). The portion of the model displayed is the double-helical duplex between d(ACATACAC) and d(TGATAG) and the protein from Glycine 15 to Asparagine 31. Tyrosine 26, Asparagine 31, Glutamine 16, Threonine 17, and the amido nitrogen–hydrogens from the backbone at positions 16 and 26 form hydrogen bonds with the phosphoryl oxygens of five bases. Only those hydrogen bonds between donors and acceptors on the protein and acceptors and donors on the DNA are drawn. Note the double hydrogen bond between Glutamine 27 and an adenine. This drawing was produced with MolScript.⁵⁷³

asparagine and a histidine among others.⁴¹¹ And in three successive phosphodiester in the complex between deoxyribonuclease I and DNA, an arginine, two histidines, an aspartic acid, an asparagine, a tyrosine, and a threonine provide the donors.⁴¹²

Donors to phosphoryl oxygens are also provided by molecules of water that are incorporated into the complex and form bridges to donors and acceptors on the protein.⁴¹³ In the complex between the repressor from bacteriophage λ and DNA, five amido nitrogen–hydrogens, two lysines, two tyrosines, five asparagines, two glutamines, and 11 waters together provide all of the donors for the 10 phosphodiester in contact with the protein.^{414,415}

Some proteins that recognize only DNA and not specific sequences within it use the regularity of its double-helical structure as a key. For example, each of the octameric complexes of histones around which the DNA winds in chromatin has a surface with a repeating pattern that matches the helical repeat of DNA.⁴¹⁶

Proteins that are required to associate with **specific sequences in DNA**, rather than simply DNA in general, recognize the patterns of donors and acceptors for hydrogen bonds in its grooves in addition to providing donors and acceptors of hydrogen bonds for the phosphodiester backbone and its associated water. The **major groove** in the DNA is the main key used by a protein in recognizing a specific sequence of base pairs. It is in the major groove that the patterns of donors and acceptors projected outward by the pairs of bases (**6–13**, **6–14**, **6–15**, and **6–16**) are the most legible. The protein usually inserts one or two of its segments of polypeptide into the major groove. Often it is an **α helix**. For example, the c-Jun subunit of transcription factor AP-1 (Figure 6–46)⁴¹⁷ and the ETS-domain protein Elk-1⁴¹⁸ insert α helices into the major groove. Such an α helix can participate in hydrogen bonds with donors and acceptors from as many as five⁴¹⁹ or six base pairs⁴¹⁸ in the major groove as well as donors and acceptors on riboses and phosphoryl oxygen from additional base pairs. In the case of the c-Jun subunit of transcription factor AP-1, the α helix inserted into the major groove is the splayed end of one strand of an α -helical coiled coil (Figure 6–29). In each of these complexes the α helix runs along the groove.

Other proteins, such as the *met* repressor from *E. coli*,⁴²⁰ the replication terminator of *E. coli*,⁴²¹ and the *arc* repressor from *E. coli*,⁴²² insert two strands of **β structure** running parallel to the major groove. The α helix or strands of β structure inserted into the major groove provide donors and acceptors to the acceptors and donors projected into the groove by the pairs of bases.

The **hydrogen bonds** formed during the reading of these patterns (Figure 6–47)⁴²³ are as varied as one might expect. A common pair is the double hydrogen bond between a guanine and an arginine (Figures 6–46 and 6–47),^{417,424–428} either at the two η nitrogens of the arginine (Figure 6–46)

6-17

or at one of its η nitrogens and its ϵ nitrogen (Figure 6-47),^{418,423} Arginine also can span two bases, offering a donor to an acceptor on each. Lysine, with its three donors, is often found occupying a single acceptor on a base or spanning two bases.^{429,430} In fact, it is in providing donors to acceptors for the neutral bases, rather than for the negatively charged phosphoryl oxygens, that arginine and lysine seem to be most frequently employed.

Another common hydrogen bond is that between a glutamine or an asparagine and adenine (Figure 6-45)^{414,422,431}

6-18

but often glutamine or asparagine (Figure 6-46)^{417,421,429} or even aspartate (Figure 6-47) bridges a donor on one base and an acceptor on its neighbor. Other donors and acceptors are commonly provided by histidine, serine, and threonine. Aspartate⁴³² can provide an acceptor; tyrosine,⁴²⁶ a donor and an acceptor; tryptophan,⁴³³ a donor; and cysteine,⁴²⁹ a donor and an acceptor. The nitrogen-hydrogen of a cytosine located in the major groove (6-14) makes a hydrogen bond with the π system of a tryptophan in the complex between transcription factor Rob and its cognate DNA.⁴³⁴

Many of the amino acids providing donors and acceptors to the bases in the major groove are themselves **pinned by hydrogen bonds** at one or more of their other donors and acceptors to other amino acids in the protein (Figure 6-47), and some of these other donors and acceptors can make hydrogen bonds to phosphoryl oxygens from the backbone of the nucleic acid to buttress the hydrogen bonds in the center of the groove.^{414,435}

Although there are a few examples in which almost every donor and acceptor in the major groove forms a direct hydrogen bond to an acceptor or donor on the pro-

tein (Figure 6-47),⁴²³ usually a significant fraction of the donors and acceptors from the amino acids on the protein form hydrogen bonds with **waters** that were present at fixed positions in the major groove before the protein bound to it and were subsequently incorporated into the complex.⁴⁰⁵ These waters then bridge donors and acceptors on the protein and donors and acceptors on the DNA. They are as much a key for recognition of the DNA by the protein as the bases themselves. One dramatic indication of this fact is that in crystallographic molecular models of

Figure 6-46: α Helix of a protein running along the major groove of a segment of double-helical DNA and reading the donors and acceptors of its bases.⁴¹⁷ The protein in the crystals used to gather the data set for the crystallographic molecular model (Bragg spacing ≥ 0.3 nm) was only the bZIP region (Glutamate 256 to Methionine 313) of the human transcription factor AP-1 expressed in *E. coli*, and the portion displayed in the figure is only the α helix from Arginine 259 to Lysine 279 that fills the major groove of the DNA. Only the portion of the DNA containing the sequence d(AGTCATA) and its complement is displayed. Note the hydrogen bonds between Lysine 268 and Arginines 259 and 263 and phosphoryl oxygens. Four base pairs are recognized as well as phosphodiester on one base pair above and two base pairs below those four. This drawing was produced with MolScript.⁵⁷³

Figure 6-47: Hydrogen bonds formed in the major groove to all of the donors and acceptors on three consecutive base pairs.⁴²³ The crystallographic molecular model is for the complex between *NgbMV* type II site-specific deoxyribonuclease from *Neisseria gonorrhoeae* and the double helix of the self-complementary DNA d(TGGCCGGCGG). Only the portion of the protein—Alanine 33 to Serine 36, Serine 40, Threonine 189 to Alanine 195, Glutamate 222, and Arginine 227—that recognizes specific bases in the DNA and the portion of the DNA that it recognizes, d(GGC) and its complement d(GCC), are drawn. The latter segment of the DNA has been cleaved between its G and the next C by the site-specific deoxyribonuclease in the crystal. All hydrogen bonds are included in the drawing. Three arginines form hydrogen bonds with the three guanines (6-17), and Aspartate 193 spans two cytosines. Note that the carboxylates of Aspartate 193 and Aspartate 34 are both solvated by four nitrogen-hydrogens, three on one oxygen and one on the other of each. The open circles are the locations for oxygens of five molecules of water, one of which screens the carboxylate of Aspartate 193 from an adjacent phosphoryl group. This drawing was produced with MolScript.⁵⁷³

closely related but distinct complexes between related molecules of DNA and related molecules of protein, many of the waters occupy the same locations.⁴³⁶

Waters bridging donors and acceptors on the DNA and donors and acceptors on the protein are common features of the extensive network of hydrogen bonds found at the interface between protein and DNA in the major

groove (Figure 6-48).^{415,425,435} On average, within a crystallographic molecular model between a protein and a molecule of double-helical DNA there are 10 molecules of water that form hydrogen bonds with “both the protein and the DNA simultaneously and thus mediate recognition directly.”⁴³⁷ On average, six of these 10 sit between two acceptors, none between two donors, and four between an acceptor and a donor too distant to form a direct hydrogen bond. These 10 include molecules of water between donors and acceptors on the protein and acceptors on phosphoryl oxygens as well as donors and acceptors on the bases themselves. Many of the waters in such complexes reside between two functional groups with the same charge number and serve to screen the electrostatic repulsion (see for example Aspartate 193 in Figure 6-47).

In Figure 6-47, every donor and acceptor directed into the major groove by the three base pairs is occupied by an acceptor or donor from the protein with the exception of one, which is occupied by a molecule of water. In Figure 6-48, only five of the donors and acceptors directed into the major groove by the three base pairs are occupied, all five by molecules of water bridging DNA and protein. These are the two extremes of a continuously occupied spectrum of hydrogen bonding in the major groove.

The **methyl groups of the thymines** also project into the major groove (Figure 3-9) and are used as keys for recognition. In the crystallographic molecular model of a complex between DNA and a protein that recognizes a particular sequence, the methyl groups on thymine are provided hydrophobic contacts by the protein. For example, the propyl group of a valine,⁴³⁸ the phenyl group of a phenylalanine,⁴²⁹ the butyl group of an isoleucine,⁴³¹ the methylenes of an arginine,⁴²¹ the methyl group of an alanine,⁴¹⁸ or the methyl group of an alanine and the methylene of a serine (Figure 6-46) can cradle the methyl group of a thymine in the major groove.

Although it is narrower and more difficult to enter (Figure 3-9), the **minor groove** is also exploited by proteins recognizing specific sequences in the DNA. Usually, because it is so narrow, only a single loop of polypeptide is inserted into it,^{421,439,440} and a protein that inserts a segment of its polypeptide into the minor groove will also insert a sizeable segment into the adjacent major groove.^{441,442} The less formal arrangement in the minor groove permits even the amido nitrogen-hydrogens of the backbone to occupy acceptors projecting from bases.⁴⁴⁰ Otherwise, the donors and acceptors from the protein that occupy acceptors and donors in the minor groove are the same as those in the major groove. **Lysines**⁴²¹ and particularly **arginines**^{421,439,443,444} are common because their side chains are long, thin, and flexible, but even a short negatively charged aspartate can provide acceptors for donors in the minor groove.^{404,440}

It was originally believed, before crystallographic molecular models of these complexes became available,

that the problem of recognizing a specific sequence would simply require reading enough of the pattern of donors and acceptors in the major groove and minor groove and methyl groups from thymine in the major groove to make an unequivocal identification of the sequence. Although there are a few instances in which side chains on the protein are able to form hydrogen bonds to every donor and acceptor in the major groove (Figure 6-47),⁴²³ and usually many of these features are recognized by the protein either directly or through intervening molecules of water, it is often the case that fewer are recognized than would be necessary to make a positive identification.⁴²⁵ Consequently other strategies must be used to make a positive identification.

The most obvious of these is the use of **packing** to recognize shape, just as in the center of a molecule of protein the dense packing of the side chains of the amino acids is used to position the secondary structures. For the crystallographic molecular models of complexes between a protein and its complementary DNA, calculations of atomic volumes "performed in the presence and absence of water molecules, showed that protein atoms buried at the interface with DNA are on average as closely packed as in the protein interior. Water molecules contribute to the close packing, thereby mediating shape complementarity."⁴⁰⁶ This close packing means that the shape of the surface of the protein fits tightly into the shape of the surface of the DNA and its water, particularly in the major groove.⁴⁰⁵ As the **shape of the surface of the DNA** and water in the major groove represents its sequence, it is the shape of the surface of the protein as much as anything else that reads the sequence of the DNA.

Much of this complementarity in shapes is the networks of hydrogen bonds (Figure 6-47), but the hydrophobic hydrogen-carbon bonds of the protein also contribute to its complementary shape. In fact, there are hydrophobic side chains such as phenylalanines, leucines, and valines^{445,446} that are found in the interface between the protein and the major groove, the functions of which are not just to cradle the methyl groups of the thymines but to form a mold for the DNA. When one such side chain, Leucine 22 in the interface between DNA and transcription factor AREA, was mutated to a valine, the specificity of the transcription factor changed dramatically as it recognized a different set of sequences in the DNA.⁴⁴⁷

The structure of the protein looking for a particular sequence of DNA also recognizes **variation in the overall shape** of a segment of DNA produced by the particular sequence of bases it contains.^{405,425} For example, certain sequences of bases cause the minor groove to become narrower, and this feature of the DNA is recognized by the protein, often by the insertion of an arginine into the minor groove to gauge its width.^{443,448} Overwinding or underwinding of the DNA by particular sequences is recognized,^{420,449} as well as intrinsic curva-

ture of the double helix.⁴²⁵ This strategy of recognizing preexisting, sequence-dependent peculiarities in the structure of the DNA, however, is difficult to separate experimentally from a strategy of recognizing sequence-dependent differences in the resistance of the DNA to distortion by the protein because only rarely⁴⁰⁵ is the preexisting structure of the segment of DNA found in the crystallographic molecular model of the complex known.

When proteins bind specifically to a segment of

Figure 6-48: Incorporation of molecules of water into the interface between protein and DNA.⁴²⁵ The portion of the interface between protein and double-helical DNA displayed in the figure is from the crystallographic molecular model (Bragg spacing ≥ 0.19 nm) of the complex between the *trp* repressor from *E. coli* and a segment of double-stranded DNA with the self-complementary sequence d(TGTACTAGTAACTAGTAC). The portion displayed contains the second d(AGT) and its complement and Lysine 71 to Threonine 82 from the *trp* repressor. The unattached oxygens (open circles) are locations for molecules of water within the major groove of the DNA that have been incorporated into the complex. Only hydrogen bonds between the bases and hydrogen bonds to the molecules of water are drawn. This drawing was produced with MolScript.⁵⁷³

Figure 6-49: Abrupt kinks produced in double-stranded DNA by the association of a protein.⁴⁵³ The complete crystallographic molecular model (Bragg spacing ≥ 0.30 nm) of the complex between the catabolite gene activator protein from *E. coli* and a segment of double-helical DNA 30 base pairs in length containing the sequences recognized by the protein is displayed. The protein contains two identical folded polypeptides, each forming one of its subunits, and is represented by the two backbones of those two subunits, one drawn with thicker lines than the other. The DNA is drawn with even thicker lines. The two subunits sit side by side joined by a long coiled coil of two α helices, one from each of them. Upon association, each of the two identical subunits of the protein produces an abrupt kink in the DNA. The irregular solid line drawn through the center of the molecule of DNA connects the centers of the consecutive pairs of bases. The dotted lines are drawn arbitrarily to indicate the mean axis in each of the three segments of DNA bounded by the two kinks. The angles are those made by the three dotted lines with each other. This drawing was produced with MolScript.⁵⁷³

DNA with a particular sequence, they often distort its structure. One of the most obvious examples of this fact is the complex between the purine repressor from *E. coli* and its cognate double-helical DNA.⁴⁵⁰ This protein thrusts two of its leucine side chains that are positioned within the minor groove of the DNA into the space between the guanine–cytosine pair and the cytosine–guanine pair at the center of the sequence recognized by the protein. This wedge cants these two pairs of bases and creates an abrupt 45° bend in the DNA centered on this **distortion**. In the complex between TATA-box-binding protein and its cognate DNA, two pairs of phenylalanines from β strands running across the top of the minor groove insert between two pairs of bases, the thymine–adenine and the adenine–thymine at positions 1 and 2 and the thymine–adenine and guanine–cytosine at positions 7 and 8 of the sequence recognized by the protein to cause an overall bend in the DNA of $65\text{--}80^\circ$.^{451,452}

Many proteins **bend the DNA** when they bind to it. Sometimes they form abrupt kinks (Figure 6-49),⁴⁵³ but often the bend induced has a gradual curvature following the curvature of the surface of the globular protein.^{429,454} In the complex with the repressor from bacteriophage 434, the DNA is bent in an irregular arc with a radius of curvature of 6.5 nm closely cleaving to the surface of the globular protein (Figure 6-50).^{449,454} In human DNA-(apurinic or apyrimidinic site) lyase, a rigid, cationic, preformed surface acts as a template upon which the DNA that the protein recognized is bent.⁴⁵⁵ Sometimes two successive segments of DNA that contain sequences recognized by two different proteins, which in turn form a complex with each other, bend smoothly around that pair of proteins.⁴⁵⁶ The ultimate extrapolation of such complexes that smoothly bend DNA is that found in chromatin between the segment of DNA 150 base pairs in length and the complex of eight histones around which the DNA wraps in a smooth superhelix with a radius of curvature of 4.3 nm and two almost complete turns.⁴⁵⁷

Often the bending induced by the protein serves a purpose. The superhelices of double-helical DNA in the complexes with the octamers of histones that constitute chromatin store the DNA compactly. The separate complexes between the two adjacent sites on the DNA and the homeodomain protein MAT α 2 and the MADS-box protein MCM1 bring the two proteins together so they can interact.⁴⁵⁸ It has been proposed, however, that the bending or distortion of the DNA in other instances contributes to the recognition of its particular sequence by the protein.

It is believed that particular sequences of nucleotides are more prone to distortion than others and that the ease with which a double helix of DNA distorts can be recognized by the protein as it bends the DNA during the formation of the complex. The standard free energy required to distort a segment of DNA from the linear B form should be positive and unfavorable. If the standard free energy for

a particular distortion of a particular sequence is significantly less positive than the standard free energies for same distortion of other sequences, then when a complex is formed that requires this distortion, the free energy of formation of the complex will be more negative when the easily distorted sequence is bound.

There are experimental observations indicating that a base pair between adenine and thymine is more flexible than one between guanine and cytosine and that this susceptibility to distortion can be used to recognize this base pair.⁴⁵⁹ In the complex between the repressor protein CI of bacteriophage 434 and its complementary DNA (Figure 6-50), the central six pairs of bases are not part of the sequences on either side that are indispensable for the recognition, but their sequence also determines the magnitude of the dissociation constant between protein and DNA.⁴⁴⁹ When they are **adenine-thymine pairs** rather than guanine-cytosine pairs, the free energy of formation of the complex is more negative. In the crystallographic molecular model of the complex, this region of the DNA is significantly distorted by the protein in a manner that seems as though it should be more readily tolerated by adenine-thymine pairs than it would be by guanine-cytosine pairs.^{449,454} The DNA mismatch repair protein MutS from *E. coli* seems to take advantage of the instability of double-helical DNA at a position where the bases are mismatched to introduce a kink at such a location.^{460,461} The uncomplexed segment of DNA recognized by the *trp* repressor of *E. coli* is already distorted in the direction in which it will be distorted by the complex but is further distorted when the complex forms. It is thought that the partial distortion of the uncomplexed DNA demonstrates the susceptibility of this sequence to the ultimate distortion to which it will be submitted.⁴⁰⁵ It is also thought that the decrease in free energy of formation observed when the N6 anilino group of an adenine in the segment of DNA recognized by *EcoRI* site-specific deoxyribonuclease is deleted results from an increase in the ease with which this segment can be distorted by the protein.⁴⁶²

Just as the DNA is often distorted upon forming a complex with a protein, the protein often has a different conformation in the complex than in solution. Such **conformational changes** are often significant. For example, the carboxy-terminal α helix of *BamHI* site-specific deoxyribonuclease unwinds, and the disordered polypeptide that results turns almost 180° to enter the minor groove of the DNA.⁴⁴⁰ Usually, however, the conformational change of a protein on binding to DNA is the establishment of structure from a disordered segment of the polypeptide⁴⁴⁰ or the tying down of flexible segments of the protein⁴⁶³ by their association with the DNA.

There are several proteins, such as topoisomerase I,⁴⁶⁴ the human Ku heterodimer,⁴⁶⁵ and protein gp 45 from bacteriophage T4,⁴⁶⁶ that have a hole passing through them large enough to contain a double helix of DNA. These are proteins that are required to sur-

round a double-helical molecule of DNA to perform their functions, and they recognize the double helix in part by its fit to the hole. In the empty state, the **ring of protein** around the hole is continuous but always contains at least one interface through which the polypeptide does not pass. It is at such an interface that the ring of protein splits apart to allow the DNA to enter the hole and then closes back around it.^{467,468}

There are also proteins that bind to **single-stranded DNA**. Unlike double-helical DNA, the structure of single-stranded DNA is undefined, but when it is bound by one

Figure 6-50: Gradual bend produced in DNA as it cleaves to the surface of a globular protein.⁴⁵⁴ The complete crystallographic molecular model (Bragg spacing ≥ 0.25 nm) of the complex between the DNA-binding portion (Serine 1 to Arginine 69) of the repressor protein CI from bacteriophage 434 and a segment of double-helical DNA 20 base pairs in length containing the sequences recognized by the repressor is displayed. The protein is formed from two identical folded polypeptides, each of which participates in an extensive interface with the double-helical DNA that produces the adhesion of the DNA to the surface of the protein. Skeletal structures of the two subunits (above and below each other) are presented with both the backbone (thick lines) and the side chains (thin lines) drawn. Note the arginines inserted into the minor groove and the α helices inserted into the major groove. This drawing was produced with MolScript.³⁷³

Figure 6-51: Stacking of bases in single-stranded DNA between each other and against aromatic amino acids in the protein.⁴⁶⁹ The crystallographic molecular model (Bragg spacing ≥ 0.24 nm) is that of a complex between the DNA-binding portion (Lysine 183 to Glutamine 420) of the DNA-binding subunit (616 aa) of human replication protein A and octadeoxycytidine (drawn with thicker lines). The entire molecule of single-stranded DNA in the complex is displayed as well as the side chains of the four aromatic amino acids (drawn with narrower line segments) participating in the stacks, numbered by their positions in the sequence of the protein. This drawing was produced with MolScript.⁵⁷³

of these proteins, it assumes a structure dictated by that protein. In this sense, the binding of single-stranded DNA is no different from the binding of any other large flexible ligand by a molecule of protein. Replication protein A is a protein that recognizes segments of single-stranded deoxyribonucleic acid with many different sequences. In the crystallographic molecular model of the complex between single-stranded octadeoxycytidine and human replication protein A, the octanucleotide in the complex is stretched into a linear form that is almost fully extended.⁴⁶⁹ The protein forms a number of hydrogen bonds with the phosphoryl oxygens of the backbone similar to those in complexes between double-helical

DNA and proteins that recognize DNA nonspecifically. The hydrogen bonds to the donors and acceptors of the individual bases in the particular complex that was crystallized, however, are thought to arise only from the requirement that these must be occupied somehow to avoid losing hydrogen bonds from the solution upon association of the DNA with the protein. There are sufficient acceptors and donors of sufficient flexibility on the protein in these locations to satisfy any sequence of bases, as replication protein A is required to do.

The novel feature of this complex is the interactions between π systems of amino acid side chains on the protein and the π systems of the bases that are no longer enclosed within the core of a double helix. Phenylalanines 238 and 269 sandwich one stacked pair of cytosines, and Tryptophan 361 and Phenylalanine 386 sandwich another (Figure 6-51).⁴⁶⁹ Both Phenylalanine 238 and Tryptophan 361 have their π aromatic systems normal to those of the cytosines. An almost identical sandwich occurs between a phenylalanine and a tryptophan in single-stranded DNA binding protein from *E. coli* and a stacked pair of cytosines.⁴⁷⁰ Similar sandwiches occur between tyrosines in the telomere end-binding protein of *Oxytricha nova* and pairs of stacked guanines.⁴⁷¹ A different arrangement is found in the same complex between single-stranded binding protein from *E. coli* and single-stranded DNA, in which another tryptophan is surrounded by a cluster of four cytosines.^{470,472-477}

Just as the paradigm of the structure of DNA is the double helix (Figure 3-9), the paradigm of the structure of RNA is a molecule of **transfer RNA** (Figure 6-52).⁴⁷²⁻⁴⁷⁷ There are several novel structural features of RNA that are not encountered in DNA.

Although there are two double helices in the crystallographic molecular model in Figure 6-52, a horizontal one at the top of the structure containing 13 pairs of bases and a vertical one at the bottom containing 5 pairs of bases, neither is formed from two separate strands of RNA because the entire molecule is formed from only one strand of RNA.* The vertical double helix of 5 pairs of bases is formed from the two uninterrupted lines of a **double-helical hairpin of RNA**. At the bottom of the hairpin there is a **loop** in this RNA of 7 bases (2'-O-Methylcytosine 32† to Adenine 38). In transfer RNA, this loop displays the anticodon, but in most double-helical hairpins, this loop has only a structural function. One of the most common sequences in such a loop in which the chain reverses is UUCG, which produces a structure referred to as a **tetraloop** containing five hydrogen bonds that efficiently change the direction of the RNA.⁴⁸⁰ A

* You should trace the polynucleotide backbone (O-P-O-C-furanose-O-P-O-C-furanose-O-...) through the whole molecule of transfer RNA.

† Just as some proteins are posttranslationally modified on their side chains, all transfer RNAs are posttranscriptionally modified on many of their bases.^{478,479}

double-helical hairpin and its loop is one of the basic structures formed by RNA.

Double-helical hairpins of RNA can be as long as 50 or more pairs of bases, but they are usually interrupted one or more times with **bulges** at which there is a mismatch of the bases on the two strands that face each other. The mismatch causes an interruption in the double helix. A bulge can be as small as one or two extra unmatched bases that protrude out of the double helix on one of the strands while the strand on the other side contains no mismatched base. Uracil 59 and Cytosine 60, found between the 12th (Guanine 53 and Cytosine 61) and the 13th (5-Methyluracil 54 and 1-Methyladenine 58) pairs of bases of the horizontal double-helical hairpin in Figure 6-52, form such a small bulge immediately before the loop of three bases (Pseudouracil 55 to Guanine 57) following the 13th base pair. Bulges can also occur across from each other on both strands of double-helical RNA. The number of bases on one strand of such a bulge can be the same as or different from the number of bases on the other strand, and the two strands are usually independent of each other until they rejoin in the double helix at the other end of the bulge. An inconsequential bulge of one mismatched pair of bases occurs at Guanine 4 and Uracil 69 in the horizontal double-helical hairpin in Figure 6-52.

The most interesting bulges, however, are the larger ones. For example, the entire lower portion (Uracil 8 to Cytosine 48) of the transfer RNA in Figure 6-52 is a bulge out of the horizontal double-helical hairpin. It protrudes between the seventh pair (Uracil 7 and Adenine 66) and the eighth pair (5-Methylcytosine 49 and Guanine 65) of bases while the opposite strand of the horizontal double helix does not skip a beat. The returning strand of this bulge picks up the beat at the eighth pair of bases that was dropped by the departing strand at the seventh pair.

In the central region of a molecule of transfer RNA (Uracil 8 to N^2,N^2 -Dimethylguanine 26 and Adenine 44 to Cytosine 48 in Figure 6-52), the polynucleotide strand **meanders randomly** through the region, forming a complex **tertiary structure** that rigidifies the molecule and holds the two double helices perpendicular to each other. In this region, there are numerous intramolecular hydrogen bonds orienting the strand of RNA as it passes through. It is in this central region that the RNA becomes almost reminiscent of a molecule of protein.

There is, however, one unique characteristic of this central region in which the structure is unmistakably nucleic acid. Even though the structure has become random meander, most of the bases are still **stacked** one upon the other as they are in the double-helical regions. Even the last two bases to the right, beyond the end of the horizontal double-helical hairpin, are stacked upon themselves and the last base of the double helix.

These novel features—double-helical hairpins, bulges, rigid random meander, and stacking of nonhelical bases—are regularly found in molecules of RNA.

Unlike DNA, which is rarely unassociated with protein, there are species of RNA such as transfer RNA and messenger RNA that spend at least a part of their lives free in solution. Unlike DNA, in which the proteins with which it is associated change dramatically as it is transferred from storage, to transcription, to replication, and to recombination; complexes between RNA and protein, such as ribosomes and the small nuclear ribonucleoprotein particles that form spliceosomes, often have fixed structures that remain essentially unchanged during their lifetimes. Such **ribonucleoproteins** are biologically distinguished from proteins only by the fact that they almost always operate on other molecules of RNA.

Many of the atomic details of the association

Figure 6-52: Crystallographic molecular model (Bragg spacing ≥ 0.19 nm) of phenylalanyl transfer RNA from *S. cerevisiae*.^{472,477} The structure is formed from a single, folded molecule of RNA 76 bases long. The last two bases, which are fully extended to the right of the upper double helix, have been omitted. Fourteen of the bases in this particular transfer RNA have been posttranslationally modified by reduction, methylation, and isomerization,^{478,479} but the modifications are difficult to spot at this magnification. This drawing was produced with MolScript.⁵⁷³

between proteins and RNA are indistinguishable from those for the association of proteins and DNA. There are **hydrogen bonds** formed to the acceptors on the phosphoryl oxygens and the donors and acceptors on the bases, and molecules of water are participants in these networks of hydrogen bonds.^{481–485} The main difference is that many of the bases are not in pairs, and in those bases all of their donors and acceptors of hydrogen bonds are available for recognition by acceptors and donors on both the side chains and the polypeptide backbone of the protein. **Hydrophobic contacts** are also made, often with the exposed π systems of the bases, which are accessible in the regions of the RNA that are not double-helical.⁴⁸⁶ There are even instances of α helices lying in grooves of the RNA.⁴⁸⁶

When a large globular molecule of RNA such as a transfer RNA is bound in a transient complex by a protein such as an aminoacyl-tRNA ligase, the complex is reminiscent of one between a protein and double-helical DNA in that the surface of the protein and the surface of the RNA in the interface fit together as cast in mold.^{487,488} In the more **permanent complexes**, however, the RNA and protein are more intimately intertwined. For example, in the U1 small nuclear ribonucleoprotein particle, a representative component of the spliceosome, 10 separate proteins form a complex with one molecule of RNA in which some individual proteins and multimeric complexes of other proteins associate with different segments of the RNA.⁴⁸⁹ The RNA contains four double-helical hairpins in an open, extended structure, and the proteins bind to the ends of individual hairpins⁴⁹⁰ or to the double-helical portions emerging from the center of the molecule of RNA.⁴⁸⁹ In such a small nuclear ribonucleoprotein particle, only 20% of the mass is RNA, and the RNA is a loose scaffold that ties together the proteins, which are responsible for most of the structure of the particle.

The ultimate complex between protein and RNA is a **ribosome**. A ribosome is a ribonucleoprotein that is by mass about two-thirds RNA and one-third protein. It contains three different molecules of RNA, about 3000, 1500, and 120 bases long, respectively, and about 50 different molecules of protein, totalling about 7200 aa, the largest about 350 aa long, the smallest about 50 aa long.* There are two different subunits comprising a ribosome. The 50S subunit contains the largest and smallest molecules of RNA and 30 of the proteins; the 30S subunit contains the RNA 1500 bases long and 20 of the proteins. Yonath and her associates have obtained crystals of the 50S subunit from *Haloarcula marismortui*^{491,492} and the 30S subunit from *Thermus thermophilus*,⁴⁹³ and Yusupov and his associates have obtained crystals of the intact ribosome from *T. thermophilus*^{494–496} and the 30S subunit from *T. thermophilus*.^{495,497} All of these crystals have

proven satisfactory for crystallographic studies, and crystallographic molecular models have been obtained from data sets gathered from them.^{498–503} These crystallographic molecular models provide the atomic details of the structure of a ribosome as well as insight into its ability to translate messenger RNA into protein.⁵⁰⁴

As the distribution of mass suggests, the basic structural element of a ribosome is the RNA. The 4600 bases of the three molecules of RNA form a **globular structure** with which the proteins associate. The RNA, although it is 60 times larger, is reminiscent of a molecule of tRNA and displays all of its characteristic features: double-helical hairpins, loops, bulges, and random meander. One of the few novel features is that many of the hairpins are so long that they form smoothly curved double helices that wrap around other curved double-helical hairpins in structures reminiscent of coiled coils.

For the most part, the various **proteins** are found associated with the outer surface of the much larger globular RNA. Many of the proteins are entirely globular, but some of them have long segments of polypeptide, either interior loops or segments at their carboxy-terminal or amino-terminal ends, emerging from their globular portions and meandering widely through the RNA. Some of the globular portions of these proteins sit upon the surface of the RNA, others are buried within it, but all are subordinate to it both structurally and functionally.

The RNA is responsible for the ability of a ribosome to translate messenger RNA into protein. The RNA of the 30S subunit aligns the codon of the messenger RNA with the anticodon of the transfer RNA,⁵⁰⁵ and the RNA of the 50S subunit appears to catalyze⁵⁰⁶ the formation of the peptide bond from aminoacyl transfer RNA and the peptidyl tRNA.⁵⁰⁷

There is a set of small modules of protein known as **zinc fingers** that recognize specific sequences of double-helical DNA mainly by forming bonds within the major groove (Figure 6–53).⁵⁰⁸ Each of the many different zinc fingers is capable of recognizing the specific sequence of a segment of DNA 3–4 bases in length, and each recognizes a different sequence.^{509,510} Sets of these **modules** are strung together within the same polypeptide and together recognize longer specific sequences in DNA. Four of the five zinc fingers in the zinc finger protein GLI1 from *Homo sapiens* (Figure 6–53) together recognize a segment of DNA 14 bp long by binding consecutively to segments 3–4 bp in length.⁵⁰⁸

Transcription factor IIIA has nine successive zinc fingers sequentially joined together within a segment of its overall sequence.^{511,512} These nine zinc fingers together associate with a segment of DNA 55 bp long but directly recognize sequences only in a segment 11 bp long beginning 8 bp from one end of the overall segment, a segment 10 bp long beginning 9 bp from the other end, and a segment 3 bp long in the middle. The first three zinc fingers each associate with overlapping sequences 4 bp long in the segment 10 bp long, the fifth zinc finger

* The uncertainty reflects both experimental ambiguity and differences among species.

associates with the sequence 3 bp long in the middle, and the last three zinc fingers associate with the segment 11 bp long.⁵¹³ Side chains from the various fingers associate with the phosphoribosyl backbone outside of the three segments the sequences of which are recognized. The fourth and the sixth zinc fingers do not enter the major groove and consequently do not recognize and bind to sequences of base pairs.

Each zinc finger is a segment of polypeptide about 30 amino acids long. Ordinarily a segment of polypeptide this short would be unable to form a specific structure because the small size would prevent the folded protein from removing a sufficient number of hydrogen-carbon bonds from contact with the water to provide enough of a hydrophobic effect to overcome the change in standard entropy required for folding.⁵¹⁴ The most common solution to this problem is that a small protein or small module of protein will contain several cysteines in its core, the cross-links of which provide sufficient rigidity to the structure to overcome this deficit in standard free energy. The zinc finger solves the problem in a similar way, but instead of using cysteines, it uses a Zn^{2+} cation that forms four **covalent bonds** with two cysteines and two histidines in the sequence of the module (Figure 6-53), cross-linking the four amino acids together:

Consequently, a zinc finger is an interesting example of a metalloprotein.

Problem 6-12: What is the sequence of the segment of DNA in Figure 3-9?

Problem 6-13: List the hydrogen bonds between the amino acids of the zinc finger in Figure 6-53 and the bases in the DNA with which it is associated. Identify the amino acids and bases by their respective positions

in the sequences and the functional groups of each by their names and their numbers (2-9, 2-10, 2-11, and 2-12 and Figure 4-14).

Figure 6-53: A zinc finger bound to the major groove of the double-helical DNA that it recognizes.⁵⁰⁸ The crystallographic molecular model (Bragg spacing ≥ 0.26 nm) is that of the complex between the five consecutive zinc fingers (Valine 232 to Alanine 391) of the human zinc finger protein GLI1 expressed as a separate protein and a segment of double-helical DNA 21 base pairs in length containing sequences recognized by those five fingers. Only the fifth zinc finger (Proline 361 to Glycine 388) and the four pairs of bases [d(GACC) paired with d(GGTC)] that it recognizes in addition to one pair of bases on each side (dG-dC and dA-dT, respectively) are included in the figure. The view is down the axis of the B conformation of the DNA. The DNA is in the bottom of the figure and the zinc finger is in the top. The polypeptide is numbered according to the complete amino acid sequence of the zinc finger protein GLI1. Side chains from the protein read the donors and acceptors projecting into the major groove of the DNA, but none of the responsible hydrogen bonds has been drawn. In the protein crystallized, the Zn^{2+} had been replaced by Co^{2+} . The Co^{2+} is the gray sphere near the top of the finger forming four tetrahedrally arranged covalent bonds (dashed lines) with Cysteines 364 and 369 and Histidines 382 and 387. Although its van der Waals radius is about 10% shorter than that of Co^{2+} and it is a somewhat softer acid, Zn^{2+} would have formed covalent bonds with the same four ligands to produce the identical tetrahedral geometry. This drawing was produced with MolScript.⁵⁷³

Metalloproteins

As does a zinc finger, many proteins incorporate one or more **metallic cations** into their structure. Aside from cations such as lithium, sodium, potassium, rubidium, magnesium, and calcium that are dissolved in the cytoplasm or the extracellular solution and bind adventitiously and randomly over the surface of a protein, there is a set of metallic cations that participate as specific and necessary structural and functional elements of **metalloproteins**. These are the cations of sodium, potassium, magnesium, calcium, vanadium, manganese, iron, cobalt, nickel, copper, zinc, molybdenum, and tungsten. The nontransition metals, sodium, potassium, magnesium, and calcium, and zinc, a transition metal inactive in oxidation–reduction, occur exclusively in their most common oxidation states: Na^+ , K^+ , Mg^{2+} , Ca^{2+} , and Zn^{2+} , respectively. Because of the availability of two or more readily accessible oxidation levels, the other transition metals, for example, iron or copper, are often used as one-electron carriers, and in this role alternate between oxidation levels, for example, Fe^{2+} and Fe^{3+} or Cu^+ and Cu^{2+} . In other situations transition metals, such as the Ni^{2+} in urease or the Fe^{2+} in myoglobin (Figure 4–18), fill roles in the active sites of enzymes in which no changes in oxidation level are required and in fact are to be avoided.

Eventually, the role of a metallic cation in **maintaining the structure** of a protein must be distinguished from its role as a **catalytic functional group** in its active site. Aspartate carbamoyltransferase from *E. coli* is a protein constructed from two different folded polypeptides, the regulatory subunit ($n_{\text{aa}} = 152$) and the catalytic subunit ($n_{\text{aa}} = 310$). In the crystallographic molecular model of aspartate carbamoyltransferase, a Zn^{2+} is tetrahedrally coordinated to the four sulfurs of Cysteines 109, 114, 137, and 140 in the regulatory subunit.⁵¹⁵ This Zn^{2+} forms a tetrahedral, covalent complex with the structure

that resembles closely structures observed in polynuclear clusters that form between Zn^{2+} and small mercaptans. When the zinc is displaced from the thiols by organic mercurials, the two subunits separate from each other but can be reassociated^{516,517} by reincorporating the Zn^{2+} . In the crystallographic molecular model, the Zn^{2+} is located adjacent to the boundary between the regulatory subunit and its neighboring catalytic subunit but distant from both the active site of the enzyme located on

the catalytic subunit and sites for binding ligands on the regulatory subunits. Therefore, the role of the Zn^{2+} is entirely structural. Its complexation with the thiols creates and stabilizes the proper structure at the surface of a regulatory subunit. Only when this stable structure is formed can the properly folded regulatory subunit associate with a complementary structure on the surface of a catalytic subunit, just as only when the proper structure of a zinc finger is formed by the binding of the Zn^{2+} can it associate with the proper site on DNA (Figure 6–53). A metallic cation fulfills such a structural role because the bonds it forms either covalently or ionically with lone pairs of electrons on bases within the protein are strong ones, especially when the protein itself assists in orienting the bases advantageously.

In the case of aspartate carbamoyltransferase, removal of the Zn^{2+} from the protein produces catalytic subunits with full enzymatic activity. In most instances, however, the removal of a metallic cation from a protein leads to loss of function, and separating the effect of the cation on the structure of a protein, which itself is responsible for that function, from a direct effect at an active site, in which a metallic cation is often a catalytic group, is difficult. For example, when mammalian liver arginase, which is formed from four identical folded polypeptides, is treated with the chelating agent *N,N,N',N'*-tetracarboxymethyl-1,2-diaminoethane (**5–1**), it loses all of its enzymatic activity.⁵¹⁸ At the same time, however, it dissociates into individual folded polypeptides. When Mn^{2+} is added to the inactive protein, enzymatic activity is regained, but the individual folded polypeptides reassociate. It was possible that the dissociation of the tetramer was responsible for the inactivation and that the Mn^{2+} required for activity was necessary to retain the proper structure of the protein rather than as a catalytic group in the active site. If, however, a crystallographic molecular model of the protein is available it is possible to determine, as was the case with both a zinc finger and aspartate carbamoyltransferase, whether or not the metal is distant from sites involved in the function of the protein and consequently performs purely a structural role. In the case of arginase, for example, it has been shown crystallographically that Mn^{2+} cations form a binuclear cluster within the active site intimately involved in the catalysis performed by the enzyme.⁵¹⁹

The metallic cations incorporated into proteins in aqueous solution, because they are themselves **Lewis acids**, are at all times surrounded by **Lewis bases**. The strongest Lewis bases present in biological fluids are the lone pairs of electrons on oxygens, nitrogens, and sulfurs and the chloride ion. The proton is also a Lewis acid, and in biological fluids every acidic proton is usually surrounded by lone pairs of electrons on oxygens, nitrogens, or sulfurs. The proton is so small, however, that it can accommodate directly only two Lewis bases at a time in one hydrogen bond. Because metallic cations have core electrons, they are larger than a proton and can accom-

moderate more Lewis bases simultaneously. The metallic cations incorporated into proteins are always surrounded by pairs of electrons from oxygens, nitrogens, sulfurs, or halides. The atoms providing the lone pairs of electrons surrounding a metallic cation are its **ligands**, and the number of ligands surrounding the cation is its **coordination number**. The complexes formed between metallic cations and proteins are tetra-coordinate, penta-coordinate, hexa-coordinate, hepta-coordinate, octa-coordinate, and nona-coordinate.

The preferences of a metallic cation for a particular type of lone pair of electrons are usually discussed in terms of the **hardness or softness** of the Lewis acid and the Lewis base.⁵²⁰ The rule is that hard acids prefer hard bases and soft acids prefer soft bases. For the divalent metal ions of importance to the structure of proteins, the series of hardness is $\text{Mg}^{2+} > \text{Ca}^{2+} > \text{Mn}^{2+} > \text{Fe}^{2+} > \text{Co}^{2+} > \text{Ni}^{2+} > \text{Cu}^{2+}, \text{Zn}^{2+}$. For the commonly encountered bases, the series of hardness is lone pairs on oxygen > lone pairs on chloride > lone pairs on nitrogen > lone pairs on sulfur. These rankings, for example, are consistent with the fact that calcium ion has a strong preference for oxygen ligands while zinc ion has a preference for thiol ligands. It also explains why the ligands on metallothionein, a protein responsible for chelating and thus removing from solution soft, toxic heavy metal cations, are entirely the thiols of cysteine side chains in the protein.

The Lewis bases surrounding a metallic cation in solution are attached to it by bonds the characteristics of which span the **spectrum between ionic and covalent**. The bonds between hard cationic Lewis acids and hard Lewis bases are usually ionic, and those between soft cationic Lewis acids and soft Lewis bases are usually covalent. The calcium dication is an example of a hard, purely ionic metallic cation. In biological solutions, its ligands are invariably oxygen atoms,⁵²¹ the hardest of bases, and those oxygens are held by ionic bonds. The zinc dication in the crystallographic molecular model of aspartate carbamoyltransferase (6–20) is a good example of a metallic cation participating in covalent bonds. In this arrangement, a soft metallic cation, Zn^{2+} , is bonding covalently to four soft bases, $(\text{RS}^-)_4$. Soft bases such as sulfur or even nitrogen are rarely found as ligands to hard metallic cations such as Na^+ , K^+ , Mg^{2+} , and Ca^{2+} , but one way that a protein reconciles the steric difficulty of arranging ligands precisely enough to form unhindered covalent bonds with soft metallic cations such as Fe^{2+} ,

Cu^{2+} , and Zn^{2+} is to use hard bases such as oxygen or nitrogen as ligands. The bonds formed by these harder ligands, because they have more ionic character, are more flexible in their angles. Regardless of whether the bonds are ionic or covalent, their lengths are usually governed by the size of the ion, which is reflected in its **ionic radius** (Table 6–7).

The major structural difference between ionic bonds and covalent bonds is the directional properties of the arrangements of the ligands. **Ionic bonds** are created by the electrostatic forces between the metallic cation and an anion or a dipole on a ligand. If the forces holding the ligands are entirely ionic, the number and orientation of the Lewis bases around the cation are determined solely by steric considerations. In the case of Ca^{2+} , the number and orientation of the oxygens surrounding the dication depend entirely on the size and shape of the functional groups that provide them.⁵²³ When ligands are bonded ionically, the larger the cation or the smaller the bases, the more ligands will be gathered. **Covalent bonds** result from the overlap of atomic orbitals to form bonding molecular orbitals. Because the degree of overlap determines the strength of the bond and because the degree of overlap depends on the bond lengths and bond angles, covalent bonds are characterized by specific bond lengths and bond angles. Because zinc is a d_{10} transition metal, its $2d$ shell is filled. As a result, the covalent bonds between Zn^{2+} and sulfur in the regulatory subunit of aspartate carbamoyltransferase are formed from sp^3 hybrid orbitals on the zinc, and this produces the usual tetrahedral arrangement. A similar tetrahedral disposition is assumed by the four Lewis bases around the Zn^{2+} in a zinc finger (Figure 6–53). Covalent bonds position the participating atoms in strict geometric orientations while ionic bonds are completely malleable, resembling pigs at a trough.

The fact that covalent bonds involving metals are so rigid is reflected in the practice during crystallographic refinement of considering them as fixed geometrically as the bonds involving carbon, nitrogen, and oxygen. For example, in the initial crystallographic molecular model of aspartate carbamoyltransferase built directly from the unrefined map of electron density, the arrangement of the four sulfurs around the Zn^{2+} was restrained to a tetrahedral geometry, just as an sp^3 carbon would have been, and this geometry was retained in all the subsequent refinement.⁵²⁴ This practice can be dangerous, however,

Table 6–7: Ionic Radii and Lengths of Bonds to Ligands of Metallic Cations Found as Structural Elements in Proteins

	Na^+	K^+	Mg^{2+}	Ca^{2+}	Mn^{2+}	Fe^{2+}	Ni^{2+}	Cu^{2+}	Zn^{2+}

particularly if the ligands to the Zn^{2+} are harder, less covalent bases.⁵²⁵ In such intermediate cases, various mixtures of ionic and covalent behavior are observed. The main indication of such deviations from covalent behavior is the loss of directional ligation.

The monovalent cations of **sodium** and **potassium** are hard Lewis acids and are almost always surrounded by lone pairs from oxygen in any situation, as they are when they are dissolved in water. There is, however, one crystallographic molecular model in which a Na^+ has the π system of a tryptophan as one of its ligands.^{526,527} Because cytoplasm has a high concentration of K^+ and a

Figure 6-54: A site at which a structural K^+ is bound in the crystallographic molecular model (Bragg spacing ≥ 0.175 nm) of the bifunctional protein containing phosphoribosylaminoimidazolecarboxamide formyltransferase and IMP cyclohydrolase from *G. gallus*. Segments of the folded polypeptide from Valine 426 to Valine 434, Serine 539 to Alanine 541, and Leucine 590 to Histidine 593 are drawn. All of the ligands to K^+ are provided by the protein. Histidine 593 is the carboxy terminus of the protein. The binding site for K^+ is in the enzymatic domain responsible for the activity of phosphoribosylaminoimidazolecarboxamide formyltransferase (Lysine 200 to Histidine 593). This drawing was produced with MolScript.⁵⁷³

low concentration of Na^+ , it is K^+ that is almost invariably incorporated as a structural metallic cation in cytoplasmic proteins. There are examples, however, of cytoplasmic proteins incorporating Na^+ during their crystallization, in one case at a site formed by five acyl oxygens from the backbone and the oxygen of a carboxylate⁵²⁸ and in another at a site formed from two acyl oxygens from the backbone and a molecule of water forming three hydrogen bonds with groups on the protein.⁵²⁹ Whether or not these sites are occupied by Na^+ when the proteins are in the cytoplasm is unknown. Extracytoplasmic proteins, such as α -thrombin, however, do seem to incorporate Na^+ .⁵³⁰

In structural sites for K^+ ,⁵³¹⁻⁵³⁴ the complex can be anywhere from tetracoordinate to heptacoordinate. The ion is large enough (Table 6-7) to support seven oxygens easily, but the final number of ligands is dictated by the structure of the protein. The ligands to a structural K^+ in a crystallographic molecular model of a protein are contributed by as many as three acyl oxygens of the peptide backbone, as many as three waters, sometimes a hydroxyl from a serine or the acyl oxygen of a glutamine or asparagine, and often, but not always, one of the oxygens of a carboxylate from an aspartate or glutamate. For example, in the hexacoordinate structural site for K^+ in phosphoribosylaminoimidazolecarboxamide formyltransferase from *G. gallus*, the cation is liganded by the hydroxyl groups of two serines, the carboxylate oxygen of one aspartate, and three acyl oxygens from the backbone (Figure 6-54).⁵³⁵ The eight ligands from the protein to the two potassium cations bound within the selectivity filter of the KcsA potassium channel, however, are all acyl oxygens from the polypeptide backbone,⁵³⁶ and at the entry to the selectivity filter a potassium can be observed liganded by four acyl oxygens from the backbone and four molecules of water, presumably in the act of being dehydrated.⁵³⁶ In keeping with the size of the potassium cation and the hardness of both the cation and the oxygens, the bonding is ionic, the geometry of the ligands around the cation is unpredictable, and unlike those of most other metallic cations, the bond lengths span a large range (Table 6-7).

Calcium ion, a hard Lewis acid like K^+ , also participates in purely ionic bonds with no particular geometric requirements. Its smaller ionic radius (Table 6-7) is more than compensated by its increased charge, and it associates with as many as nine ligands. Calcium ion has a low affinity for nitrogen,⁵²¹ and it can be distinguished from Mg^{2+} by this characteristic. It is probably the dication that is most often bound by proteins, and its role is usually entirely structural.

When bound to proteins, Ca^{2+} serves in its structural role by gathering around itself oxygens from the backbone of the polypeptide, its side chains, and molecules of water. This **exclusive preference for oxygen** is entirely consistent with its hardness. The octacoordinate site on the surface of endopeptidase K (Figure 6-55)⁵³⁷

that binds Ca^{2+} with a dissociation constant⁵³⁸ of 8×10^{-8} M is typical of a complex between a Ca^{2+} and protein. It is representative of such complexes because the Ca^{2+} is surrounded by molecules of water, one of which is positioned by the molecule of protein, by acyl oxygens from the backbone and by the carboxylate of an aspartate that provides simultaneously two oxygens as a bidentate ligand. The charge number on the Ca^{2+} in this site is not matched by that of its ligands, as is also the case in the heptacoordinate site for Ca^{2+} in α -lactalbumin from *Papio cynocephalus*, in which the ligands are the carboxylates of three aspartates, each a monodentate ligand to the Ca^{2+} , as well as two molecules of water and two acyl oxygens from the backbone.⁵³⁹ There are also structural Ca^{2+} that are more completely surrounded by the protein, such as the heptacoordinate site in thermolysin,⁵⁴⁰ which is surrounded by three acyl oxygens from the backbone, an acyl oxygen of the side chain of an asparagine, a single oxygen of the side chain of an aspartate, and the two carboxylate oxygens of another aspartate acting as a bidentate ligand.

In these complexes, the distance between the Ca^{2+} and the heteroatoms of the ligands is between 0.22 and 0.26 nm (Table 6–7). The position taken by the Ca^{2+} relative to an acyl oxygen of the backbone is remarkably similar to that of an amido nitrogen–hydrogen in a hydrogen bond to such an acyl oxygen (Figure 5–11) with a broad distribution of angle b from 140° to 180° and a strong tendency to lie in the plane of the peptide.⁵⁴¹

These complexes are usually specific for Ca^{2+} . The specificity is provided by the distribution of the oxygens within the protein and the donors and acceptors of hydrogen bonds between the protein and molecules of water (Figure 6–55) retained by the Ca^{2+} as it enters the complex. The number of ligands provided by the protein and the conformation to which they are confined by the rest of its structure⁵⁴² permits them to recognize both the two units of charge number and the radius of the Ca^{2+} . For example, Aspartate 200 in the complex between Ca^{2+} and endopeptidase K (Figure 6–55)⁵³⁷ is positioned properly by resting in a groove formed by the backbone and Cysteine 178/249 as well as by a hydrogen bond to an amido nitrogen–hydrogen of the backbone.

A **magnesium** cation, although also a hard, alkaline earth metallic cation, displays directional bonding reminiscent of a covalent-coordinate metallic cation not because of covalence but because of the intensity of its electrostatic field and the steric effects associated with its significantly smaller ionic radius (Table 6–7). Its complexes are almost always hexacoordinate with the ligands in an octahedral arrangement enforced by the severe steric effects, and the interatomic distances between the metal and the ligands are shorter and much less variable (0.20–0.21 nm) than those for calcium (0.22–0.26 nm). In a structural role, Mg^{2+} is often associated with phosphoryl oxygens, as for example those on nucleic acid. When bound to protein or nucleic acid, Mg^{2+} usually retains

several of its waters, often all of them.⁴⁸⁵ For example, in the complex between Mg^{2+} and inorganic diphosphatase from *E. coli*, the Mg^{2+} retains all six of its octahedrally arrayed molecules of water, each of which forms one to three hydrogen bonds with donors and acceptors on the protein.⁵⁴³

It appears from crystallographic and spectral⁵⁴⁴ observations that Mg^{2+} , when bound to a protein, prefers oxygen ligands exclusively, in particular the oxygens of phosphates and carboxylates, but the dication of **man-**

Figure 6–55: A site at which a structural Ca^{2+} is bound on the surface of the crystallographic molecular model (Bragg spacing ≥ 0.15 nm) of endopeptidase K from *Tritirachium album* Limber.⁵³⁷ Segments of the folded polypeptide from Glutamate 174 to Valine 180 and Leucine 199 to Isoleucine 201 are drawn. Of the ligands to the Ca^{2+} , the two acyl oxygens are provided by the second and fourth amino acids of a β turn of type I (Glutamate 174 to Valine 177) that has been stretched out of its normal conformation as it cradles the cation, and the bidentate carboxylate is provided by an aspartate from elsewhere in the amino acid sequence. The unattached oxygens (open circles) are locations for molecules of water. The Ca^{2+} is the gray sphere in the center of the cluster of ligands. The interior of the protein is beyond the valines, the leucine, the isoleucine, and the cysteine to the back and right of the drawing and the water is to the front and left. This drawing was produced with MolScript.⁵⁷³

manganese, Mn^{2+} , a softer metallic ion that is about the same size as Mg^{2+} and that gathers its ligands just as tightly (Table 6–7), forms complexes with both nitrogen and oxygen bases such as ammonia, imidazole, 1,2-diaminoethane, water, alcohols, carboxylates, the carbonyl oxygens of ketones and aldehydes, and the acyl oxygens of amides. Consistent with its degree of hardness, oxygen bases and nitrogen bases are roughly equivalent in their affinities for Mn^{2+} . In aqueous solution, the hexammine complex is observed only at concentrations of ammonia greater than 2 M, but hexaimidazole salts can

Figure 6-56: Site for the structural Mn^{2+} in the crystallographic molecular model (Bragg spacing ≥ 0.20 nm) of lectin IV from *Griffonia simplicifolia*.² Only one intact segment of the folded polypeptide (Valine 128 to Valine 156) is drawn. It surrounds the Mn^{2+} and provides all of the ligands directly to the metal and to its two bound molecules of water (open circles). The side chain of Asparagine 135 has been erased to provide a better view of the metal and its ligands. The Mn^{2+} is the gray sphere in the center of the cluster of ligands. This drawing was produced with MolScript.⁵⁷³

be crystallized from anhydrous ethanol. Because of its small size and degree of hardness, all of the complexes between Mn^{2+} and such unhindered hard and intermediate bases are hexacoordinate and octahedral, reminiscent of directional covalent bonds; and in these complexes, mixtures of various ligands around manganese can occur. For example, each of the species $[\text{Mn}(\text{OH}_2)_n(\text{NH}_3)_{6-n}]^{2+}$ with $0 < n < 6$ is observed in mixtures of ammonia and water. When Mn^{2+} is bound to a protein, it is complexed octahedrally by Lewis bases both from amino acids on the protein and from molecules of water (Figure 6–56).²

Iron, when it is found in a protein, is almost always in a coenzyme such as a heme (Figure 4–18) or an iron–sulfur cluster:

In most of these instances, the iron acts either as an electron carrier because of its ability to convert between $\text{Fe}(\text{II})$ and $\text{Fe}(\text{III})$ or as a catalytic group that can bind and activate oxygen, but the iron–sulfur cluster in DNA-(apurinic or apyrimidinic site) lyase of *E. coli*,⁵⁴⁵ as well as the one in glycosylase MutY from *E. coli*,⁵⁴⁶ performs a structural role. In a heme the Fe^{2+} is hexacoordinate, but in an iron–sulfur cluster it is tetracoordinate, consistent with the softness of the thiolates. There is also a pentacoordinate site for a structural Fe^{2+} in UTP-hexose-1-phosphate uridylyltransferase in which the ligands are the nitrogens from three histidines and the two carboxyl oxygens of a glutamate acting as a bidentate ligand.⁵⁴⁷ The irregular arrangement of the ligands in this case is permitted by their hardness, which causes the ligation to be more ionic. One of the most peculiar sites for an iron cation is that on nitrile hydratase of *Rhodococcus*, in which the Fe^{3+} is liganded by two amido nitrogens from the backbone and the sulfurs of three cysteines, one of which is oxidized to a sulfenic acid and another to a sulfinic acid (Figure 2–8).⁵⁴⁸

Cobalt is incorporated into proteins as the metal in the center of coenzyme B_{12} . **Nickel** is used as a Lewis acid in the active site of urease⁵⁴⁹ and as the electrochemically active component in the active site of a few enzymes catalyzing oxidation–reduction.^{550–552} In at least one of these latter enzymes, it is found coordinated within a tetrapyrrole that resembles a porphyrin.⁵⁵³ **Molybdenum** and **vanadium** are found in nitrogenases and **molybdenum** and **tungsten** in other enzymes catalyzing oxidation–reduction such as nitrate reductase, aldehyde:ferredoxin oxidoreductase, and xanthine oxidase. In each of these proteins, the molybdenum, tungsten, or vanadium is enclosed within a pterin coenzyme that provides the

thiols coordinating the metallic cation and holding it within the protein.⁵⁵⁴

Copper exists in biochemical situations as the kinetically stable cations Cu^+ and Cu^{2+} . It is usually used as a one-electron carrier, often in reactions involving oxygen activation such as those catalyzed by monooxygenases. Although it is a soft metallic cation, Cu^{2+} can form a number of coordination complexes with lone pairs from oxygen, nitrogen, and sulfur. The variety of these complexes defies categorization. They range from dicoordinate to octacoordinate. Even in the more common tetracoordinate and hexacoordinate stereochemistries, the terms used to describe the variations, such as square planar, compressed tetrahedral, elongated tetragonal octahedral, and trigonal octahedral, indicate that the arrangement of many of the Lewis bases around copper, as with calcium, is governed mainly by steric effects among the ligands, rather than by covalent bonding. Examples of complexes between Cu^{2+} and simple biochemical ligands are $[\text{Cu}(\text{NH}_3)_5]^{2+}$

in which four of the nitrogens are equivalent and the fifth forms a longer bond to Cu^{2+} , and $[\text{Cu}(\text{imidazole})_4(\text{OH}_2)_2]^{2+}$ and $[\text{Cu}(\text{formate})_2(\text{OH}_2)_2]^{2+}$, which are both elongated tetragonal octahedral structures. Simple thiols such as mercaptans reduce Cu^{2+} to Cu^+ and form complex polymeric structures with Cu^+ in which the coppers are multidentate and the thiols are bidentate.

The azurins and the plastocyanins are related metalloproteins involved in one-electron transfers in which the single copper passes reversibly from Cu^{2+} to Cu^+ to carry the electron. In crystallographic molecular models of these proteins,^{555,556} the copper is coordinated to two histidines, a methionine, and a cysteine with no particular geometric regularity. In the apoprotein,* the two nitrogens and the two sulfurs that surround the copper in the holoprotein assume the same orientations even though the copper is not present.⁵⁵⁷ Consequently, unlike the situation in a zinc finger in which the Zn^{2+} dictates the structure assumed by the protein, azurins and plastocyanins are large enough proteins that they dictate the stereochemistry of the ligation.

The most versatile metallic dication performing

* The metal-free form of a metalloprotein is the apoprotein, and the form of the metalloprotein when it contains the metal is the holoprotein.

structural roles in proteins is that of **zinc**. Its versatility in this role arises from its ability to form both tetracoordinate and pentacoordinate complexes with Lewis bases and its ability, even though it is one of the softest metallic cations, to form complexes with lone pairs from **oxygen and nitrogen, as well as sulfur**. Often a mixture of two or three of these rather different bases forms the site on a metalloprotein for the Zn^{2+} . When it is bound by four sulfurs, which are soft bases complementary to the soft Zn^{2+} , the bonds are covalent and tetrahedral. The complex between Zn^{2+} and the harder base ammonia is tetracoordinate $[\text{Zn}(\text{NH}_3)_4]^{2+}$ and tetrahedral, probably because it is also covalent. This tetrahedral covalent form of Zn^{2+} is the most common and is observed when Zn^{2+} forms complexes with 1,2-diaminoethane, cyclic lactams, and imidazole. As the ligands become harder, however, geometries become more variable. For example, the complex $[\text{Zn}(\text{OH}_2)_6]^{2+}$ between Zn^{2+} and water, a hard base, is hexacoordinate and octahedral; but as protons are removed, it eventually decreases its coordination to four, as $[\text{Zn}(\text{OH})_3(\text{OH}_2)]^-$, as a result of electrostatic repulsion. An ionic, octahedral complex forms with carboxylates:

Zinc dication forms a pentacoordinate complex with, among other ligands, 8-aminoquinazoline,⁵⁵⁸ in which the four nitrogens from two aminoquinazolines and a molecule of water are the five Lewis bases that generate the complex $[\text{Zn}(\text{N}_2\text{C}_9\text{H}_8)_2(\text{OH}_2)]^{2+}$.

A **pentacoordinate complex** is formed by the structural Zn^{2+} in the periplasmic zinc-binding protein TroA of *Treponema pallidum*. In this complex with the protein, the Zn^{2+} is surrounded by the two oxygens of the carboxylate of Aspartate 257 as a bidentate ligand and three imidazolyl nitrogens from Histidine 46, Histidine 111, and Histidine 177 in an irregular arrangement (Figure 6-57).⁵⁵⁹ Most structural sites for zinc, however, are tetracoordinate, resembling the one in a zinc finger (Figure 6-53). For example, in the structural sites for zinc in UTP-hexose-1-phosphate uridylyltransferase from *E. coli* and alanine-tRNA ligase from *E. coli*, the cations are also surrounded by two histidines and two cysteines in a tetrahedral array.^{547,560}

There are a number of proteins that contain mod-

Figure 6-57: Site for the structural Zn^{2+} in the crystallographic molecular model (Bragg spacing ≥ 0.18 nm) of periplasmic zinc-binding protein TroA from *Treponema pallidum*.⁵⁵⁹ In this case, unlike that of the Mn^{2+} binding site in lectin IV (Figure 6-56), the four ligands to the Zn^{2+} are provided by side chains distant from each other in the amino acid sequence. Consequently, four short segments of the folded polypeptide (Valine 43 to Valine 47, Phenylalanine 108 to Valine 112, Alanine 176 to Alanine 179, and Aspartate 257 to Alanine 258) are drawn as well as two others (Glutamate 226 to Serine 227 and Leucine 69 to Leucine 71) that provide acceptors for hydrogen bonds buttressing the ligands to the metal. The Zn^{2+} is the gray sphere in the center of the cluster of ligands. A molecule of water, not a ligand to the metal, is drawn as an open circle. The amino acid sequence is numbered according to that of the posttranslationally modified version of the protein. This drawing was produced with MolScript.⁵⁷³

ules resembling zinc fingers in that they bind to specific sequences in DNA and are also zinc metalloproteins. Some of them have complexes that resemble the one in the regulatory subunit of aspartate carbamoyltransferase (**4-48**) because the zinc forms covalent bonds with four cysteines.^{438,561} Others have a site formed from three cysteines and only one histidine.⁵⁶² Others contain clusters formed from two Zn^{2+} and the sulfurs from six cysteines

that resemble iron-sulfur clusters (**6-21**) and in which each Zn^{2+} forms covalent bonds to four sulfurs.⁵⁶³⁻⁵⁶⁵ In all of these modules, as in the zinc fingers, the cross-linking of the polypeptide performed by the respective complex is essential for maintenance of the proper structure.

Because the distances (Table 6-7) at which the ligands are held by Mn^{2+} , Fe^{2+} , Ni^{2+} , Co^{2+} , and Zn^{2+} in a crystallographic molecular model are so similar, it is not surprising that these metallic cations are often **interchangeable in their structural roles**. For example, even though Zn^{2+} is the only cation found in aspartate carbamoyltransferase when it is purified from *E. coli*, Ni^{2+} and Co^{2+} are capable of promoting the proper reassembly of the apoprotein.⁵¹⁷ The metal site within the active site of arylalkylphosphatase⁵⁶⁶ is as happy with Ni^{2+} or Mn^{2+} as it is with the Zn^{2+} it naturally contains. The diphtheria toxin repressor from *Corynebacterium diphtheriae* under normal conditions of growth incorporates an Fe^{2+} into its structure,⁵⁶⁷ which is required for it to fold properly. The structural role of this Fe^{2+} can be played just as well by Ni^{2+} or Mn^{2+} .⁵⁶⁸ In the properly folded form of this protein, the metallic cation is octahedrally coordinated by the carboxylate oxygen of an aspartate, the carboxylate oxygen of a glutamate, the imidazolyl nitrogen of a histidine, the sulfur of a methionine, an acyl oxygen from the backbone, and a molecule of water, making this site one of the most eclectic (Figure 6-58).⁵⁶⁷

Sometimes the site for a structural metallic cation associates with its metallic cation so weakly that the cation is lost during its purification. If several metallic cations are as effective at producing its proper conformation, it is difficult to say with any certainty which is used in vivo.

Problem 6-14: The drawing in the figure on the next page is of a site for the binding of Mg^{2+} within the crystallographic molecular model of inorganic pyrophosphatase from *E. coli*.⁵⁴³ This drawing was produced with MolScript.⁵⁷³

Identify the donors and acceptor for each of the hydrogen bonds.

Figure 6-58: Site for the structural Fe^{2+} in the crystallographic molecular model (Bragg spacing ≥ 0.24 nm) of diphtheria toxin repressor from *Corynebacterium diphtheriae*.⁵⁶⁷ The protein purified from the bacterium contains an Fe^{2+} at this site, but that Fe^{2+} was replaced with Ni^{2+} for the crystallographic study. The Ni^{2+} is the gray sphere in the center of the cluster of ligands. Presumably, an Fe^{2+} would gather the same ligands (Table 6-7). The ligands are provided by side chains and backbone from two α helices. The amino-terminal portion of the upper α helix and a segment amino-terminal to it (Leucine 4 to Threonine 14) and the carboxy-terminal portion of the lower α helix and a segment carboxy-terminal to it (Histidine 98 to Valine 107) are drawn. Together they provide all of the ligands to the metal and donors and acceptors for hydrogen bonds buttressing the ligands. Note the pair of hydrogen bonds between Arginine 13 and Glutamate 105 and the hydrogen bond between Aspartate 6 and the open amido nitrogen-hydrogen at position 9 at the amino-terminal end of the upper α helix. This drawing was produced with MolScript.⁵⁷³

Chapter 7

Evolution

Although it is mutations in the DNA that produce the diversity upon which natural selection operates, it is within the proteins encoded by that DNA that most of the diversity is expressed. Consequently, natural selection accepts or rejects mutated proteins, not mutated genes. The two genes encoding the two calmodulins in *Arbacia punctulata*, which arose from the duplication of a single gene, differ in nucleotide sequence from each other at 45 out of 393 positions, but in the two calmodulins themselves, which unlike the genes have been continuously scrutinized by natural selection, only two of those 45 differences have been permitted to change the amino acid sequence.¹

It is within the proteins existing today that the history of evolution by natural selection can be read. The later episodes of this history are read by comparing the amino acid sequences of the same protein from different species. Two new species arise from one ancestral species as soon as subpopulations of that ancestral species become so different from each other that two individuals of different sex, one from each of the subpopulations, are no longer able to breed successfully. Even when two closely related species that have only recently diverged from their common ancestor are compared, the amino acid sequences of the same respective proteins from each species will often differ at one or more positions. For example, myoglobin from domestic sheep differs in amino acid sequence at three of its 143 positions from myoglobin of domestic goats. Even the amino acid sequences of the myoglobins from human and chimpanzee differ at one of their 153 positions.

The reason for this divergence of amino acid sequence is that once speciation has occurred and interbreeding becomes impossible, two versions of the same protein are established. These two versions begin to evolve in isolation from each other, and mutations occur at random in the respective genes encoding each version. Once in a while one of these mutations in one version that produces an acceptable change in amino acid sequence of the protein is fixed by genetic drift or natural selection independent of any fixation occurring in the other version, and slowly the amino acid sequences of the encoded proteins become different, one position at a time. Because the geologic instant at which the two species were established from one common ancestral species coincides with the instant at which the two versions of the same protein began to evolve separately,

amino acid sequences retain the history of the speciation of organisms. This history can be reconstructed by comparing the amino acid sequences of the same protein from an array of different species.

Even in the most advantageous instances in which amino acid sequences are compared to each other, connections can usually be made only as far back as the common ancestors of prokaryotes and eukaryotes. What has been found, however, is that the tertiary structure of a particular protein, when viewed in crystallographic molecular models from distantly related species, changes less rapidly than its amino acid sequence during evolution by natural selection. Because of this, comparisons of crystallographic molecular models permit one to look back in evolutionary history to the time at which the individual proteins themselves were diverging from common ancestors: to the time, for example, when L-lactate dehydrogenase and glyceraldehyde-3-phosphate dehydrogenase or triose-phosphate isomerase and indole-3-glycerol-phosphate synthase diverged from their common ancestor. Through such comparisons, the speciation of proteins can be traced. Because amino acid sequences change more rapidly than tertiary structures, only a few of the pedigrees of proteins, those that diverged recently in geologic time or those in which mutations are fixed slowly, can be traced by comparing amino acid sequences. Most of our insight into the speciation of organisms has come from comparisons of amino acid sequences, but most of our insight into the speciation of proteins has come from comparisons of tertiary structures.

From the comparisons that can be made among the tertiary structures that are now available, it has become clear that the larger proteins often, if not always, have arisen during evolution by the chance fusion of two genes encoding smaller proteins, each of which could fold independently and each of which usually had an independent function prior to the fusion. As a consequence of such fusions, larger and larger proteins appeared. If a particular fusion produced a protein that was not impaired functionally, the new gene for the larger protein may have been fixed in the population by genetic drift; or, if the fusion produced a protein with advantageous features, the new gene for the larger protein may have been fixed in the population by natural selection. The history of these fusions can be observed in the existing domains from which these larger proteins

are constructed. The domains of a protein are discrete regions in the tertiary structure of that protein which arose from separate, previously independent proteins that were fused together, one after the other, to produce the present protein. Because a polypeptide shorter than about 70 amino acids usually cannot fold spontaneously to form a tertiary structure, domains, when defined in this way, are usually larger than this. They appear in the crystallographic molecular model as independently folded regions. Because they are the fundamental units in the evolution of proteins, domains must be identified by a set of conservative, objective criteria, if our description of the evolutionary history of a set of proteins is to be accurate.

It may be possible, by examining enough crystallographic molecular models, to trace the ancestry of the proteins that presently exist, in a sense to derive a molecular phylogeny of the proteins. Because most of the existing proteins were produced by fusion of smaller units, this molecular phylogeny of the proteins must be based on a reconstruction of two processes. First, the family trees of the individual, ancestrally related domains from different proteins must be reconstructed. In almost every instance these family trees must be based on patterns in which the secondary structures are arranged to form the tertiary structures of the domains being compared because similarity in amino acid sequence has been completely lost. Second, the separate events that produced each of the fusions of the independent domains to produce the larger chimeric proteins must also be reconstructed.

Although the most interesting question may be how the large array of existing proteins arose from a much smaller array of smaller proteins present in the distant past, it should be stressed that new proteins are continuously being made by this process of fusion of different pieces. We know this because, in some instances, domains that have homologous amino acid sequences can be found in otherwise completely different proteins. Because similarity in amino acid sequence usually disappears quite rapidly over geologic time, these domains must have been separately incorporated into their respective proteins fairly recently; the greater the similarity of amino acid sequence among them, the more recently the separate fusions must have occurred.

Molecular Phylogeny from Amino Acid Sequence

The amino acid sequences of a set of related polypeptides retain a record of the history of their evolution by natural selection. That record provides information about the speciation of organisms, the specialization of tissues, and the conversion of older proteins into newer ones. This evolutionary history is read from aligned amino acid sequences.

As the amino acid sequences of the same protein from different species have become available, it has usually been found that they are similar enough to be readily aligned with each other. An **alignment** of two or more amino acid sequences is a display in which positions that are thought to be directly related to each other from the respective sequences are aligned directly above and below each other. The decision that the aligned positions are related is based on the fact that they are occupied by the same amino acid or the fact that they are each surrounded by similar sequences of amino acids. The cytochromes *c* from human, corn, and yeast can be readily aligned (Figure 7–1A).^{2,3} There is no uncertainty about the alignment even though the three proteins are from distantly related species.

The fact that, in most instances, the amino acid sequences of the three respective proteins responsible for a particular function in humans, yeast, and corn can be readily aligned, as can the three cytochromes *c*, is the strongest evidence for the fact that these three species share a **common ancestor**. Consequently, each of the proteins that are responsible for a particular function and the amino acid sequences of which can be aligned also share a common ancestor. Any two proteins that have descended from a common ancestor are **homologues** of each other.

In the distant past, when only the common ancestral species was present, all of the individuals in the population of that ancestral species contained, for all practical purposes, a cytochrome *c* the amino acid sequence of which was the same, just as all individuals of an extant species contain a cytochrome *c* with the same sequence. As natural selection operated upon the genetic

Figure 7–1: Alignment of amino acid sequences of cytochromes *c* and replacements observed at each of the positions in the common sequence. (A) Alignment of ungapped amino acid sequences. The three amino acid sequences below the numerical scale are the aligned amino acid sequences of the cytochromes *c* from *Homo sapiens*, *Zea mays*, and *Saccharomyces cerevisiae*. The amino acid sequence of cytochrome *c* from *Thunnus alalunga* is immediately above the numerical scale, which is based on this latter sequence. Above each position in this top sequence is a list of the other amino acids found in this position in a collection of 40 cytochromes *c* from various eukaryotes.^{2,3} Letters below the horizontal lines in each of the columns are variations found among cytochromes *c* of animals, and letters above the horizontal lines are the additional variations found in fungi and plants, more distantly related eukaryotes. (B) Insertion of gaps for the purpose of alignment. The two aligned amino acid sequences are those for cytochromes *c* from *T. alalunga* and *Paracoccus dinitrificans*. Each set of dashes represents a gap that must be made in one of the sequences to align it reasonably with the other sequence. You should convince yourself that the gaps are inescapable. When the two sequences are aligned in this way, the size of each gap is determined by the number of extra amino acids in the sequence that does not have a gap. (C) Gaps visualized as insertions. Instead of introducing gaps to permit the alignment shown in panel B, the extra amino acids in each intervening segment are shown as loops. This presents a more realistic picture of the situation but is a significantly more awkward method for displaying an alignment.

variation present within the population of that ancestral species, varieties arose that occupied different ecological niches. These varieties eventually diverged sufficiently to become separate species. At that point, the genes for cytochrome *c* in these two new species became disconnected, and the amino acid sequences encoded by those genes from that time forth were altered independently and continuously by mutation, genetic drift, and natural selection. As a result of a long series of such disconnections, the distantly related species *Homo sapiens*, *Zea mays*, and *Saccharomyces cerevisiae* eventually appeared. The differences and similarities between the three extant amino acid sequences for the three respective cytochromes *c* are the accumulated result of the individual steps in this process of speciation. An underlying assumption of this description is that a function performed only by the protein encoded by a certain gene remains the exclusive property of the product of that gene as it passes from species to species. Although this is usually the case, there are isolated examples in which the amino acid sequence of a protein from one species seems to be unrelated to that of the protein performing the same role in another species and must be the result of convergent rather than divergent evolution.⁴

Evolution by natural selection is usually viewed from its optimistic side. Natural selection operates on the variation inherent in any large population of a given species of organisms to shift the distribution of its assembled abilities gradually in a direction that makes that species or its descendant species more successful. Beneficial traits are patiently nurtured and multiplied. The major portion of the variation upon which natural selection operates to achieve this progress is variation in the sequences of the proteins within the population of a given species.

It is unlikely, however, that more than a small number of the differences seen when two aligned amino acid sequences are compared (Figure 7-1A) reflect improvements in the ability of the individuals of that species to survive relative to that of individuals of other species or their common ancestors. There is little evidence that the cytochrome *c* from either *H. sapiens* or *Z. mays* is an improved version of the cytochrome *c* that was used by their common ancestor or that any of the proteins the amino acid sequences of which are being presently compared are improved versions. The majority of the differences that accumulate in the sequences of the same protein in two lineages, following their divergence from their common ancestor, are neutral replacements.^{5,6} A **neutral replacement** is a change of one amino acid for another that is harmless enough that the biological function of the protein does not deteriorate sufficiently to cause the elimination of the replacement by natural selection. These neutral replacements arise from mutations in the DNA encoding the protein. Each that is now in existence began as a mutation in the genome of one individual and then spread through the

population of its species, or became **fixed**, by **genetic drift**. When one views aligned sequences of the same protein from different species, one is examining the record of this gradual increase in entropy.

This increase in entropy, however, is biased. From examining aligned amino acid sequences of the same protein from many species, it is clear that each position in the underlying sequence that gives the protein its unique character is under a different degree of negative selective pressure. Mutations can occur with equal frequency at any position in the sequence of the DNA encoding for the sequence of a protein. Each of these individual mutations is assessed by natural selection, and the majority⁵ disappear almost immediately because they adversely affect the function of the protein or are otherwise deleterious. For example, in the human population, there are many mutant forms of hemoglobin that bind oxygen improperly or are unstable proteins.⁷ These represent deleterious mutations that survive for a limited time before disappearing from the population. These mutant forms can be contrasted with fetal hemoglobin that has been fixed in the human population because it is a stable protein and has beneficial properties. The most **deleterious mutation** is one that kills the individual in which it arises before that individual has had an opportunity to mate or otherwise reproduce after the mutation occurs. The more critical a particular amino acid in the sequence of the protein is to its function, the less prone will that position be to substitution over time. For this reason, the aligned amino acid sequences of the same protein from an array of species evaluate the scope of the intolerance to variation expressed at each position in the sequence of the protein.

This **record of intolerance** can be read from examining consecutively each position in the aligned sequences of a large collection of the same proteins from different species. Above the numerical scale in Figure 7-1A, the sequence of cytochrome *c* from *Thunnus alalunga* is presented, and above each of its positions in a column of letters are tallied the amino acids found there in the cytochromes *c* from 40 other eukaryotes.^{2,3} The horizontal lines in each of these columns of letters separate amino acids found in the sequences of cytochromes *c* from animals, of which far more are available, from amino acids found in the sequences of cytochromes *c* from fungi and plants, which represent more distant relationships. A similar record of intolerance is observed when the amino acid sequence of a particular protein is mutated at random and the resulting mutants are selected for their ability to function properly.⁸

This intolerance to substitution is most strongly manifested at an invariant position. An **invariant position** in a protein is a position at which no replacement has been made over the history encompassed by the aligned amino acid sequences. A few of the positions in the aligned sequences of the cytochromes *c* have remained absolutely invariant, for example, Cysteine 14, Cysteine 17, Histidine 18, and Methionine 80 because

these are functionally irreplaceable and consequently define a cytochrome *c*. Some positions such as those occupied by Glycine 6, Glycine 34, Glycine 41, Glycine 77, and Glycine 84 are invariant among the eukaryotes but are replaced in bacterial cytochromes *c*. Several of these glycines are examples of the fact that glycines with angles ϕ and ψ outside the boundaries on a Ramachandran plot (Figure 6-4B) are difficult to replace.⁹ Nevertheless, their eventual replacement demonstrates that a designation of invariant is always provisional. As more and more amino acid sequences of the same protein from different species become available, the number of invariant positions usually decreases.¹⁰

The fact that any designation of invariant is necessarily based on a limited set of amino acid sequences may explain why site-directed mutation of amino acids at apparently invariant positions often has little effect on the function of a protein.¹¹⁻¹⁵ For example, site-directed mutation of five of the 15 highly conserved amino acids in lathosterol oxidase had little effect on its function.¹⁶ Consequently, the intuition that an invariant position must be structurally or functionally important is unreliable. The situation is even more confusing when a position known to be functionally critical nevertheless displays several replacements even among closely related species.¹⁷

Many of the changes accumulating over time seem to be conservative replacements. A **conservative replacement** is a replacement at a position in which only similar amino acids, either in size or in chemical properties, can be tolerated. For example, only valine, isoleucine, phenylalanine, and leucine, each of the side chains of which is a hydrocarbon, seem to occur in position 35 of eukaryotic cytochrome *c* (Figure 7-1A). Either glycine or alanine, the side chains of which are small, seems to be necessary in position 29. Either serine, threonine, or glutamine, the side chains of which are polar but uncharged, seems to be necessary in position 42.

It was once thought that each position in the amino acid sequence of a protein could be assigned unambiguously to one of a few categories, for example, invariant, conservative, physicochemically constant, and variable.¹⁸ When it became possible, however, to compare the amino acid sequences of the same protein from a large number of distantly related species, the majority of the replacements observed could not be easily explained. This fact suggests that even the specific designations just presented may themselves be rationalizations of more subtle processes that are not understood. A close examination of the actual results, however, sequence position by sequence position (Figure 7-1), does produce an intuitive feeling for the play of evolution.

In addition to the capacity of a particular amino acid to be tolerated at a particular position in the sequence of a protein, the nature of the **genetic code** itself also affects the patterns in which replacements in the sequence

occur during evolution. Because there are three bases coding for each amino acid and mutation occurs one base at a time, replacements requiring one base change should be more common than those requiring two or more.⁵ There are, however, some interesting apparent exceptions to this generalization that occur even in the comparisons of the various eukaryotic cytochromes *c* (Figure 7-1). For example, at position 31, only asparagine and alanine are found; at position 72, only lysine and serine; at position 45, only lysine and glycine; and at position 19, only glycine and threonine. Each of these four replacements would require that two bases of the respective codon be mutated consecutively. Although these are unlikely events, the constraints on the occupation of these positions seem to have been severe enough to confine the replacements among the eukaryotes to these choices. In the short term, however, the difficulty of changing more than one base to effect a replacement is more acute. When the detailed history of the mutational events that have occurred during the recent evolution of artiodactyl fibrinopeptides⁵ was examined, it was observed that replacements requiring the mutation of only one base were far more frequent than those requiring two consecutive mutations. It is altogether likely that, in circumstances where two consecutive mutations seem to have occurred, the amino acid sequence of the protein displaying the intermediate single mutation, although it exists, has not yet been determined.

One approach to examining quantitatively the progress of natural selection has been to calculate a mutation probability for every pair of possible replacements.² This was accomplished by reconstructing a probable sequence of events in the evolution of 10 different groups of closely related sequences. Sequences for common ancestors were predicted from alignments, and all of the replacements that should have occurred following the divergence of the progeny from that ancestor were tabulated to provide the basis for the calculation of probabilities. The results of this study were presented as mutation probabilities. A **mutation probability** is the probability that a certain replacement will occur during a time long enough for a particular number of replacements to accumulate for every 100 amino acids of the sequence.

Values for mutation probabilities over a period of time long enough for two replacements for every 100 amino acids (Table 7-1) register changes that occur over the **short term**. Almost all of the replacements with the highest mutation probabilities over this period require only one base change to occur and are also remarkably conservative. For example, the 12 most frequent replacements do not involve any change in charge number or even polarity. Replacements involving **alanine** are the most frequent by a considerable margin, an observation suggesting that a truncation to the β carbon is the most readily tolerated change. A large number of replacements are not tolerated well at all (mutational probab-

^aPairs of amino acids occupying the same position in pairs of aligned sequences.

^bMinimum number of changes required to change a codon from one member of the pair into a codon for the other. ^cProbability that the given pair will occur at the same position in two aligned sequences that have only two replacements for every 100 positions.² Only pairs with probabilities greater than or equal to 0.5% are tabulated (24 of the 190 possible pairs).

ity $\leq 0.005\%$) over the short term (Table 7-1). Many of these require two or three consecutive base changes. The frequency at which other amino acids are turned into tryptophan or methionine or into cysteine, tyrosine, or phenylalanine will also be decreased by the fact that these amino acids have only one or two codons, respectively.⁶ The amino acids most intolerant to promiscuous replacement are tryptophan, tyrosine, arginine, and cysteine (mutation probabilities are less than 0.005% for 11 or more of the 19 possible replacements), in part because they along with glycine and proline are so peculiar. The amino acids that are the most promiscuously replaced are alanine, serine, glutamine, threonine, valine, methionine, lysine, and asparagine (mutation probabilities are greater than 0.12% for 11 or more replacements).

There are several ways in which the DNA encoding a protein can be altered over time. The most common is by **point mutation**, which is the ultimate source of the exchanges of one amino acid for another that are observed in the alignments of the four eukaryotic cytochromes *c* (Figure 7-1A). It is also possible for a **start site** or a **stop site** for translation to be mutated and another start site or stop site, either already present or

arising by mutation, to take over, causing the protein to become longer or shorter at one or the other of its ends (Figure 7-1A). Because the amino-terminal and carboxy-terminal segments of a protein are seldom involved in its function, this is usually an inconsequential change.

Eukaryotic genes contain **introns**. These are segments of DNA, often quite long, inserted at several locations within the coding sequence of the genomic DNA. Introns are removed by **splicing** at the level of the messenger RNA. Often a cell will contain two or more¹⁹ versions of the same protein, one in which all the splices were successful and one or more in which one or more of the splices has failed. For example, there are two crystallins found in the lenses of the eyes of *Zapus hudsonius*, the longer containing an unremoved insert between positions 63 and 64 in the amino acid sequence of the shorter.²⁰ Errors in splicing can also lead to two forms of a protein that differ in their amino-terminal sequences because amino-terminal segments under the control of two different promoters, respectively, have been alternatively spliced to the same coding sequence for the remainder of the protein.²¹ Likewise, there are two different versions of subunit β of isocitrate dehydrogenase (NAD⁺) in *Bos taurus* that differ only in their carboxy-terminal sequences. Both are encoded by the same genomic DNA. One ends with a sequence of 28 aa; the other, with a completely different sequence of 26 aa even though their sequences are exactly the same for the first 357 aa. The former results from a messenger RNA in which the final exon in the genomic DNA is properly spliced to those that go before; the latter, from a messenger RNA in which this exon is skipped and the following exon is spliced to those that go before.²² Each of these types of **alternative splicing** has the potential to produce different versions of the same proteins.

One of the common changes that occurs over evolutionary time is the **insertion** into or the **deletion** from a protein of a short segment of amino acids. For example, most forms of adenylate kinase have an additional 25 aa in their amino acid sequence between the valine and the aspartate in the sequence –GRVDDN– found near position 140 in the amino acid sequences of isoform 1 of adenylate kinase from mammalian cytoplasm.²³ This additional segment of 25 aa is present in the adenylate kinases from bacteria, fungi, and mitochondria, so it can be concluded that it must have been deleted during one of the genetic events leading to the appearance of mammalian isoform 1. Usually, however, it is difficult to tell whether a deletion or an insertion has occurred. Because such insertions or deletions appear as frequently in proteins from prokaryotes as they do in proteins from eukaryotes, they must arise from processes independent of alternative splicing. When the sequences of two proteins that differ by a deletion or an insertion are aligned, a gap is included in the shorter to permit the alignment of the sequences on the two sides of the aberration.

A **gap** is a series of blank spaces inserted into one

amino acid sequence that is missing a segment of amino acids present in the other amino acid sequence with which the first is being aligned. For example, it is necessary to insert three gaps of 6, 5, and 8 spaces in length into the amino acid sequence of cytochrome *c* from *T. alalunga* and two gaps of 1 and 3 spaces in length into the amino acid sequence of cytochrome *c*-550 from *Paracoccus denitrificans* in order to achieve the most reasonable alignment of these two proteins (Figure 7-1B). On either side of each gap, the alignments are convincing enough to justify the insertions of the gaps required to bring those alignments into register. It must be kept in mind that in the actual polypeptide there is no gap; rather it is the other polypeptide, the one with the ungapped sequence, that has additional amino acids at that point (Figure 7-1C). The use of a gap is simply a convenient method for displaying the alignment of the sequences.

When two sequences are aligned, their similarity is usually quantified by stating their percentage of identity and the gap percentage. The **percentage of identity** is the percentage of the average number of positions in the two aligned sequences that are occupied by the same amino acid. The **gap percentage** is the number of gaps that had to be inserted for every 100 amino acids in the alignment. For example, in the alignment of the cytochromes *c* from *T. alalunga* and *P. denitrificans* (Figure 7-1B), an average of 110.5 positions from the two sequences are aligned, there are 38 identities for a percentage of identity of 34% identity, and there are 5 gaps for a gap percentage of 4.5 gap percent.*

The alignments of the cytochromes *c* in Figure 7-1 are so obvious that they can be performed unassisted. Even for the cytochromes *c* from *T. alalunga* and *P. denitrificans*, with only 34% identity and 4.5 gap percent, the sequences are easily aligned by eye. The amino acid sequence of each protein changes, however, at a different rate during evolution. Although there are proteins that change more slowly than cytochrome *c*, such as histone H4 (20 times more slowly), calmodulin (4 times more slowly), α tubulin (2 times more slowly), ubiquitin (2 times more slowly), and protein phosphatase 2A (2 times more slowly),²⁴ most proteins change more rapidly than cytochrome *c*. As more and more time has passed following the divergence of the amino acid

sequences of two proteins from that of their common ancestor, the percentage of identity decreases and the gap percentage increases until it becomes difficult to align them. Appropriately programmed digital computers are used to align such distantly related sequences.²⁵

The **computational alignment** of two distantly related amino acid sequences is accomplished by constructing a **matrix**.²⁶ If one sequence A has *p* amino acids, arranged in the order $a_1 a_2 a_3 \dots a_p$, and the other sequence B has *q* amino acids, arranged in the order $b_1 b_2 b_3 \dots b_q$, the product of these two vectors is a matrix C, the coefficients of which, c_{ij} , are equal to $a_i \times b_j$, where a_i and b_j are particular amino acids. For example, in the alignment of the cytochromes *c* from *T. alalunga* and *P. denitrificans* (Figure 7-1B), $a_9 \times b_{11}$ would be Thr \times Glu. The numerical value assigned to a particular position c_{ij} in the matrix representing $a_i \times b_j$ depends on the schemes chosen to weight the comparisons.

The simplest scheme is to decide that when $a_i = b_j$, $c_{ij} = a_i \times b_j = 1$, and when $a_i \neq b_j$, $c_{ij} = a_i \times b_j = 0$. This produces a matrix the coefficients of which, c_{ij} , are either 1 or 0. When the amino acid in position a_i in the first sequence is the same as the amino acid in position b_j in the second sequence, $c_{ij} = 1$; when they are different, regardless of the difference, $c_{ij} = 0$. Such a matrix, spread upon a two-dimensional field, can be represented diagrammatically by placing a dot on every position with a score of 1 (Figure 7-2).²⁷ In such a **dot matrix**, the alignment is represented by diagonal strings of dots. In the dot matrices comparing the amino acid sequence of the cytochrome *c* of human with those of monkey and fish in Figure 7-2, the diagonals are obvious and unbroken. In the matrix comparing those of human and bacterium, the alignment is a set of at least three diagonal segments that can be picked out by eye if the figure is tilted and viewed along the diagonal direction. The offsets between the diagonal segments are the gaps in the alignments.

There are, however, 231 different outcomes* for $a_i \times b_j$ if one assumes symmetry, namely, that Glu \times Thr = Thr \times Glu, if one treats cysteine and cystine as separate amino acids, and if one treats each of the 21 types of identity as a unique result. It has always seemed that some of these 231 outcomes are more probable and that recognition of this probability with the proper weighting scheme might enhance the ability to align distantly related sequences. Each of the more than 18 available **weighting schemes**²⁸ is a table of numbers assigned to the 231 possible identities and replacements. Each of these entries reflects the author's view of the probability that such an outcome is the result of evolution by natural selection.

The ultimate goal in aligning two amino acid sequences is to decide whether position a_i in sequence A and position b_j in sequence B arose from the same position in the sequence of a common ancestor or position a_i

* There is no agreement as to the length of amino acid sequence to be used in calculating the percentage of identity. The most common choice is the length of the shorter sequence. The justification for this choice is that the inserts in the longer protein cannot be compared to anything and should therefore be discounted. This choice, however, in a self-contradiction, ignores the inserts in the smaller protein. Probably, the best choice would be to use the length of the common amino acid sequence in which a gap appears in neither protein. The problem with this choice is that it would inflate both percentages and would be misleading in the absence of universal agreement. The choice made in the present calculations was to use the mean length of the two sequences being compared, which produces somewhat smaller percentages than any of the other choices.

* $[(21 \times 20)/2] + 21$.

Figure 7-2: Dot matrices²⁷ for the amino acid sequences of the cytochromes *c* from *Macaca mulatta*, *T. alalunga*, and *Rhodospirillum rubrum*, each compared to the amino acid sequence of human cytochrome *c*. The sequence of human cytochrome *c* is the vertical vector (top to bottom, amino to carboxy terminus), and the respective sequences with which it is compared are the horizontal vectors (left to right, amino to carboxy terminus). A dot is placed in the matrix when the amino acids at those two positions, horizontal and vertical, are the same. Reprinted with permission from ref 27. Copyright 1970 Springer-Verlag.

in sequence A and position b_j in sequence B are unrelated to each other either because protein A and protein B do not share a sufficiently recent common ancestor that they can be aligned or because the two sequences are misaligned. If the two amino acid sequences are unrelated, $a_i \times b_j$ is governed solely by chance. If the respective positions are descended from the same position in an ancestral sequence, then $a_i \times b_j$ should retain some of the biases enforced by natural selection, and these biases, if they can be quantified, should be considered while a decision is reached. If a particular replacement has a higher probability of occurring as a result of evolutionary change than it does of occurring as a result of random change, then whenever that particular replacement is encountered, those two positions have a higher probability of being evolutionarily related than of being unrelated. For example, every $a_i \times b_j$ where a_i and b_j are interconvertible by only one base change should have a higher probability of being evolutionarily related than those $a_i \times b_j$ where a_i and b_j are interconvertible only by two or three base changes.²⁹ Every $a_i \times b_j$ where a_i and b_j are similar in size or chemical properties should have a higher probability of being evolutionarily related than those in which they are dissimilar.³⁰ The mutation probability (Table 7-1)² can also be used to weight $a_i \times b_j$.

The net effect of any one of the different weighting schemes, or some combination of them, is to assign a number to every coefficient c_{ij} of the matrix. The magnitude of this number is thought to quantify either the effect of natural selection relative to chance on the par-

ticular replacement $a_i \times b_j$ or the probability that the particular replacement $a_i \times b_j$ would arise as the result of evolution rather than chance. Consequently, logarithms of these probabilities are used as entries in the matrix so that the summation to be performed will represent products of probabilities.² It is also possible to incorporate weights into a dot matrix by assigning a dot to any c_{ij} the weight of which exceeds a certain threshold.³¹

When the matrix has been constructed to the taste of the practitioner, the alignment can be performed.²⁶ Any alignment of the two sequences A and B can be represented as a set of consecutive diagonal segments running through the matrix, for example, the three diagonal segments in the dot matrix comparing the cytochromes *c* of humans and *R. rubrum* (Figure 7-2). To be included in the alignment, the end of one of these diagonal segments must be in line with, above, or to the left of the beginning of the next diagonal segment when the diagonals run from top left to bottom right as in Figure 7-2. Each discontinuity requiring a negative vertical shift or a positive horizontal shift to connect the previous diagonal to the next diagonal represents a gap in one of the sequences being aligned. Associated with each individual alignment is an **alignment score**

$$AS = \sum_i \sum_j c_{ij} - \sum_k P_k \quad (7-1)$$

where the respective sums are over all c_{ij} intersected by the diagonal segments and over all gaps k that must be

inserted and P_k is a penalty assessed for creating the gap k . A computer can be programmed to find the **path of diagonal segments** through the matrix that has the largest alignment score,²⁶ and this path produces the most appropriate alignment of the two sequences dictated by the choice of weighting scheme and gap penalty.

The penalty assessed for each gap is an estimate of the logarithm of the probability of a gap the length of gap k appearing during evolution by natural selection on the same numerical scale used to assign the logarithms of the probabilities to each c_{ij} . It is possible to optimize such a gap penalty for the particular weighting scheme being used.²⁸ For example, it has been shown that when values of 1 are assigned to identities and values of 0 are assigned to nonidentities, the appropriate **gap penalty** is

$$P = 1.2 + 0.23l \quad (7-2)$$

where l is the length of the gap.

The most important responsibility of an investigator who performs such a computation and produces an alignment with the maximum alignment score is to provide an assessment of its **statistical significance**. The accepted criterion for this assessment is a statistical evaluation of a set of alignments produced from randomly jumbled sequences of the same length and amino acid composition as the actual amino acid sequences.² First the two actual sequences are aligned, and a maximum alignment score for the optimum alignment is calculated. Then each of the two actual sequences is randomly jumbled a number of times to produce for each a set of nonsense sequences that have the same amino acid composition and length as the actual amino acid sequence from which they were generated. This produces two sets of randomly **jumbled amino acid sequences**, one derived from each of the two actual sequences. All of the different combinations of one jumbled sequence from one of these two sets and one jumbled sequence from the other set are aligned by the same algorithm that was used to align the two actual, unjumbled sequences, and a large number of maximum alignment scores for the nonsense sequences is gathered in this way. The mean and standard deviation of the alignment scores of this collection of randomly jumbled nonsense sequences are calculated by the usual statistical formulas.

The number of standard deviations that the alignment score for the two actual amino acid sequences lies above the mean for the maximum alignment scores for the jumbled sequences is a measure of the confidence that can be assigned to the decision that the two actual sequences share a common ancestor and to the decision that the alignment has juxtaposed positions in the sequence that have evolved independently from the same position in the ancestral sequence. For example, when human $\beta 2$ microglobulin was aligned with the κ -constant region of human immunoglobulin, the maxi-

mum alignment score was 3.5 standard deviations larger than the mean of the alignments of the jumbled sequences (Table 7-2). Unfortunately, there is no accepted level of statistical significance above which an alignment is judged to be real. Consequently, each person is left to make her own decision. Two sequences of amino acids are considered to be homologous to each other once the decision has been made that their alignment is statistically significant.

As the data bases from which candidates for alignment are drawn become larger and larger, the risk that the alignment of the amino acid sequences of two unrelated proteins will nevertheless be judged to be statistically significant becomes greater. For example, if the lengths of the sequences are disregarded, in a data base containing 100,000 amino acid sequences, each of the amino acid sequences should be able to be aligned with two or three other unrelated sequences in the data base with alignment scores that are at least 4 standard deviations greater than the means of the jumbles.

There is a frequently encountered sleight of hand that is practiced in the alignment of amino acid sequences and that violates the rules of statistics. This trick is to align two sequences and then select only the regions in which there is a higher frequency of coincidence for the statistical test. Because the sample has been preselected, it usually shows a higher frequency of coincidences than occurs when jumbled sequences of the same small regions are compared. Ordinarily, statistical evaluation of an alignment of two amino acid sequences shorter than those of complete, naturally occurring, and logically defensible domains within the native protein should not be accepted without the closest scrutiny.

At the present time, statistically significant alignments can be made only between two amino acid sequences that have a **percentage of identity of 15% or greater** upon alignment.^{28,29,32} If a set of three or four amino acid sequences can be assembled, however, that are from a set of proteins that share some structural or functional feature, it is often possible to demonstrate with high statistical confidence that the members of this set all share the same common ancestor even when pairwise comparisons between the members of the set fail to demonstrate convincing homology.^{33,34} In these instances, the statistical significance only becomes convincing when the whole set is aligned together. Such methods for multiple alignment can detect with statistical significance many more correct relationships between distantly related proteins than can pairwise alignments.³⁵

Although they also identify statistically significant^{36,37} relationships among proteins, computational procedures that rapidly **search large banks of amino acid sequences** should be distinguished from the computational procedure for aligning two sequences by using a complete matrix. Banks of the currently available

amino acid sequences, such as the Swiss-Prot Sequence Database (www.expasy.ch) and the Protein Sequence Database of the Protein Information Resource (<http://pir.georgetown.edu>), contain the sequences of hundreds of thousands of proteins. When the sequence of a new protein becomes available, it is not possible to attempt a complete computational alignment between it and each of the proteins in such large collections. Consequently, other strategies have been developed to search such a bank and rapidly find as many candidates for a relationship as possible. Each of these candidates can then be aligned by the standard matrix method with the new amino acid sequence to validate statistically significant relationships.

The methods that are used to search the banks take advantage of the fact that evolution operates unevenly over a sequence of amino acids. Because segments of the sequence in the core of the structure of a protein or in functionally important locations change far less rapidly than regions on the surface;³⁸ in distantly related amino acid sequences, identities and conservative replacements tend to be clustered. For example, in the amino acid sequences of the group of proteins containing the ATP-binding cassette, the sequence –SGCGKST–, or limited variations of it in which the first serine is replaced by a proline or a threonine, the cysteine is replaced by a serine, the second serine is replaced by a threonine or a glycine, or the threonine is replaced by a serine or a glutamine, appears in all of the members even though the rest of the amino acid sequences show low percentages of identity.³⁹ Consequently, searching a bank for **short segments of amino acid sequence** that have a high degree of similarity with short segments in the new amino acid sequence has a significant probability of locating relatives and has the advantage that it can be done rapidly.

The bank of amino acid sequences is searched for short segments of sequence that are similar to any of the segments of a certain length in the newly sequenced protein. The similarity is quantified by summing the weights given to each identity and each replacement in the aligned segments by use of the weighting scheme preferred by the investigator. If the score for the match is above a certain predetermined threshold, the amino acid sequence in the bank containing this segment is judged to be a candidate for a relationship.

The three most widely used **algorithms** for searching banks of amino acid sequences differ only in how they find the segments. In the BLAST algorithm,⁴⁰ every sequence four amino acids in length that appears in the complete sequence of the protein is tabulated. The amino acid sequences in the bank are then searched for segments identical or highly similar to one of the tabulated segments. When such a match is found, the alignment is extended in both directions to find a longer segment that has a high degree of similarity to the corresponding segment of the sequence being matched. It is

the score for this longer segment, based on the identities and replacements it contains, that must exceed the final threshold. In the FASTA algorithm,⁴¹ regions within the new amino acid sequence and regions within an amino acid sequence in the bank with the highest density of identities are located. Ten of these regions are then trimmed until the portion of each giving the highest score is identified. All of these regions with scores above a threshold are joined, and the gaps resulting from the joining are penalized. It is the score for this rough alignment of a portion of the protein that must exceed the final threshold. The SSEARCH algorithm^{32,42} searches directly each sequence in the bank for the segment that has the highest score when aligned with a segment of the new sequence. Because each of these procedures focuses only on short segments of the sequences being searched, each misses some statistically significant matches, but the advantage gained is that they are rapid enough that such searches of the large extant banks of sequences can be performed in a reasonable amount of time.

Computer-assisted searches of banks and complete computational alignments have permitted the relatives of a **newly sequenced protein** to be located so that it can be joined with a known group. The most obvious successes occur when the new amino acid sequence is identical to one that already is known, because this identification often demonstrates that the same protein has two different, unsuspected, and unconnected functions.⁴³ For example, it has been discovered that the protein responsible for the function of neuroleukin, autocrine motility factor, maturation factor, and myofibril-bound serine endopeptidase inhibitor is glucose-6-phosphate isomerase.⁴⁴ It also happens that the amino acid sequence of a protein of known function can be matched with known amino acid sequences of proteins with unknown function and such an alignment gives a strong indication of the identity of that hitherto unknown function.^{45,46} When a new genome is sequenced, one of the banks is searched for matches to the new amino acid sequences of each of the previously unidentified proteins it contains. For example, when the genome of *Archaeoglobus fulgidus* had been sequenced, it was found to encode 1797 proteins that could be matched with amino acid sequences already known while it encoded only 639 proteins that could not be matched.⁴⁷

The aligned amino acid sequences of polypeptides have been used to provide information about the **speciation of organisms**. The sequences of the same protein from a set of different species, for example, the sequences of the cytochromes *c* from different eukaryotic species, serve as the data on which such studies are based. The goal of the exercise is to construct a **phylogenetic tree** (Figure 7–3)⁴⁸ that displays the evolutionary history of the species bearing that protein. The lengths of the limbs in the tree are estimates of the evolutionary distances between any two present-day species and their common ancestor, represented by the node at which the

Figure 7-3: Phylogenetic tree⁴⁸ for the cytochromes *c* from 53 species of eukaryotes. Each of the possible 1378 pairs of sequences was aligned and the minimal mutational distance between each pair was tabulated. These numerical values were then adjusted statistically for mutations that would have not left a trace to obtain estimates of evolutionary distances. The magnitudes of these corrections are indicated in the upper right corner. These estimates of evolutionary distance were used to construct the phylogenetic tree. If one passes along the branches of the tree between any two species, the numbers on the branches that are passed through sum to give the estimated evolutionary distance. For example, the evolutionary distance between carp and dogfish is 67. The noted length of the branches, in evolutionary distance, and the positions of the nodes are determined by the most parsimonious sequence of events that satisfy the requirement that the evolutionary distances from the alignments of the sequences of amino acids equal the distances along the branches. In this figure, the nodes connecting marsupials (kangaroo) with the eutheria (the rest of the mammals), reptiles and birds with mammals, amphibians (frog) with amniotes (reptiles, birds, and mammals), fish (tuna, bonito, and carp) with tetrapods (amphibians, reptiles, birds, and mammals), and cartilaginous fish (lamprey and dogfish) with bony fish were placed on the scale of geologic time (millions of years) by using the dates from the fossil record at which the respective divergence from a common ancestor took place. Adapted with permission from ref 48. Copyright 1976 Academic Press.

branches to those two species join. The **evolutionary distance** between the amino acid sequences of two proteins is the value of any quantity that is thought to be directly proportional to the time that has elapsed since those proteins shared a common ancestor. The first step in constructing a phylogenetic tree is to estimate the evolutionary distances between each of the $(n^2 - n)/2$ pairs of sequences in the set of n sequences.

There are a number of **problems** involved in transforming the differences in the aligned sequences of two proteins into an evolutionary distance.^{5,49} First, the number of replacements observed in the two aligned sequences is always an underestimate of the number of replacements that have actually occurred since the two proteins diverged from a common ancestor because several successive unregistered replacements at the same site have often taken place. Second, each position in the two aligned sequences varies at a different rate (Figure 7-1A), each type of amino acid has a characteristic sus-

ceptibility to replacement (Table 7-1), and each protein has its own characteristic rate of change.²⁴ Third, there are examples of accelerated changes occurring along only one branch of a tree containing species that seem indistinguishable from each other. For example, rat ribonuclease seems to have accumulated replacements at 4 times the rate of its close relatives the ribonucleases from mice, muskrats, and hamsters.⁵⁰ Such accelerations in the replacement of amino acids are also observed in those members of a related set of proteins that happen to be involved in the battle between a species and one of its pathogens because the weapons of such a battle are often rapid changes in amino acid sequence either on the part of the pathogen to avoid the defenses or on the part of the attacked to reinstate defenses.⁵¹ Fourth, the size of the population of a given species or its generation time may affect the rate at which mutations become fixed. This may explain why the sequences of the cytochromes *c* from three closely related strains of the

bacterial genus *Pseudomonas* show as much variation in their amino acid sequences (78–61% identity)⁵² as is shown between mammals and amphibians (82% identity) or between mammals and insects (67% identity). These problems have been addressed with varying success by the two methods used to estimate evolutionary distance. One method relies on the percentage of identity between the two aligned sequences; the other, on the minimal mutational distance between them.

It has been shown, both theoretically⁵³ and by simulation,⁵⁴ that

$$q = \frac{\ln(1 + D)}{2D} \quad (7-3)$$

where q is the fraction of the positions in the alignment occupied by identical, unreplaced amino acids and D is the evolutionary distance. This equation corrects for the variations in rate of replacement both among the different positions in the two aligned sequences and among the different types of amino acids and provides an estimate of evolutionary distance from the percentage of identity.

The minimal mutational distance, however, focuses on the changes that have occurred rather than on the positions that have remained unchanged. In theory, there should be more information in these replacements of one amino acid for another because they are progressive rather than static, but the corrections required to account for the unrecorded changes that have occurred over time are inaccurate enough that the advantages of the greater information are significantly diminished.

To calculate its minimal mutational distance, a pair of aligned amino acid sequences in the set is compared position by position, and the minimum number of mutations that had to be fixed to accomplish each replacement is scored. Because of the redundancy of the genetic code, these individual minimum numbers of mutations are most accurately assessed if the actual codons used for each amino acid are known from the nucleic acid sequence. These individual minimum numbers of mutations are added together to obtain the minimum total number of mutations that had to be fixed to convert either of the two sequences into the other. This sum is the **minimal mutational distance** between the two proteins.⁵⁵

The actual number of mutations that were fixed in the two lineages diverging from the common ancestor represented by each of the comparisons between two species is almost always greater than the number calculated, even when the nucleic acid sequences are known, because mutations fixed in the past but then replaced by mutations fixed at the same position at a later date cannot be scored. If the nucleic acid sequence encoding either protein is unknown, mutations to an alternative codon for the same amino acid are also missed. The minimal mutational distances must be corrected statisti-

cally^{48,56} for all of these missing mutations to obtain estimates of evolutionary distances (Figure 7-3).

The major contributors to the minimal mutational distances calculated for each pair of aligned amino acid sequences are the regions of the protein that have experienced the greatest change over time. Unfortunately, these are also the most difficult segments of the amino acid sequences to align convincingly. As a result, the choice of the method used to align the sequences can have a significant effect on the structure of the final tree. With this in mind, a method of **progressive alignment of amino acid sequences** has been developed to provide the most suitable and internally consistent alignments of a large collection of sequences of the same protein from different species.⁵⁷ The basis of this method is the assumption from the beginning that all of the amino acid sequences to be aligned share a common ancestor and have diverged from that common ancestor along their own unique lineages. The most closely related sequences are aligned first, and the gaps in these more certain alignments are retained as the more distant alignments are made. This is advantageous because it is the uncertainty in the precise location of the gaps that must be inserted to align distantly related sequences that creates the greatest uncertainty in the final value for the minimal mutational distance. An example of the product of this method is the progressive alignment of the amino acid sequences of 11 globins (Figure 7-4).⁵⁷ The important feature of these alignments is that the gaps are confined to specific locations rather than being more randomly distributed as would result from simple pairwise alignments.

The tabulated values of evolutionary distances are used to construct a tree the branches of which connect the species being compared (Figure 7-3).⁴⁸ The tree is arranged so that the connections made produce the **most parsimonious sequence** of events that can reproduce the observed evolutionary distances. The overall length of the line segments connecting any two present day species is equal to the evolutionary distance between the two aligned sequences of the proteins from each of them. The branching order in such a tree conveys a historical sequence of the relationships among the species represented, and these historical sequences seem to be reasonable, based on the fossil record and anatomical resemblances.

Usually the phylogenetic trees that are built from the amino acid sequences of only one protein, for example, those of the cytochromes *c* (Figure 7-3), are unsatisfactory. Often there are sequences of a particular protein available for only a limited number of species. Often the phylogenetic tree based on the amino acid sequences of one protein disagrees with the phylogenetic tree based on the sequences of another.⁵⁸ There are a number of solutions to this problem. For example, a more comprehensive and detailed phylogenetic tree of the eukaryotes than the one displayed in Figure 7-3 has been built by

combining alignments of the amino acid sequences of α -tubulins, β -tubulins, actins, and elongation factors 1 α .⁵⁹ The conflicts between three phylogenetic trees for gnathosomes were resolved by considering the positions in the sequences of gaps, the patterns of alternative splicing, and the distributions of introns in the genomic DNA.⁵⁸ Nevertheless, disagreements on the branching order of phylogenetic trees, especially the most ancient, persist.⁶⁰

Because the rate of replacement varies dramatically among the positions in the sequence of a protein (Figure 7-1A), minimal mutational distance changes more rapidly than percentage of identity over the short term, and corrections of minimal mutational distance are also less significant over the short term (Figure 7-3). Consequently, historical sequences based on minimal mutational distance are preferred for examinations of **recent speciation**. For example, a detailed phylogenetic tree for the order of artiodactyls covering the last 50 million years has been constructed from considerations of minimal mutational distances for aligned fibrinopeptides⁶¹ and pancreatic ribonucleases.⁶² In fact, ribonucleases with the amino acid sequences predicted for common ancestors at the nodes on that tree were produced by site-directed mutation and shown to display the functional traits characteristic of artiodactyl ribonucleases.

The phylogenetic tree, however, in addition to the historical sequence of events, conveys estimates of the evolutionary distances from existing species to common ancestors. These evolutionary distances can be calibrated (Figures 7-3 and 7-5)⁴⁹ with estimates from the fossil record of the time at which divergence occurred. Eutheria and marsupials diverged from a common

ancestor 130 million years ago (mya); mammals and either reptiles or birds, 300 mya; amniotes and amphibians, 365 mya; and tetrapods and fish, 405 mya.⁴⁹ The respective nodes on the tree should fall at these dates (Figure 7-3). Once the distances are calibrated, the times at which divergences unavailable in the fossil record have occurred can be estimated by extrapolation. To overcome the problems of the different rates of change from one protein to the other and rapid rate of change of a particular protein within a particular branch of the tree, these calibrations are usually performed with sets of amino acid sequences for as many proteins as possible (Figure 7-5).⁴⁹ In this way, the final factor converting evolutionary distance to time should be as reliable as possible to permit a realistic **extrapolation beyond the fossil record** to be performed.

Because the corrections required to convert minimal mutational distances to estimates of evolutionary distance become more significant and less reliable over the long term (Figure 7-3), estimates of evolutionary distance by percentage of identity (Equation 7-3) are preferred for assigning a date to distant common ancestors. For example, it has been estimated from percentage of identity that eukaryotes and archaebacteria diverged from a common ancestor 2.3 billion years ago.⁴⁹ Estimates, however, from both percentage of identity⁴⁹ and minimal mutational distance⁵⁶ agree that deuterostomes and protostomes diverged from a common ancestor 0.7 billion years ago.

At the point at which the lineages of two presently existing species diverged from their common ancestor, the gene for a particular protein carried by the common ancestor became two separate and disconnected genes,

Figure 7-5: Calibrating evolutionary distance with dates from the fossil record.⁴⁹ Sets containing amino acid sequences of the same protein from different species were assembled. Within each set, the amino acid sequences were aligned and the percentage of identity of all pairs of aligned sequences were converted into evolutionary distances with Equation 7-3. Within each set, the evolutionary distances between pairs of sequences in which the two members were from two different groups were sorted into five categories based on which two groups they respectively represented (eutheria and marsupial, mammal and either bird or reptile, amniote and amphibian, tetrapod and fish, and gnathostome and lamprey). The evolutionary distances for pairs of sequences that diverged at these nodes were averaged over each set and then over all of the sets, and the means and standard deviations of these averages are plotted against the date (million years ago, mya) at which the groups in each set diverged from a common ancestor, as determined by the fossil record: 130, 300, 365, 405, and 450 mya, respectively. Averages are also plotted for comparisons of major mammalian groups that diverged from a common ancestor 100 mya. The sets of amino acid sequences did not each have representatives of all groups being compared. The number of sets of amino acid sequences of the same protein from different species that could be used were 48 for mammal/mammal, 3 for eutheria/marsupial, 16 for mammal/bird or reptile, 11 for amniote/amphibian, 15 for tetrapod/fish, and only 1 for gnathostome/lamprey.

one carried by each of the new, independent ancestral species. At that time, natural selection began to operate on these two genes independently, and the differences now observed in the sequences of the same protein from the two existing species began to accumulate. A similar disconnection of two genes for the same protein can occur within a single genome by gene duplication.⁵

Gene duplication is the result of a mistake in recombination causing the DNA in an individual suddenly to contain two copies of the same gene where before there was only one. If this duplication spreads through the population by genetic drift and becomes fixed,* the

* Gene duplication is a fairly common event, its spread, however, over the entire population of a species is a rare event.

genome of the affected species will now contain two copies of the same gene. Both copies will usually continue to produce their respective proteins; but, because of the disconnection, the amino acid sequences of these two proteins have become capable of independent variation to produce isoforms of a given protein or isoenzymes of a given enzyme. **Isoforms** of the same polypeptide are polypeptides found in the same organisms that are encoded by different genes and have different amino acid sequences but nevertheless share a common ancestor and, when properly folded and assembled, perform the same function.

Two proteins are homologues of each other if they both descended from a common ancestor, usually as a result of the speciation of organisms but often as a result of gene duplication. Two proteins are **orthologues** of each other if they both descended in direct lineage from a common ancestor and neither lineage contains a point of gene duplication. Two proteins are **paralogues** of each other if the gene encoding one of them descended in direct lineage from one member of a pair of duplicated genes in the genome of a common ancestor and the gene encoding the other descended in direct lineage from the other member of the same pair of duplicated genes. Isoforms are always paralogues of each other. The A isoform of L-lactate dehydrogenase from dogfish muscle and the A isoform of L-lactate dehydrogenase from pig muscle are orthologous to each other, but the B isoform of L-lactate dehydrogenase from pig heart and the A isoform of L-lactate dehydrogenase from pig muscle are paralogous to each other.

The advantage of having separate isoforms to both the ancestral species and those that diverged from it was that these isoforms could gradually specialize to meet separate demands. These demands are often expressed at the level of individual tissues within the organism, and the sequences of the two isoenzymes or isoforms diverge, in part, in response to the particular demands of sets of tissues. For example, one set of tissues may require that an enzyme respond to changes in levels of its substrates in a different range from the range in which it should respond to them in another set of tissues, and the respective isoenzymes can be tailored to the separate sets of requirements. **Positive selection** causes advantageous mutations that produce changes in biological properties causing the isoform of a protein to be more suitable to a particular set of tissues to be preferentially fixed in the populations at the expense of the parental types, and it is in the adaptation of isoforms of the same protein that positive selection of amino acid sequences is perhaps most readily detected.

It is alignments of the amino acid sequences of the isoforms of a given protein in one species with those of the isoforms of the same protein in another species that permit them to be identified and classified^{63,64} and the history of their divergence to be described.⁶⁵ For example, among the tissues of mammals and birds, at least

have evolutionary histories that are independent of the histories of the organisms carrying them.

The genome of a particular species can encode two or more paralogues of a given protein if the appropriate gene duplications have occurred. It is the potential to **evolve into a new protein** that distinguishes such a set of paralogues from a single, unduplicated orthologue. As long as there is only one gene for a given protein in the genome, the protein that it encodes is required to perform its designated function. That protein evolves along its lineage as its gene diverges into separate species, but it must remain the same protein. If there are two or more paralogues in each individual of a species, one of those paralogues has the opportunity to become a new protein with a new function. Even though paralogues usually retain the same function and specialize to handle different situations, as in the case of the isoenzymes of L-lactate dehydrogenase, often one of them changes sufficiently to perform another function as in the case of chymotrypsinogen and haptoglobin (Table 7–2).

One way to demonstrate that a paralogue, freed from the necessity of performing its function by the existence of a sibling, is able to change sufficiently to perform an entirely new function is by alignment of amino acid sequences. In addition to alignments of the same protein from different species and alignments of different isoforms of the same protein, it has been possible to perform statistically significant **alignments of the amino acid sequences of different proteins** (Table 7-2).²⁵ Many of these connections make sense from a functional standpoint. For example, parvalbumin can be successfully aligned with troponin *c* (Table 7-2); hemoglobin, with myoglobin (Table 7-2); the coiled coil of human vimentin, with the coiled coil of human lamin A (36%

^aAlignment was performed on a matrix where $a_i \times b_j = 1$ when $a_i = b_j$ and $a_i \times b_j = 0$ when $a_i \neq b_j$ and the gap penalty was 2.5. When $a_i = b_j = \text{cysteine}$, at $a_i \times b_j = 2.0$. Reproduced from Doolittle.²⁵ ^bTwo proteins the amino acid sequences of which were aligned. Number of amino acids in each protein is shown in parentheses. ^cPercentage of the positions in the aligned sequences at which the same amino acid was found in both sequences, based on the length of the shortest. ^dTotal number of gaps that had to be introduced to get the best alignment. ^eDistance in standard deviations that the alignment score for the actual sequences was above the mean of the alignment scores of 36 comparisons of jumbled sequences. Represents only a portion of the entire sequence.

identity, 1.2 gap percent);⁷⁰ vacuolar H⁺-transporting two-sector ATPase from *Daucus carota*, with the β subunit of H⁺-transporting two-sector ATPase from *Spinacia oleracea* (15 standard deviations above the mean of the jumbles);⁷¹ dihydrolipoyllysine acetyltransferase from *Escherichia coli*, with dihydrolipoyllysine succinyltransferase of *E. coli* (30% identity, 1.7 gap percent);⁷² tripeptidyl-peptidase II from *H. sapiens*, with subtilisin from *Bacillus subtilis* (34% identity, 5.3 gap percent);⁷³ acetolactate synthase III from *E. coli*, with tartronate-semialdehyde synthase from *E. coli* (34% identity, 0.7 gap percent);⁷⁴ and 4-hydroxy-2-oxoglutarate aldolase from *E. coli*, with 2-dehydro-3-deoxy-phosphogluconate aldolase from *E. coli* (45% identity with no gaps).⁷⁵

The identification of a set of paralogues in the same species by alignment of their sequences often provides clues as to the functions of those members of the set that have not yet been studied.⁷⁶ For example, the fact that three **proteins of unknown function** in *E. coli* were paralogues of methylmalonyl-CoA mutase and acetate CoA-transferase allowed them to be identified as a methylmalonyl-CoA decarboxylase, a succinate-propionate CoA-transferase, and another methylmalonyl-CoA mutase.⁷⁷

The more interesting though rarer connections, however, are those between **functionally unrelated proteins**. For example, ovalbumin can be successfully aligned with antithrombin III (Table 7-2); bovine angio-

genin, with bovine ribonuclease (33% identity, 3.2 gap percent);⁷⁸ chicken $\delta 2$ crystallin, with human argininosuccinate lyase (69% identity, 0.2 gap percent);⁷⁹ and glucarate dehydratase from *Pseudomonas putida*, with mandelate racemase from *P. putida* (23% identity, 5.6 gap percent).⁸⁰

All of these alignments demonstrate that the evolution of duplicated proteins is completely analogous to the evolution of species. The fixation of the two forms of a duplicated gene within a population produces two paralogues of the ancestral protein. As the paralogues of the protein evolve independently, they drift slowly from isoforms with the same function, to proteins with similar but different functions, just as daughter species drift apart from each other, creating separate genera. Occasionally, a dramatic leap occurs, for example, the one turning argininosuccinate lyase into $\delta 2$ crystallin, a change resembling on a small scale the appearance of chordates. Usually, however, the process is one of slow, continuous divergence. The alignment of amino acid sequences gives only hints of the evolving pedigrees. A more complete picture is seen only when the crystallographic molecular models of proteins are superposed.

Vogt, G., Etzold, T., & Argos, P. (1995) An assessment of amino acid exchange matrixes in aligning protein sequences: the twilight zone revisited, *J. Mol. Biol.* 249, 816–831.

Problem 7-1: Calculate alignment scores (Equation 7-1) for the five cytochromes *c* aligned in Figure 7-9 based on the rules that when $a_i = b_j$, $a_i \times b_j = 1$; when $a_i \neq b_j$, $a_i \times b_j = 0$; and $P = 1.2 + 0.23 l$.

Problem 7-2: This exercise will illustrate the method for assessing the validity of a particular alignment of two sequences. Pick a number between 1 and 80 at random and write it on a piece of paper. Turn to Figure 7-1 and the alignment of the two amino acid sequences of the cytochromes *c* from *T. alalunga* and *P. denitrificans*, respectively. Start at the amino acid in the sequence of the cytochrome *c* from *T. alalunga* corresponding to the number you picked at random, and write the next 20 amino acids in that sequence across the page. Below this sequence write the corresponding amino acids of the aligned sequence from the cytochrome *c* of *P. denitrificans*, as in the figure. Calculate an alignment score by the rules in Problem 7-1 for these two segments of aligned sequences. Take 20 playing cards and to each of them assign one of the 20 amino acids in the amino acid sequence from the cytochrome *c* of the amino acid sequence with the least number of gaps. Shuffle the cards well and deal them into a row. Copy out the jumbled sequence dictated by

this shuffle on a piece of paper. Align this jumbled sequence with the segment of real amino acid sequence from the other cytochrome *c* by shifting and gapping until you think the alignment will give the highest alignment score. Record that score. Repeat the process five times. How do the alignment scores of the jumbled sequences compare to the alignment score of the one unjumbled sequence?

Problem 7-3: On the basis of their locations in the crystallographic molecular models of proteins, their structural roles, and their chemical properties, the amino acids can be divided into three categories: hydrophobic, neutral, and hydrophilic. The hydrophobic amino acids are isoleucine (I), valine (V), leucine (L), phenylalanine (F), cystine (C–C), methionine (M), and alanine (A). The neutral amino acids are glycine (G), cysteine (C), threonine (T), tryptophan (W), serine (S), tyrosine (Y), and proline (P). The hydrophilic amino acids are histidine (H), glutamate (E), glutamine (Q), aspartate (D), asparagine (N), lysine (K), and arginine (R).

The following alignment is from Figure 7-1B:

```
T F V Q K C A Q C H T V - - - - - E N G G
E F - N K C K A C H M I Q A P D G T D I I K
```

Because cytochrome *c* is a cytoplasmic protein, none of the cysteines participates in a cystine.

- (A) Construct a 16×21 matrix on a sheet of graph paper for the two segments of sequence involved in this alignment using the following rules:
 - (1) $a_i \times b_j = 1$ for an identity
 - (2) $a_i \times b_j = 0.6$ for hydrophobic \times hydrophobic
 - (3) $a_i \times b_j = 0.6$ for apathetic \times apathetic
 - (4) $a_i \times b_j = 0.6$ for hydrophilic \times hydrophilic
 - (5) $a_i \times b_j = 0.2$ for hydrophobic \times apathetic
 - (6) $a_i \times b_j = 0.2$ for apathetic \times hydrophilic
 - (7) $a_i \times b_j = 0.0$ for hydrophobic \times hydrophilic
- (B) Trace the alignment presented above through the matrix.
- (C) Calculate an alignment score for that trajectory with the gap penalty of Equation 7-2.
- (D) What is the most serious difficulty with the rules?

Problem 7-4: From the genetic code, calculate the minimum number of base changes between the amino acid sequences of the γ and β polypeptides of human hemoglobin as they are aligned in Figure 7-4. To do this, make a list containing all of the replacements between the two sequences, find the minimum number of base changes required for each, and add up the individual minimum base changes to obtain the total.

Problem 7-5: The sequences of the fibrinopeptides A and B from a series of primates are given in the table

below.⁸¹ Construct a tree of minimal mutational distances. Treat a gap as if it were two base changes.

primate	fibrinopeptide A	fibrinopeptide B

^aPyrrolidone-5-carboxylic acid, a cyclized form of glutamine.

Molecular Phylogeny from Tertiary Structure

Just as the amino acid sequences either of two different proteins or of the same protein from two different species can be aligned, so can their tertiary structures be superposed.⁸² The crystallographic molecular models of two proteins that have tertiary structures so similar to each other that they are thought to share a common ancestor are chosen for comparison. Those pairs of respective α carbon atoms that unambiguously occupy equivalent positions in equivalent strands of secondary structure in the two crystallographic models are identified statistically⁸³ and designated as forming the **cores** of the structures to be superposed. To **superpose** these two crystallographic molecular models is to translate and rotate one of them relative to the other until the sum of the squares of the distances between these pairs of equivalent α carbon atoms in the cores of the two structures is minimized. Because two different crystallographic molecular models are being superposed, the structures never coincide exactly, even if they are of the same protein. The two proteins the crystallographic molecular models of which are being compared are considered to be homologous once a decision has been made by the investigator that the superposition of the two crystallographic molecular models is significant enough to demonstrate that they share a common ancestor.

An example of such a superposition is that between porcine pancreatic elastase and trypsin from rat mast cells (Figure 7-7A).^{83,84} These proteins are both serine endopeptidases sharing a common enzymatic mechanism, their amino acid sequences are readily aligned (33% identity, 2.5 gap percent), and the superposition confirms the fact that they share a common ancestor. A more distant relationship was validated by the superposition of a portion (amino acids 157-403) of creatinase from *P. putida* and methionyl aminopeptidase from *E. coli* (Figure 7-7B).⁸⁵ Although both of these enzymes catalyze the hydrolysis of an amide and their amino acid sequences can be aligned computationally, their respective substrates are quite different from each other and the alignment is marginal (17% identity, 1.9 gap percent).

The degree to which two superposed structures

coincide is usually quantified by the root mean square deviation. The **root mean square deviation** is the square root of the mean of the values for the squares of the distances between only those pairs of α carbon atoms designated as belonging to the cores. Consequently, both the root mean square deviation and the percentage of the total number of α carbons that were included in the cores from the two crystallographic molecular models must be noted (Table 7-3). For example, in the superposition of porcine pancreatic elastase and trypsin from rat mast cells (Figure 7-7A), 65% of the α carbons were included in the two cores and they aligned with a root mean square deviation of 0.07 nm. When the crystallographic molecular model of 4- α -glucanotransferase from *Thermus aquaticus* was superposed in turn upon the crystallographic molecular models of nine amylases from bacteria, fungi, and mammals, 270-320 aa (41-65% of the entire amino acid sequences of these proteins) was designated as belonging to the cores, and those amino acids in the cores aligned with root mean square deviations between 0.29 and 0.35 nm.⁹³

An alternative method of quantifying the superposition of two crystallographic molecular models is to note the percentage of the total number of α carbons in the superposition that lie less than a certain distance from their equivalent partners. For example, in the superposition of creatinase from *P. putida* and methionyl aminopeptidase from *E. coli* (Figure 7-7B), 86% of the α carbons lie less than 0.25 nm from their partners.

As two proteins diverge steadily from a common ancestor, first as orthologues in different species, then, following gene duplication, as paralogues of the same protein, then as paralogues with related functions such as adenosine kinase and ribokinase, and finally as paralogues with unrelated functions such as phosphoribosylamine-glycine ligase and glutathione synthase, their structures drift apart from each other by greater and greater deviations (Table 7-3).

Whenever the crystallographic molecular models of two proteins, the amino acid sequences of which can be aligned computationally with statistical significance, have been compared, they could always be unambiguously superposed.⁹⁴⁻¹⁰⁰ The root mean square deviation of a pair of superposed crystallographic molecular models can be plotted as a function of the percentage of identity between the respective aligned amino acid sequences (Figure 7-8).^{101,102} When the percentage of identity in just the segments chosen as the core reaches around 15%, the range in which statistically meaningful alignments of complete amino acid sequences can no longer be made, the root mean square deviation of the α carbons of the amino acids in the core (50% or greater of the total α carbons) was only 0.2 nm, and the topological similarity between the structures being compared was still unmistakable.

Consequently, structural superpositions are able to establish more **distant evolutionary relationships** than

Figure 7-7: Superposition of the α carbons of crystallographic molecular models. (A) Superposition of the α -carbon diagrams of crystallographic molecular models of pancreatic elastase from *Sus scrofa* (open lines) and trypsin from mast cells of *Rattus norvegicus* (solid lines).⁸⁴ The α carbons of 152 amino acids in each crystallographic molecular model were determined statistically⁸³ to be respectively equivalent to each other. The two models were rotated and translated until the root mean square deviation for these 152 pairs of α -carbons was minimized (0.07 nm). The resulting superposition is numbered according to the amino acid sequence of trypsin. There was no electron density for amino acid 171 of trypsin. (B) Superposition of the α -carbon diagrams of the enzymatic portion of creatinase (amino acids 157–403) from *P. putida* (solid lines) and methionyl aminopeptidase from *E. coli* (open lines).⁸⁵ The α carbons of 218 amino acids from each crystallographic molecular model were determined to be respectively equivalent and the two models were rotated and translated until the root mean square deviation for these 218 pairs was minimized. The numbering is for the methionyl aminopeptidase.

Table 7-3: Levels of Coincidence for the Superposition of Crystallographic Molecular Models^a

proteins superposed	rms ^b (nm)	α carbons ^c (%)
superoxide dismutase <i>Thermus thermophilus</i> superoxide dismutase <i>E. coli</i> ⁸⁶	0.11	90
hexokinase <i>H. sapiens</i> hexokinase <i>S. cerevisiae</i> ⁸⁷	0.13	80
lysozyme <i>Gallus gallus</i> lysozyme bacteriophage λ ⁸⁸	0.20	44
adenosine kinase <i>H. sapiens</i> ribokinase <i>E. coli</i> ⁸⁹	0.24	91
chaperone protein PapD <i>E. coli</i> immunoglobulin G CH2 <i>H. sapiens</i> ⁹⁰	0.23	50
thiamin pyridinylase <i>Bacillus thiaminolyticus</i> D-maltodextrin binding protein <i>E. coli</i> ⁹¹	0.36	84
phosphoribosylamine-glycine ligase <i>E. coli</i> glutathione synthase <i>E. coli</i> ⁹²	0.38	64
phosphoribosylamine-glycine ligase <i>E. coli</i> biotin carboxylase <i>E. coli</i> ⁹²	0.50	57

^aThe two crystallographic molecular models were superposed by use of the respective coordinates of equivalent α carbons in the cores of the two structures. ^bRoot mean square deviation between atoms in the respective cores that were considered to be equivalent during the superposition. ^cPercent of the total number of α carbons in the two crystallographic molecular models that were designated as being in the core and that were aligned in pairs during the superposition.

those established by alignment of amino acid sequences. For example, by superposing crystallographic molecular models it could be shown that adenylyl-sulfate kinase, adenylate kinase, guanylate kinase, and 6-phosphofructo-2-kinase are all members of a large group of kinases that share a common ancestor.¹⁰³ This ability to recognize distant relationships has permitted the history of the evolution of proteins to be traced just as the alignment of amino acid sequences has permitted the history of the evolution of species to be traced.

From Figure 7-8, it can be concluded that whenever two proteins have amino acid sequences that can be aligned with statistical significance, they will also have superposable tertiary structures. For example, the fact that the amino acid sequences of the three enzymes Ca^{2+} -transporting ATPase, Na^+/K^+ -exchanging ATPase, and H^+/K^+ -exchanging ATPase can be aligned¹⁰⁴ demonstrates that their tertiary structures are superposable.¹⁰⁵ This rule is important because far more sequences are available than tertiary structures. If the amino acid sequence of a protein the crystallographic molecular model of which is unavailable can be related to a protein for which a crystallographic molecular model is available

Figure 7-8: Relationship between superposition of crystallographic molecular models and the alignment of amino acid sequence.¹⁰¹ Thirty-two pairs of homologous proteins were chosen for which a crystallographic molecular model of each member of the pair was available. Structural cores were defined for each superposed pair of molecular models by including all α carbon atoms in the polypeptide backbone the distance between which was less than 0.3 nm. The cores for the pairs that were most distantly related included only 50% of the amino acids in the sequence. The root mean square distance between pairs of aligned α carbon atoms of the cores were calculated and plotted against the frequency at which the same amino acid was found at the equivalent positions in the two cores, expressed as a percentage. By this procedure, the percentage of identity is considerably higher than it would be if the entire sequences had been aligned. Reprinted with permission from ref 101. Copyright 1986 IRL Press.

through a valid alignment of the two amino acid sequences, reliable conclusions can be drawn about the unknown tertiary structure by a comparison with the known tertiary structure.

Cytochromes *c* are present in all organisms, they are small proteins, and their structures have changed at a rate such that comparisons between them illustrate many of the facts that can be learned from superposition of tertiary structures. The eukaryotic cytochromes *c* are indistinguishable from each other in tertiary structure,¹⁰⁶ if those from rice and tuna are assumed to represent the evolutionary extremes. Consequently, the eukaryotes can be represented by the crystallographic molecular model of the protein from the tuna (structure C in Figure 7-9).^{107,108} The other four of the five α carbon drawings of the crystallographic molecular models in Figure 7-9 are those of four bacterial cytochromes *c*: the one from *Chlorobium thiosulfatophilum* (Figure 7-9A), the one from *Pseudomonas aeruginosa* (Figure 7-9B), the one from *Rhodospirillum rubrum* (Figure 7-9D), and the one from *P. denitrificans* (Figure 7-9E). A similar comparison of the crystallographic molecular models of four other bacterial cytochromes *c* with that of a eukaryotic cytochrome *c* is also available.¹⁰⁹

When the drawings of the crystallographic molecular models of the cytochromes *c* (Figure 7-9) are compared, the **reason for the gaps** in their aligned sequences (lower part of Figure 7-9) is immediately apparent. They represent **loops** in the longer protein that are smaller or are missing entirely from the shorter protein. These loops (darkened in the figure) can appear or disappear because positions in the sequence at their bases are near enough to each other to be connected without disrupting the structure in a major way. It has usually been observed that the insertions and deletions that are found in superposed tertiary structures of proteins and that are responsible for the gaps in the aligned amino acid sequences occur in regions such as these that are peripheral to the central elements of the structure. The resulting loops usually extend out into the solvent, for example, the loop between positions 20 and 30 in the cytochromes *c* (Figure 7-9), or extend across the outer surface of the protein, for example, the loop between positions 210 and 230 in methionyl aminopeptidase (Figure 7-7B). An interesting spreading apart of two flexible flaps, however, to accommodate the large loop present in the cytochrome *c* from tuna but missing in the two smaller bacterial cytochromes illustrates a more disruptive outcome.

These loops that come and go can be of **various lengths**. An insertion of one amino acid often causes almost no change in the structure of the protein except for a small bulge sufficient to accommodate two amino acids where there is only one in the shorter cousin;¹¹⁰ the two amino acids to the sides of the bulge remain in the same positions. The extra two amino acids in elastase between positions 60 and 64 (Figure 7-7A) cause a bulge that is unmistakable but completely confined to this

Figure 7-9: Tertiary structures of five cytochromes *c*.^{107,108} Ribbon diagrams with creases at each α carbon were made from the crystallographic molecular models of (A) cytochrome *c*-555 from *Chlorobium thiosulfatophilum*, (B) cytochrome *c*-551 of *Pseudomonas aeruginosa*, (C) cytochrome *c* of tuna mitochondria, (D) cytochrome *c*₂ of *R. rubrum*, and (E) cytochrome *c*-550 of *P. denitrificans*. The hemes, the iron ions of which are each liganded by a methionine and a histidine, and a conserved phenylalanine are also drawn. The sequences of these five cytochromes *c* are structurally aligned at the bottom of the figure (identified by the respective letters). The alignment of *R. rubrum* is represented by the dot matrix in Figure 7-2. Filled portions of the ribbon diagrams highlight loops representing insertions into the basic structure. The central structure for tuna cytochrome *c* is numbered with the same numbers as those used in the alignments. Reprinted with permission from ref 107. Copyright 1982 Academic Press.

short segment, but the one extra amino acid in tryptase between positions 180 and 188 seems to be more disruptive. If the loops become long enough they can assume structure of their own. The extra amino acids between positions 203 and 266 in methionyl aminopeptidase from *Pyrococcus furiosus*, relative to methionyl aminopeptidase from *E. coli*, form an almost spherical knob containing three α helices and some random meander sitting on the surface of the common structure.¹¹¹ The extra amino acids between positions 180 and 317 in serine-type carboxypeptidase from *S. cerevisiae* relative to the structures of other members of the group of related hydrolases form a compact globular structure, but a long loop of polypeptide protrudes from it and wanders over the surface of the common structure.¹¹² The events that produced such insertions can be mimicked by inserting segments of synthetic DNA into the gene encoding a protein and expressing the elongated version. When these inserts are placed at a location where they can loop out of the original structure, they cause little alteration in that structure.¹¹³

The structural alignment of the five amino acid sequences presented in Figure 7–9 is based on superpositions^{114,115} of the five crystallographic molecular models. A **structural alignment** of two amino acid sequences is an alignment in which two respective amino acids that occupy the same positions upon superposition of the two respective crystallographic molecular models also occupy the same position in the alignment.

A structural alignment of amino acid sequences often differs significantly from a computational alignment of the same sequences. For example, a previously performed computational alignment of human basic fibroblast growth factor and human interleukin 1 β agreed with the subsequent structural alignment from positions 90 to 144 but was out of register with the structural alignment by at least seven amino acids between positions 20 and 89.¹¹⁶ It has been argued that when they are available, structural alignments of amino acid sequences are more reliable than computational alignments. This is an interesting argument because it assumes that no relative movement of β strands relative to each other or advancement of the screw of an α helix has occurred during the divergence from a common ancestor. There is some support for this assumption.¹¹⁷

Because the tertiary structures of proteins change more slowly than their amino acid sequences, a structural alignment based on a superposition can be performed between the amino acid sequences of two proteins that diverged from their common ancestor so long ago that a computational alignment would be insignificant. For example, the amino acid sequence of phosphopyruvate hydratase can be structurally aligned with that of mandelate racemase,¹¹⁸ that of P1 nuclease from *Penicillium citrinum*, with that of phospholipase C from *Bacillus cereus*,¹¹⁹ and that of aspartate-semialdehyde dehydrogenase, with that of glyceraldehyde-

3-phosphate dehydrogenase.¹²⁰ In such structural alignments between distantly related sequences, there are significantly more gaps than would have been inserted during a computational alignment because gaps are more readily recognized. For example, the structural alignment of coat protein VP1 from Mengo virus and coat protein from human rhinovirus 14 (13% identity) has a 4.9 gap percent, and eight of the 14 gaps are only one amino acid in length.¹²¹ When crystallographic molecular models are available for many of the members of a large group of related proteins, structural alignments of the amino acid sequences of those members for which molecular models are available can be combined with multiple computational alignments of the sequences of the rest of the members of the group to produce a statistical template that can be used to search databases for additional as yet unrecognized members of the group.¹²²

It is the ability to perform structural alignments of amino acid sequences based on superpositions that allows the frequencies with which one amino acid is substituted for another in more **distantly related proteins** to be ascertained.¹²³ In one study, crystallographic molecular models of 235 proteins from 65 different groups were chosen for superposition.¹²⁴ All of the proteins within each family were superposed, and their amino acid sequences were structurally aligned. For each type of amino acid in the alignments, the number of times that it shared that position with itself or with each of the other amino acids was tabulated. From this tabulation, the **frequency of substitution** for each amino acid could be calculated (Table 7–4).

The table of the frequency of substitution in the more distantly related proteins (Table 7–4) complements the tabulation of mutation probabilities for closely related proteins (Table 7–1). Over the longer term, there seems to be a stronger preference for maintaining the **hydropathy** of a position. This enhanced preference probably arises from the fact that enough time has elapsed that significant substitutions have accumulated in the more intolerant sites. In addition to its hydropathy, the **size** of the amino acids has a significant effect on the frequencies at which specific replacements occur. Small amino acids are usually replaced by small amino acids; the large aromatic amino acids are most often replaced by other aromatic amino acids.

Each amino acid displays a characteristic **tolerance to replacement** by any amino acid other than itself. The most peculiar amino acids, cystine, tryptophan, and glycine, are the most intolerant of replacement. Cystine is so intolerant that it is deleted more than twice as often as it is replaced by alanine, the most common substitution. Proline is also deleted more often than it is replaced by any other amino acid.

The observed frequencies of substitution listed in Table 7–4 do not reflect the full effects of the steric and chemical properties of each side chain on its capacity to replace another or its tolerance to replacement because

^aStructural alignments were performed of the amino acid sequences within each of 65 groups of proteins. Each of the 65 groups contained a different set of superposable proteins. For each of the 21 amino acids, the frequencies with which it was paired with itself or with each of the other 20 amino acids over all of the structural alignments were calculated.¹²⁴ The number to the right of each amino acid is the frequency (in percent) with which it was paired with the amino acid at the top of the column. ^bCystine. ^cThe number in boldface type at the head of each column is the number of codons that encode that amino acid, and the number in parentheses is the percentage in which it occurs in the amino acid composition of the complete data set (208,000 amino acids). ^dThe horizontal lines divide the amino acids with the highest frequencies of replacement from those with the lowest. All of the amino acids that are not listed in a given column have frequencies between the highest of the lowest group and the lowest of the highest group. ^eFrequency with which a gap occupied the aligned position. ^fFrequency of cysteine plus that of cystine. ^gCysteine; there are two codons for cysteine and cystine combined. The decision between cysteine and cystine is made post translationally.

they are biased. The most important of these **biases** is that of the number of codons for each of the amino acids (boldface numbers next to their abbreviations at the head of each column in Table 7-4). It has been shown⁶ that the frequency with which an amino acid occurs in the overall population of proteins (number in parentheses next to the number of codons in Table 7-4) is roughly proportional to the number of its codons (compare the numbers in boldface type with those in parentheses). Consequently, the number of codons for an amino acid must significantly affect its frequency of substitution over the long term. For example, if the frequencies of substitution for leucine in Table 7-4 were corrected only for number of codons of each of the amino acids, conservation would still have the highest frequency but by much less of a margin, and the preferred substitution, by almost a factor of 2, would become methionine, with valine, isoleucine, and phenylalanine tied for second place. This result would make sense because methionine has the hydrophobic side chain that is the most similar to that of leucine. In addition to the number of codons, however, other factors such as the number of base changes for a given substitution and the frequency with which the codons are used by a given species are also factors affecting the frequency of substitution. Because these effects have yet to be quantitatively assessed, no corrections were applied to the directly observed frequencies of substitution in Table 7-4.

Structural alignments also allow the success of computational alignments and the procedures for searching banks of amino acid sequences to be evaluated. To perform such an evaluation, a bank of amino acid sequences of only those proteins for which crystallographic molecular models are available is assembled. The amino acid sequences in the bank can then be distributed into groups within which each member can be superposed on every other member. Consequently, all of the members of one of these groups share a common ancestor. How many of these established relationships can be detected by a particular algorithm operating only on the amino acid sequences?

When **computational alignments** were evaluated,²⁸ the success with which they aligned two sequences known to share a common ancestor was quantified as the percentage of the positions aligned structurally that were also aligned statistically. It was found that a greater percentage of the positions was correctly matched when weighting schemes were used that assigned values to the $a_i \times b_j$ other than just 1 and 0, but the improvement at best was only 1.25 times (from a 51% rate of success to a 64% rate of success). It made no difference whether the weighting scheme was based on frequencies of identity and replacement from entirely computational alignments (Table 7-1) or from entirely structural alignments, but weighting schemes based on frequencies drawn from larger numbers of alignment performed somewhat better than those drawn from

smaller numbers of alignments. Weighting schemes that were not based on frequencies of replacement and identity, however, did almost as well as those that were. Even the best weighting scheme was unable to align sequences (<30% correctly matched positions) when the percentage of identity fell below 15%.

When the **procedures used to search databanks** were evaluated,³² the success with which they found matches was assessed by comparing coverage to error rate. **Coverage** is the fraction of the known relatives that had scores above the chosen **threshold**. **Error rate** is the percentage of the unrelated amino acid sequences in the bank that had scores above the chosen threshold. As the threshold was raised, the error rate decreased, but so did the coverage. In plots of error rate against coverage, the three currently used algorithms, WU-BLAST2, FASTA, and SSEARCH, all performed equivalently. When a bank containing sets of sequences that were known to be related by superposition but in which none of the members had a percentage of identity greater than 40% was chosen for the searches, at a threshold producing an error rate of 1%, the coverage was only 0.18. In other words, from a bank containing 100,000 amino acid sequences, the search would give 1000 false matches but miss 82% of the real relationships with percentage of identities less than 40%.

There are several different **levels of agreement** within the superposition of two crystallographic molecular models. In the core of the structure, where changes occur less rapidly, the superposition is usually acceptable (Figure 7-7). When the two proteins are functionally related, the segments of the polypeptide in the core that participate in this common function usually superpose the most precisely.¹²⁵ For example, the segments between positions 51 and 56, 102 and 108, and 195 and 200 in the superposition of tryptase and elastase (Figure 7-7A) contain the histidine, the aspartate, and the serine, respectively, that participate in their common mechanism. As more and more replacements of amino acids accumulate, the steric effects of these changes cause the backbone to shift to accommodate them. For example, the respective replacement of a serine and a valine in rice cytochrome *c* with a threonine and an isoleucine, both larger side chains, in tuna cytochrome *c* causes a displacement further into the solvent of the polypeptide to the exterior of this substitution.¹²⁶ The significant shifts of secondary structure in the polypeptide between creatinase and methionyl aminopeptidase (Figure 7-7B) within the core of the common structure result from the accumulation of such steric effects. Flexible loops such as the one between positions 32 and 42 in the superposition of tryptase and elastase (Figure 7-7A) often differ dramatically in their disposition, but such differences may reflect only the effects of crystal packing that pins down an otherwise fluctuating structure.¹²⁷

As one traces the polypeptides through the superposed α carbon diagrams (Figure 7-7), the distance

between the backbones fluctuates as one moves through the core, out through the loops, and back into the core. These fluctuations can be represented graphically in a plot of the distance between the paired α carbons as a function of their position in the amino acid sequence.¹²⁸

The **globins** are a group of the same proteins and their isoforms from different species, for which many sequences are available. They include myoglobins, hemoglobins, erythrocrurins, and leghemoglobins. The **details of the variations** that occur in the tertiary structure of a protein as amino acids are slowly replaced at the toleration of natural selection have been examined by superposing the nine available crystallographic molecular models of different globins¹¹⁷ and using these superpositions to align their amino acid sequences.¹¹⁷ Each globin is formed from eight α helices stacked one upon the others as a bundle of sticks would be in a fire. As the sequences of the globins have varied, the interdigitations of the amino acid side chains situated between the α helices has adjusted to accommodate changes in their size, and this has caused the helices to shift as rigid bodies with respect to each other. These adjustments are necessary because the amino acid side chains between the α helices are tightly packed together and many atomic contacts occur. As the shifting proceeds, accommodating changes in size, the individual pairs of atomic contacts persist between two amino acids at different positions in the amino acid sequence but next to each other in the tertiary structure even though the identities of the amino acids themselves change.

About 60 amino acids out of the 140 in the polypeptide of a typical globin remain in equivalent locations in the nine superposed crystallographic molecular models and account for the core of the native structure. Only half of these are buried; the ones on the surface remain fixed because they are within α helices that are themselves rigid structures. The regions in which the greatest variation in sequence and tertiary structure occurs are in the seven loops connecting the eight helices. This is due to their almost exclusive location at the surfaces of the molecular models but may also reflect the changes in the end to end distances between the α helices that were required to accommodate the slow shifts of the helices relative to each other as the packing among them has been altered by the substitutions.

These observations suggest that the degree of conservation that is displayed by a position in the sequence of a protein may provide an indication of its location in the tertiary structure. Positions showing the least tolerance to replacement are often located on the interior of the protein and those displaying the greatest tolerance tend to be located on flexible surface loops, but the tendency is not overwhelming.

A crystallographic molecular model of myoglobin from the sperm whale has been prepared,⁹⁴ and the structural roles of the 82 **invariant amino acids** among the 24 myoglobins that had been sequenced at the time

were tabulated (Table 7-5). This list represents a combination that has been retained since the time that all of these myoglobins shared a common ancestor. Positions marked (Hb) in Table 7-5 are those invariant among mammalian hemoglobins and myoglobins, and they represent amino acids that have been retained for an even longer period of time. Finally, the amino acids that appear at these 82 positions in the nine globins aligned by superposition have been entered into the tabulation. An examination of Table 7-5 reinforces several features of the atomic structure of molecules of protein.

Positions in the sequence that are buried in **hydrophobic clusters** are the most conserved. Usually three or four members of the group isoleucine, valine, phenylalanine, leucine, methionine, and alanine (Table 7-4) will substitute among themselves in this role, but occasionally only one or two are suitable. For example, only leucine is found at position 2NA and only valine or isoleucine at position 11E in the globins. These two preferences presumably reflect the constraints of the intricate, interlocking stereochemistry in the interior. In two locations, positions 1CD and 4CD, only phenylalanine is found among all the globins, and presumably in this location the flat disk of the phenyl ring is essential to maintain the structure. The phenylalanine at position 1CD is stacked upon the heme.

There are usually a number of locations in the structure of a protein where difficulties resulting from the packing of the backbone of the polypeptide arise. At position 2C in the globins, a proline seems essential to enforce a sharp turn. When two strands of polypeptide are forced too closely together, these **tight locations**, such as positions 6B, 8E, 5F, and 7H in the globins, are occupied by glycine, proline, alanine, serine, or threonine (Table 7-5). Both serine and threonine, by forming hydrogen bonds to acyl oxygens (Figure 6-7A), are able to hug the polypeptide. Tight fits can also result from the juxtaposition of a large and bulky amino acid. The amino acid at position 16E is crowded by the tryptophan at position 12A in both hemoglobin and myoglobin.

There are several instances in which side chains cap one end or the other of an α helix; for example, Serine 1A, Threonine 4C, Serine 1E, or Tyrosine 23H. It is often stated (Table 7-5) that this arrangement has the effect of initiating the α helix. The fact that at position 4C other globins lack an amino acid capable of forming a hydrogen bond and still contain the α helix suggests that the assignment of such a purpose in this case is an overstatement. Remarkably, four pairs of participants in **ionized hydrogen bonds** between side chains on the surface of myoglobin are invariant in the short term. When these particular interactions are examined, however, over all nine of the globins, which represent a much longer history of evolution, all of these hydrogen bonds are found to be dispensable (Table 7-6).

A deeply buried position in the sequence of a folded

polypeptide remains invariably hydrophobic, but a buried location near the surface will occasionally erupt toward the water. For example, at position 65 in cytochrome *c* (Figure 7–1) an arginine appears at a location usually occupied by hydrophobic amino acids. Presumably the alkane portion of the arginine traverses the hydrophobic region and the guanidinium can push through the surface into the solvent.

Often a hydrophilic location on the exterior is occupied by a hydrophobic amino acid. For example, position 9A in the globins (Table 7–5) is on the exterior of the protein and is usually occupied by hydrophilic amino acids, but in the myoglobins it is occupied by leucine. Because such a substitution has no effect on the free energy of folding for myoglobin compared to the other globins because the leucine is solvated equivalently in both the unfolded and folded polypeptide, such exchanges are common during evolution. There is, however, a price to be paid for such an exchange because a hydrophobic amino acid that replaces a hydrophilic amino acid on the surface of a protein makes it less soluble. The helical polymers formed by human deoxyhemoglobin S, in which a glutamate on the surface at position 4A has been replaced by a valine, are an example of such a problem.

The globins also provide a particularly informative example of the **focused constraints** that natural selection places on the gradual shifts in position among segments of secondary structure during evolution. The invariant feature of both the structure and the function of a globin is the heme (Figure 4–18). The only functions of a globin are to provide a fifth ligand to the iron, to make its heme soluble in water, and to prevent its heme from approaching another heme too closely. Through all of the alterations encountered during evolution, the amino acids responsible for surrounding the heme and supporting it within the protein were required by natural selection to maintain these roles. The record of this series of accommodations can be inferred from superposing crystallographic molecular models of present globins so that their hemes are made to coincide rather than their polypeptides. The situation is most graphically illustrated when the α subunit from equine hemoglobin is superposed in this way on leghemoglobin from *Lupinus luteus* (Figure 7–10).^{117,130} Over this long period of evolution, the amino acids supporting the heme have shifted their positions relative to it by only small distances. At the same time, however, the ends most distant from the heme of the two α helices in which these functionally critical amino acids reside (E and G in Figure 7–10) have

^aFour invariant ionized hydrogen bonds that were present in an earlier refined crystallographic molecular model (Table 7-5)⁹⁴ and a later refined crystallographic molecular model (Bragg spacing ≥ 0.16 nm)¹²⁹ of myoglobin were chosen for examination. Each of the four pairs is between the amino acids in boldface type above and below each other in the central positions of the four paired strings of letters. The two amino acids forming each of these four hydrogen bonds in the two crystallographic molecular models, aspartate and lysine, histidine and aspartate, aspartate and arginine, and lysine and glutamate, were conserved among all of the myoglobins. The amino acids occupying each of these eight positions in a structural alignment of eight other globins¹¹⁷ are listed to the right and left of the pair occupying each of the eight positions in myoglobin. ^bCode assigned to the positions in the common crystallographic molecular model of the globin class (Table 7-5). ^cThe amino acid at the respective position in each of the globins is aligned above or below the amino acid at the other position in the same globin.

shifted significantly in their position, and another α helix that provides no amino acids in contact with the heme (B in Figure 7-10) has shifted even more.

In any protein, a few amino acids that embody its function can be identified. Over evolution, natural selection maintains the relative separations and orientations of these amino acids because if it did not, the protein could no longer be what it is. An extreme example of this fact is found in the group of related enzymes to which phosphopyruvate hydratase, mandelate racemase, galactonate dehydratase, glucarate dehydratase, muconate cycloisomerase, and methylaspartate ammonia-lyase belong. Although each of these enzymes has diverged widely from its distant common ancestor, the positions of the **functional groups in the active sites** of these proteins that are responsible for the abstraction of the proton α to the respective carboxylate, a function common to the mechanism of each of them, have been conserved.¹¹⁸ The more distant a location within the protein is from such invariant points of reference, however, the more likely its position will drift as mutations accumulate that shift the orientations of the segments of secondary structure within the overall molecular structure of the protein.

An exception to this rule that functional groups are usually the most invariant features of a protein can be seen in a comparison of the crystallographic molecular models of the phospholipase A₂ from cobra venom and the phospholipase from bee venom.¹³¹ From aligned amino acid sequences and superposed crystallographic molecular

Figure 7-10: Arrangement of the α helices and contact side chains that form part of the heme pocket in the α subunit of equine hemoglobin (EHb α) and in leghemoglobin II from *Lupinus luteus* (LgHb).¹³⁰ The hemes in the two proteins are superposed. The three α helices are designated as B, E, and G, in order of their appearance in the globin molecule. The positions of homologous pairs of side chains (sequence positions in leghemoglobin are primed) that are in contact with the heme are indicated by open circles joined by arrows. The coupling of the shifts at the E-B and B-G helix interfaces keeps the side chains that form the heme pocket in the same relative positions. Reprinted with permission from ref 130, originally from ref 117. Copyright 1980 Academic Press.

models, there is no doubt that these two proteins share a common ancestor. The α helix in the protein from cobra venom that binds to the surface of a biological membrane, in which the reactants for the enzyme are found, is formed by the first 20 amino acids of the polypeptide, but these 20 amino acids are missing from the protein from the bee. The missing tertiary structure necessary for adhering the protein to the membrane is supplied by an additional α helix at the carboxy-terminal end of the polypeptide from the bee that takes the place of the α helix from the amino-terminal end of the polypeptide from the cobra. It was the ability to superpose the crystallographic molecular models of these two proteins that permitted the substitution of one segment of the polypeptide for another in a functional role to be demonstrated.

The inability to superpose two crystallographic molecular models of two proteins can demonstrate an example of convergent evolution. For proteins, **convergent evolution** is the assumption of the same function by two proteins that do not share a common ancestor. For example, as had been predicted by aligning sequences,⁴ chorismate mutase from *S. cerevisiae* cannot be superposed on chorismate mutase from *B. subtilis*.¹³² Consequently, it can be concluded that these two unrelated proteins nevertheless evolved so

that they each were able to perform the same function. Other examples of such convergent evolution are the 3-dehydroquinate dehydratases from *Salmonella typhimurium* and *Mycobacterium tuberculosis*¹³³ and the Cu,Zn-superoxide dismutase of *B. taurus*¹³⁴ and the Fe-superoxide dismutase of *M. tuberculosis*.¹³⁵ A particularly interesting example of convergent evolution that was elucidated by superposing crystallographic molecular models is that of the [2Fe-2S] ferredoxin from *Clostridium pasteurianum*. This protein is completely unrelated to the other [2Fe-2S] ferredoxins and turns out to be a thioredoxin that has been converted into a ferredoxin.¹³⁶ The more common examples of convergent evolution, however, are those in which two unrelated proteins catalyze similar but not identical functions. For example, although they share the same mechanism of activating molecular oxygen for insertion into a carbon-hydrogen bond and both use a heme to do so, crystallographic molecular models of nitric-oxide synthase and cytochrome P-450 have different, unrelated structures.¹³⁷

Often the catalytic amino acids in the active sites of examples of convergent evolution are arranged similarly in the two proteins even though the overall structures are completely different. The serine, histidine, and aspartate responsible for the nucleophilic catalysis in the active site of subtilisin are superposable on the serine, histidine, and aspartate in the active site of chymotrypsin even though the two proteins themselves cannot be superposed,¹³⁸ and the functional groups in the active site of alanine dehydrogenase are similarly arranged to those in L-lactate dehydrogenase.¹³⁹ The catalytic amino acids, however, around the flavin adenine dinucleotide in the active sites of the two flavoenzymes L-lactate dehydrogenase (cytochrome) and D-amino-acid oxidase are arranged in patterns that are mirror images of each other.¹⁴⁰

As the number of crystallographic molecular models has increased, instances have become more common in which two proteins that display no similarity in amino acid sequence nevertheless have segments of their tertiary structure that can be superposed. An example of such a **segment of recurring structure** is found in the crystallographic molecular models of L-lactate dehydrogenase,⁸² alcohol dehydrogenase,¹⁴¹ phosphoglycerate kinase,¹⁴² and phosphorylase.¹⁴³ This common segment is 140–200 aa in length and occurs at different locations in the overall sequences of these proteins. It is formed from the amino acids in the sequence between Asparagine 21 and Glycine 162 in isoform A of L-lactate dehydrogenase from *Squalus acanthius*, between Phenylalanine 207 and Serine 392 in equine phosphoglycerate kinase, between Serine 193 and Phenylalanine 319 in isoform E of equine alcohol dehydrogenase, and between Asparagine 559 and Arginine 713 in the isoform of glycogen phosphorylase from muscle of *Oryctolagus cuniculus*. All four structures can be superposed.^{82,143} The superposition of these

regions from phosphorylase and L-lactate dehydrogenase is presented in Figure 7–11A.^{82,143}

This particular topological pattern of secondary structures can be identified as a **doubly wound, parallel β sheet**. It is a sheet of six parallel β strands flanked on both sides by α helices. The basic rhythm of the recurring theme is β strand, α helix, β strand, α helix, β strand, random meander, β strand, α helix, β strand, α helix, β strand. The β strands numbered from amino terminus to carboxy terminus occur in the order 321456 across the sheet (Figure 7–20). You should trace this pattern in Figure 7–11A. The six β strands all run parallel to each other to form a pleated sheet, and the helices arch above or below the sheet to connect the end of one β strand to the next. The complete and concise theme is developed in L-lactate dehydrogenase (Figure 7–11), and there are variations on this theme in the other proteins. For example, in phosphoglycerate kinase, there are two α helices after the second β strand and a long additional loop after the third β strand, and in alcohol dehydrogenase the last α helix is replaced by an additional antiparallel β strand. An interesting variation occurs after the first β strand in the structure from phosphorylase, where a large bulge has appeared in the first β strand that pushes up the loop between the third and fourth strands of β structure (Figure 7–11A).

Flavodoxin shares this pattern but with a more significant variation. In this protein, the second α helix and the third β strand have been deleted (Figure 7–11B). This deletion seems to have been very similar to those seen in cytochrome *c* (Figure 7–9) in that the loop containing the α helix and the β strand has simply been pinched off from the open end of the common structure. Nevertheless, the superposition of flavodoxin upon the corresponding region from L-lactate dehydrogenase is quite close, even though the sequences of these two superposed polypeptides appear to be completely unrelated. When the sequences are aligned, even with the assistance of the superposition, they have identical amino acids in only 9% of their aligned positions.

The conclusion that has been drawn from these superpositions is that all of these regions from these very different proteins together share a common ancestor. As these structures represent only a portion of each of the presently existing proteins, and as the other portions of the proteins bear no resemblance to each other, this common ancestor must have been a small primordial protein that was combined covalently with other small primordial proteins by gene fusion to produce respectively these larger chimeric proteins. **Gene fusion** is a process in which genomic DNA is recombined incorrectly so that segments of different genes become fused together rather than, as in the usual process of recombination, allelic segments of the same gene being interchanged in precise alignment. Like gene duplication, gene fusion occurs frequently, but only infrequently will

Figure 7-11: Doubly wound, parallel β sheets found in three crystallographic molecular models. (A) An α -carbon diagram of the doubly wound, parallel β sheet found in isoform A of L-lactate dehydrogenase from *Squalus acanthias* (solid lines) superposed on the α -carbon diagram of this structure found in glycogen phosphorylase from muscle of *Oryzotilus cinctus* (open lines).¹⁴³ Reprinted with permission from ref 143. Copyright 1976 *Journal of Biological Chemistry*. (B) An α -carbon diagram of the doubly wound, parallel β sheet found in L-lactate dehydrogenase (solid lines) superposed on the α -carbon diagram of this structure found in flavodoxin from *Clostridium beijerinckii* (open lines).⁸² In both panels the amino termini of the α -carbon diagrams are the upper ends of the middle β strands of the sheets; the carboxy termini are the ends of the strands at the side of each of the sheets. Reprinted with permission from ref 82. Copyright 1974 *Nature*.

the gene that results from the fusion spread over the entire population of a species by genetic drift and become fixed in its genome. The evidence of early gene fusions that did spread over a primordial population can still be observed in the progeny, not only in their structures but also in the distribution of methionines that are the fossilized remains of the initiation sites of the smaller ancient proteins that were fused together.¹⁴⁴ The reason that each of the primordial proteins now resides at a different location in the sequences of the present proteins is that each was combined with different proteins in different orders during these gene fusions. This description of evolutionary history requires that at one time in the distant past each of the segments of these polypeptides now folding to produce each of these superposable regions was not attached to the remainder of the polypeptide to which it is now joined. If this is the case, then each of the doubly wound β -pleated sheets and the other regions in each of these proteins to which they are now attached were at one time separate proteins, and a significant part of the evolution of proteins is a history of the joining together of smaller proteins to produce ever larger proteins.

The alignment is based on the separate superpositions of crystallographic molecular models of each of the other nine proteins upon the crystallographic molecular model of chymotrypsin, which was chosen as the reference structure for the family. The similarity of the structures to that of chymotrypsin is given by the case and the face of the one-letter code of the amino acids. An uppercase boldface character represents an α carbon that is within a distance of 0.15 nm of the equivalent α carbon in chymotrypsin. An uppercase normal character represents a distance within 0.25 nm, a lowercase boldface character represents a distance within 0.35 nm, and a

lowercase normal character represents a distance of greater than 0.35 nm. A dash represents a gap.

- On a sheet of graph paper, construct a dot matrix for a comparison of the sequence of protein 3 and the sequence of protein 6 between the positions of the first and the third cysteines in the amino acid sequence of chymotrypsin, which is protein 1.
- Trace through the dot matrix the structural alignment of protein 3 and protein 6.
- What is the percentage of identity for the alignment in this segment?

- (A) Why are the amino acid sequences of the proteins from cat and chicken so much more similar to each other than are the sequences from the cat and the rat to each other?
- (B) Align the amino acid sequences of the proteins from rabbit muscle and cat muscle from Proline 116 to Proline 218. What is the percent identity and how many gaps are there?

The following figure¹⁴⁶ is a superposition of the α carbons between Proline 116 and Proline 218 in the crystallographic molecular models of the pyruvate kinases from rabbit muscle and cat muscle.

These portions of the models were superimposed according to the algorithm of Rossmann and Argos.¹⁴⁷ The models of the rabbit and cat enzymes are displayed with filled and unfilled lines, respectively. Those amino acids that are labeled correspond to the protein from rabbit.

- (C) What is wrong with this figure?
- (D) What is the reason that something is wrong with this figure?

Domains

Ferredoxin-NADP⁺ reductase from spinach is a protein composed of a folded polypeptide 314 aa long (Figure 7-12).^{148,149} In the native enzyme, the polypeptide between Asparagine 162 and Tyrosine 314 assumes a doubly wound, parallel β sheet of five strands (upper right of Figure 7-12) and the polypeptide between Glycine 26 and Glutamate 154 assumes an antiparallel β barrel (lower left of Figure 7-12). Doubly wound, parallel β sheets recur in many different proteins and antiparallel β barrels recur in many different proteins, but the two structures are usually not found in the same protein. In the crystallographic molecular model of ferredoxin-NADP⁺ reductase, the doubly wound, parallel β sheet seems to be folded independently from the antiparallel β barrel. Only one strand of polypeptide runs between them.

A large number of observations, among them the ones just described, have led to the conclusion that the native structures of most folded polypeptides can be divided into independent domains. A **domain** is any region within the native tertiary structure of a folded polypeptide for which evidence can be provided of an existence independent of the rest of the polypeptide. There are several types of independent existence that qualify a region within the native structure as a domain.

The most obvious evidence that two regions of the same protein are domains is that either a limited cleavage of the polypeptide or the expression of separate portions of the polypeptide produces independent fragments of the protein that retain their respective native structures. In such instances, the two or more separated fragments would be the **detachable domains** that composed the intact protein. The paradigm of a protein with detachable domains is immunoglobulin G, a circulating antibody responsible for binding to foreign proteins or other antigens. Porter¹⁵⁰ demonstrated that intact immunoglobulin G could be cleaved by the thiol endopeptidase papain into three pieces of almost equal sizes. Two of these detachable domains, the Fab fragments, retained the ability to bind antigens, and the third, the Fc fragment, was stable enough that it crystallized spontaneously during its isolation. The Fab fragments could be readily separated by cation-exchange chromatography from the Fc fragments without any loss of their biological activity. Comparisons of crystallographic molecular models of Fab fragments and Fc fragments with those of intact immunoglobulins G (Figure 7-13)^{151,152} have demonstrated that the detached and separated domains retain the respective structures that they had in the intact molecule before it was cleaved.¹⁵³

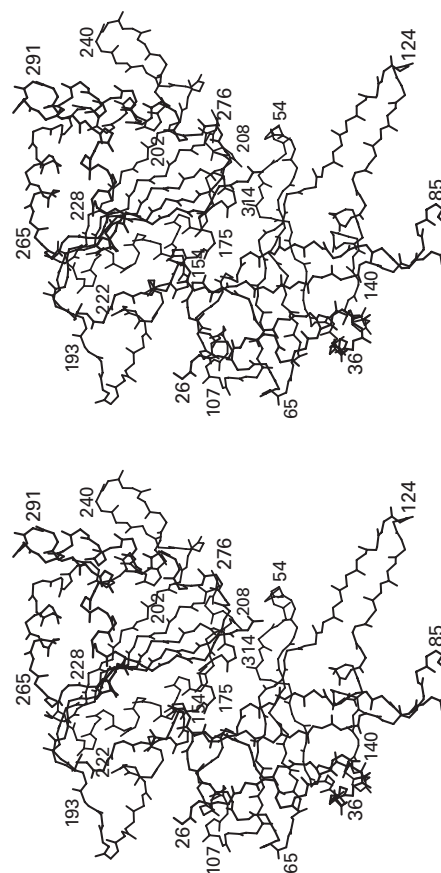

It was unfortunate that an unintended association between limited cleavage with endopeptidases and domains was established with these elegant experiments. The important fact was that Porter separated the detached

domains from each other and demonstrated that each was still structurally intact. It has already been noted that a protein must be prepared for complete digestion with endopeptidases by unfolding it. The reason for this is that most of the **peptide bonds susceptible to digestion** with a particular endopeptidase in the unfolded polypeptide are not susceptible to digestion in the native folded polypeptide. In fact, many native proteins are resistant to digestion over their entire length until they are unfolded.¹⁵⁴ When the digestion of a native protein does occur, it usually occurs at only one or two locations. The sites at which cleavage of a native protein by endopeptidases can occur are exposed, flexible loops of polypeptide on its surface that are rarely situated between domains, and domains are often not connected by such loops.¹⁵⁵⁻¹⁵⁷ If a polypeptide is cut at only one or two positions by an endopeptidase when it is folded in its native conformation, this is not evidence that the fragments observed compose separate domains in that native conformation.¹⁵⁸

If, however, the protein can be digested and the pieces that result can be separated as biologically active or structurally intact moieties, they are detachable domains. Few examples of such **endopeptidolytic detachments** have been reported, and among those are the following. A protein anchored to mammalian cellular membranes contains within its single folded polypeptide the two enzymes peptidylglycine monooxygenase and peptidylamidoglycolate lyase. This protein can be digested either during normal cellular processes or by experimental treatment with an endopeptidase to produce two soluble, detached domains, which can be separated chromatographically, one of which catalyzes the former activity and the other of which catalyzes the latter.¹⁵⁹ The enzyme sulfite oxidase can be cleaved with either trypsin, chymotrypsin, or papain to produce two detached domains that can be separated from each other by molecular exclusion chromatography.¹⁶⁰ One retains the ability to transfer electrons from sulfite to $\text{Fe}(\text{CN})_6^{3-}$; the other retains the spectrum characteristic of the heme in its native environment. The transfer of electrons from sulfite all the way to the ultimate oxidant, cytochrome *c*, can no longer occur because the domain containing the heme is no longer attached to the domain at which the sulfite is oxidized. Anion carrier is a protein in the plasma membrane of erythrocytes and is responsible for anion transport. It can be cleaved with chymotrypsin to produce a water-soluble domain that can be readily separated from the other domain, which remains in the membrane.¹⁶¹ Between them the two detached domains retain the biological functions that are displayed by the intact protein, and each retains the structure it had in the intact protein.

Once the cDNA or genomic DNA encoding a protein has become available and it has become clear exactly where the boundaries between its domains are located, they can often be detached genetically and each

Figure 7-12: Skeletal representation of the backbone of the crystallographic molecular model (Bragg spacing ≥ 0.17 nm) of ferredoxin-NADP⁺ reductase (314 aa) from *S. oleracea*.^{148,149} The published molecular model included Histidine 19 through Tyrosine 314, but the drawing begins at Glycine 26. The doubly wound, parallel β sheet is in the upper right portion of the drawing; the Greek key, antiparallel β barrel, in the lower left. Glutamate 154 identifies the covalent junction between the two domains. Note the irregular cleft between the two domains; only one strand of polypeptide, that containing Glutamate 154, runs across the cleft. This drawing was produced with MolScript.⁴⁰⁹

of them expressed separately. There are many examples of such **genetic detachments**. The two domains that catalyze indole-3-glycerol-phosphate synthase and phosphoribosylanthranilate isomerase within the bifunctional enzyme of *E. coli* can be genetically detached and expressed as separate monofunctional proteins.¹⁶² The two domains of protein S from *Myxococcus xanthus* can be genetically detached and expressed as stable monomeric proteins¹⁶³ that show no tendency to associate with each other and both of which retain their ability to bind Ca^{2+} . The domains of the AraC

protein from *E. coli* can be genetically detached and expressed as separate proteins that exhibit respectively the abilities of the intact native protein to recognize DNA containing its operator and to dimerize in an arabinose-dependent manner.¹⁶⁴ Genetic deletion of the carboxy-terminal 154 aa from cystathionine β -synthase (507 aa) actually increases its enzymatic activity.¹⁶⁵

The advantage of performing a detachment genetically is that it can be **accomplished at the precise boundary** and does not require that the polypeptide between the two domains be as extraordinarily available for digestion by an endopeptidase as are the connecting strands

between the domains in an immunoglobulin G (Figure 7-13). Consequently, there are far more examples of domains that have been successfully detached genetically than have been detached endopeptidolytically. When a domain that is buried in the structure of the native protein and consequently has an excess of hydrophobic side chains on its surface is detached genetically, it is also possible to mutate some of these hydrophobic amino acids to hydrophilic amino acids to prevent the detached domain from aggregating.¹⁶⁶

There is a protein in *E. coli* that is responsible for the two enzymatic activities of aspartate kinase and homoserine dehydrogenase. It is composed of one folded polypeptide 820 aa in length. When this protein is digested with glutamyl endopeptidase from *Streptomyces*

Figure 7-13: Crystallographic molecular model (Bragg spacing ≥ 0.28 nm) of a murine monoclonal immunoglobulin G.¹⁵¹ The two Fab domains are aligned vertically, one above the other on the right-hand side of the figure, and the Fc domain is to the left. There are four folded polypeptides that together compose an intact molecule of immunoglobulin G. In this particular case, they are two identical polypeptides 214 aa long, the light chains, and two identical polypeptides 444 aa long, the heavy chains. In the figure, one heavy chain and one light chain are drawn with thicker lines; and the other heavy chain and the other light chain are drawn with thinner lines. The light chains are each confined to their respective Fab domains, but the heavy chains each form respectively the other half of one of the Fab domains, and they also associate with each other to form the Fc domain. Each of the three detachable domains, the Fc domain and the two Fab domains, is itself formed by four internally repeating domains each about 110 aa long composed of seven antiparallel β -strands. All 12 of these smaller internally repeating domains are superposable, one on the other, and arose from multiple gene duplications. The two most peripheral internally repeating domains in the Fc detachable domain are formed respectively by the carboxy-terminal portions of the two heavy chains and associate directly with each other, as do the four respective pairs of internally repeating domains in the two Fab detachable domains. The two centrally located internally repeating domains in the Fc detachable domain, however, associate with each other through their oligosaccharides, which are drawn with the thickest lines. The two strands of polypeptide connecting each Fab fragment with the Fc fragment are open, flexible, and unstructured; consequently these three detachable domains, each a rigid body, are in constant rearrangement relative to each other when immunoglobulin is in solution. This drawing was produced with MolScript.⁴⁶⁸

griseus, it is cut into two large fragments and a short peptide as a result of cleavages following Glycine 296 and Glutamate 301.¹⁶⁷ Because chymotrypsin digests the protein only at Leucine 294; subtilisin, only at Alanine 297; and trypsin, only at Arginine 299,¹⁶⁷ the region containing these five sites of cleavage must be in a loop of about 10 amino acids on the surface of the protein. The two large fragments from digestion with glutamyl endopeptidase can be separated from each other and from their parent on chromatography by molecular exclusion. The carboxy-terminal fragment retains the homoserine dehydrogenase activity. The amino-terminal fragment, however, shows only 1% or less of the aspartate kinase activity originally present, and this small amount of activity probably results from cross-contamination with uncleaved protein. A fragment retaining normal levels of aspartate kinase activity, however, can be prepared genetically by deleting the carboxy-terminal 45% of the polypeptide.¹⁶⁸ In *B. subtilis*, aspartate kinase and homoserine dehydrogenase are separate proteins. By alignment of the amino acid sequences of these two proteins with that of the bifunctional protein from *E. coli*, it could be shown that the boundary between the two enzymatic domains in the bifunctional protein is a short segment between Phenylalanine 460 and Isoleucine 466.¹⁶⁹

From all of these results it can be concluded that, if

properly detached, each domain of this bifunctional protein from *E. coli* remains folded and enzymatically active. The cleavage by an endopeptidase within the exposed loop in domain 1, which is responsible for aspartate kinase, causes it to unfold and the unfolded amino-terminal fragment to fall away. Domain 2, which is responsible for homoserine dehydrogenase, remains folded and active after the cleavage. If the point of cleavage by glutamyl endopeptidase were a true boundary between two detachable domains, rather than an adventitious loop of polypeptide on the surface of the aspartate kinase, the aspartate kinase activity, which can readily be expressed by the genetically dissected protein, would have been unaffected. Aspartate kinase-homoserine dehydrogenase, then, is an example of a protein that has domains that cannot be detached from each other at their boundary by cleavage with an endopeptidase.

Proteins such as aspartate kinase-homoserine dehydrogenase belong to a class of proteins known as multienzyme complexes. A **multienzyme complex** is a protein that, although it is a single, discrete macromolecule, is able to catalyze two or more enzymatic activities. Usually each of the enzymatic activities in one of these multienzyme complexes is expressed by its own unique domain within the folded polypeptide or one of the folded polypeptides that form the protein. Such an **enzymatic domain** within a larger protein is a domain that is by itself independently responsible for a particular enzymatic activity. The fact that the several enzymatic activities are expressed respectively by several individual proteins in some species yet all of them are expressed by only one protein formed from one folded polypeptide in other species is sufficient evidence of an independent existence to conclude that the multienzyme complex is constructed from enzymatic domains. Proteins constructed from enzymatic domains presumably arose as the result of the fusion of the individual genes that encoded the unfused ancestors of those domains. Many artificial fusions of two genes to produce chimeric proteins have been performed, and the products that result from these artificial fusions seem to be little affected functionally.^{170,171}

A paradigm for a protein containing enzymatic domains is the CAD multienzyme complex in animal tissues that comprises a single folded polypeptide about 2220 aa in length¹⁷² responsible for the enzymatic activities of carbamoyl-phosphate synthase (glutamine hydrolysing), aspartate carbamoyltransferase, and dihydroorotase.¹⁷³ The first enzymatic reaction has two steps, the production of ammonia from the hydrolysis of glutamine at the active site of a glutaminase and the synthesis of carbamoyl phosphate from the resulting ammonia at the active site of a carbamoyl-phosphate synthase (ammonia). Each of the four component enzymatic reactions carried out by the intact complex from animals is carried out by a different discrete protein in *E. coli*. The amino acid sequences of the four **separate bacterial pro-**

teins can be aligned with four consecutive regions in the amino acid sequence of the multifunctional protein from *Mesocricetus auratus*; glutaminase with amino acids 2–355 (40% identity, 1.3 gap percent),^{172,174} carbamoyl-phosphate synthase (ammonia) with amino acids 397–1440 (40% identity, 1.1 gap percent),^{172,174} dihydroorotase¹⁷⁵ with amino acids 1457–1785 (20% identity, 3.5 gap percent),¹⁷⁶ and aspartate carbamoyltransferase with amino acids 1921–2225 (44% identity, 1.6 gap percent).¹⁷⁷ These regions are enzymatic domains 1 through 4 in the CAD multienzyme complex, respectively.

The fact that dihydroorotase has sustained so much more replacement suggests that even within the same polypeptide different domains can suffer **replacement at different rates**. In fact, rates of change can differ so much that one domain in a multienzyme complex can become defunct even as others retain their full function. In the CAD multienzyme complex from yeast, the dihydroorotase domain, although its amino acid sequence is still able to be aligned, has lost the ability to catalyze its enzymatic reaction.¹⁷⁵ A similar loss of function has occurred during the evolution of the fructose-2,6-bisphosphate 2-phosphatase domain of yeast 6-phosphofructo-2-kinase, but its enzymatic activity can be restored by mutating Serine 404 to histidine.¹⁷⁸

Because the amino acid sequences of the four discrete bacterial proteins responsible for the four enzymatic reactions catalyzed by the CAD multienzyme complex from animals can be aligned with the amino acid sequences of its four enzymatic domains, it follows that the tertiary structure of each domain in the animal protein must be superposable on the tertiary structure of the corresponding bacterial protein. Consequently, each domain in the animal protein must be a compact, independently folded unit, and these units must be **strung together** consecutively by the continuity of the polypeptide. This conclusion is supported by the fact that the enzymatically active domains responsible respectively for dihydroorotase^{175,179} and aspartate carbamoyltransferase¹⁷⁷ can be detached either genetically or by cleavage of the protein with endopeptidases at the boundaries of the domains. During the digestion with endopeptidases, however, the activity of carbamoyl-phosphate synthase (glutamine-hydrolysing) is lost and can be associated with none of the fragments smaller than 1700 aa in length. In situations such as this, digestion of one domain, for example, the carbamoyl-phosphate synthase domain, at some point on its surface could cause it to unfold and make the polypeptide much more susceptible to cleavage by endopeptidases in a region forming the boundary between that unfolded domain and a neighboring properly folded domain. An example of such a pruning of an unfolded segment of polypeptide from a properly and compactly folded protein by digestion with an endopeptidase occurred during the production of hybrids of different portions of micrococcal nuclease from *Staphylococcus*.¹⁸⁰

Anthranilate synthase, CTP synthase, phosphoribosylformylglycinamidine synthase, GMP synthase, imidazole glycerol phosphate synthase, glutamine-fructose-6-phosphate transaminase (isomerizing), and aminodeoxychorismate synthase, like the carbamoyl-phosphate synthase (glutamine hydrolysing) incorporated into the CAD multienzyme complex, all contain an enzymatic domain responsible for producing ammonia from glutamine by hydrolysis. The domain can be either

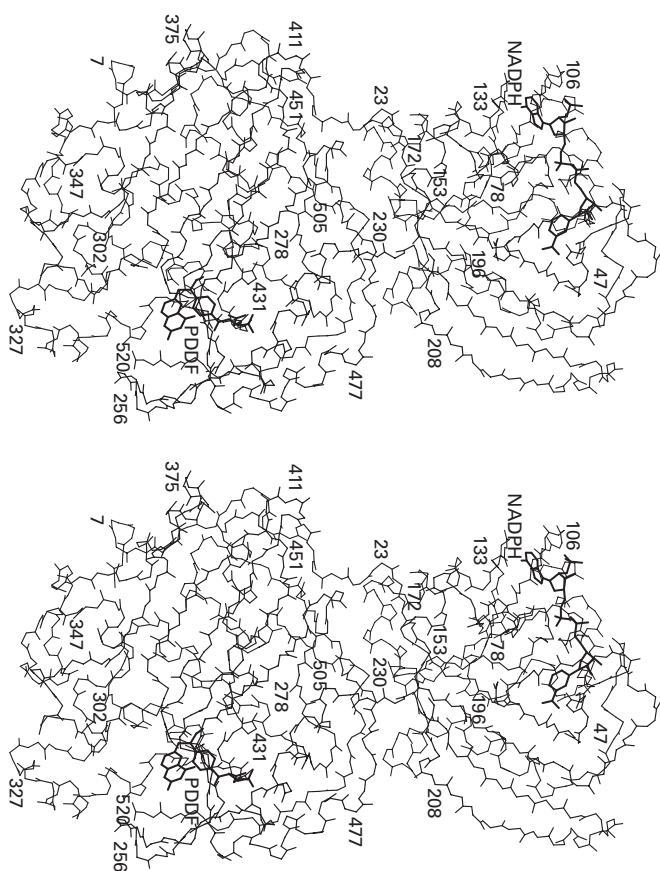

Figure 7-14: Crystallographic molecular model (Bragg spacing ≥ 0.29 nm) of the bifunctional enzyme from *Leishmania major* responsible for dihydrofolate reductase and thymidylate synthase.¹⁸³ The upper enzymatic domain (Serine 23 to Arginine 230) is responsible for dihydrofolate reductase, and its active site is identified by the bound NADPH (drawn with thicker lines). The lower enzymatic domain (Asparagine 231 to Valine 520) is responsible for thymidylate synthase, and its active site is identified by the bound 10-propargyl-5,8-dideazafolate (PDDF), also drawn with thicker lines. Aside from the amino-terminal 22 aa that adventitiously cleave to the outer surface of the opposite domain, that responsible for thymidylate synthase, the two enzymatic domains are independently folded structures separated by an irregular horizontal cleft through which only one strand of polypeptide passes, that containing Arginine 230. This drawing was produced with MolScript.⁴⁰⁸ The atomic coordinates on which this drawing is based were provided by Dave Matthews.

a separate folded polypeptide¹⁸¹ or an enzymatic domain in a longer polypeptide.¹⁸² Because the sequences of these various enzymatic domains catalyzing the hydrolysis of glutamine are homologous, it follows that they share a common ancestor that in its day was a separate, independent protein, presumably a glutaminase. The offspring of this common ancestor were **separately incorporated** into the various multienzyme complexes in which they are now found. Although each of these complexes catalyzes a quite different reaction, each uses the ammonia supplied by the respective glutaminase domain as a substrate.

The crystallographic molecular model of the bifunctional enzyme from *Leishmania major* responsible for dihydrofolate reductase and thymidylate synthase (Figure 7-14)¹⁸³ illustrates the independent existence of its two enzymatic domains. Domain 1, which is responsible for dihydrofolate reductase, comprises the folded polypeptide from Serine 23 to Arginine 230; and domain 2, which is responsible for thymidylate synthase, that from Histidine 234 to Valine 520. The respective active sites are identified by the NADPH and the 10-propargyl-5,8-dideazafolate. Each enzymatic domain is readily superposed on the crystallographic molecular model of the corresponding monofunctional enzyme from *E. coli*, and their respective amino acid sequences can be aligned with those of dihydrofolate reductase (26% identity, 3.8 gap percent) and thymidylate synthase (53% identity, 1.4 gap percent) from *E. coli*. In the bifunctional protein, the two enzymatic domains, although folded separately and once separate unassociated proteins, have nevertheless become **intimately associated** with each other at the interface between themselves.

In *Aspergillus nidulans* there is a multienzyme complex catalyzing 3-dehydroquinate synthase, 3-phosphoshikimate 1-carboxyvinyltransferase, shikimate kinase, 3-dehydroquinate dehydratase, and shikimate dehydrogenase. Although the individual enzymatic domains responsible for dehydroquinate dehydratase and 3-dehydroquinate synthase could be genetically detached as enzymatically active proteins, the enzymatic domain responsible for 3-phosphoshikimate 1-carboxyvinyltransferase was active only when attached to the neighboring domain responsible for 3-dehydroquinate synthase.¹⁸⁴ This result suggests that as time passes following their fusion, two domains may associate with increasing intimacy as a specific interface between them evolves, like that in dihydrofolate reductase-thymidylate synthase (Figure 7-14), and in the end, they may require each other's presence to fold properly as that interface becomes more and more extensive.

In most cases, the enzymatic domains gathered into a multienzyme complex all carry out reactions in the **same metabolic pathway**. The five enzymatic domains in the multienzyme complex from *A. nidulans*, the four enzymatic domains in the CAD multienzyme complex, and the two domains in dihydrofolate reductase-

thymidylate synthase catalyze successive reactions in the biosynthesis of chorismic acid, orotidine 5'-phosphate, and thymidine 5'-phosphate, respectively. Aspartate kinase-homoserine dehydrogenase catalyzes the first and third steps in the biosynthesis of homoserine. It is common in prokaryotes to find the enzymes catalyzing the reactions of a metabolic pathway gathered together in an operon. Such a gathering may have preceded the gene fusions producing multienzyme complexes and facilitated those fusions by placing the genes for the ancestors of the enzymatic domains adjacent to each other in the genome.¹⁸⁵ There are, however, examples of single enzymatic domains responsible for only one enzymatic reaction but inserted into larger proteins. The domain responsible for protein-tyrosine-phosphatase in eukaryotes is a compact enzymatic domain¹⁸⁶ that is fused into a large array of different proteins.

In prokaryotes and plants,^{187,188} the seven enzymes and the acyl carrier protein responsible for the synthesis of fatty acids from acetyl-S-CoA and malonyl-S-CoA are discrete proteins that can be separated and individually purified, but in fungi and animals all of these activities are expressed by a single multienzyme complex. In fungi, the complex is constructed from two folded polypeptides that are encoded by different genes and are completely different in sequence from each other.^{189,190} Their lengths are 1890 and 1980 aa, respectively.^{189,190} The fatty-acid synthase from animals, however, is constructed from only one polypeptide, 2440 aa in length.¹⁹¹ All seven of the enzymatic activities and the acyl carrier protein are located on the single polypeptide comprising the animal enzyme, and the domains responsible for each have been identified in the amino acid sequence.¹⁹¹⁻¹⁹³ Animal fatty-acid synthase has also been dissected both genetically and with the endopeptidase kallikrein¹⁹³ to produce several detached domains that are able to catalyze the enzymatic reactions assigned to them.

The order in which these enzymatic domains occur on the single polypeptide of the animal fatty-acid synthase is unrelated to the orders in which they appear on the two unique polypeptides from fungi.¹⁹⁴ On the basis of this fact, it has been concluded that all or most of the gene fusions that produced the animal protein and the fungal protein, respectively, must have occurred as independent events after the lineages of these two kingdoms diverged from their common ancestor. These separate processes would be ones in which each enzymatic domain has been shuffled into a larger protein. Nevertheless, the individual domains, even though **fused in different orders**, are still homologous to each other because the amino acid sequence of the one responsible for a given activity in the fungal enzyme can be aligned with that of the one responsible for the same activity in the animal enzyme.¹⁹⁴

There are a number of multienzyme complexes that are responsible for the biosynthesis of antibiotics in various fungi and bacteria. For example, the single folded

polypeptide 3131 aa in length¹⁹⁵ responsible for the biosynthesis of enniatin in *Fusarium oxysporin* catalyzes all of the enzymatic reactions required to produce this cyclic hexadepsipeptide,¹⁹⁶ and the multienzyme complex containing four folded polypeptides (3587, 3587, 1274, and 240 aa) responsible for the biosynthesis of surfactin in *B. subtilis* catalyzes all of the enzymatic reactions required to produce this cyclic octadepsipeptide.¹⁹⁷

The multienzyme complex¹⁹⁸ responsible for the biosynthesis of the polyketide 6-deoxyerythronolide B, which is the lactone at the hydroxyl on carbon 13 of the fatty acid

is composed of three distinct but related polypeptides, 3200-3600 aa long. The synthesis of the complete molecule of 6-deoxyerythronolide B proceeds by the successive condensation of six molecules of (2S)-methylmalonyl-S-CoA onto a molecule of propionyl-S-CoA. After each of the six Claisen condensations, the resulting ketone either remains untransformed (carbon 9) or is reduced to the alcohol (carbons 3, 5, 11, 13), which either remains untransformed or is dehydrated and reduced to the alkane (carbon 7). The entire sequence of reactions at each round, from condensation to alkane, requires the successive participation of an acyl carrier protein present as a domain as well as five separate enzymatic domains: an [acyl-carrier-protein] S-acyltransferase, a 3-oxoacyl-[acyl-carrier-protein] synthase, a 3-oxoacyl-[acyl-carrier-protein] reductase, a 3-hydroxyacyl-[acyl-carrier-protein] dehydratase, and an enoyl-[acyl-carrier-protein] reductase. On its three polypeptides erythronolide synthase has 22 enzymatic domains and 6 acyl carrier proteins.

The elongating substrate is passed along the **assembly line** from the first acyl carrier protein to the sixth acyl carrier protein through six successive stations. At each station, it is operated on by the enzymatic domains assembled at that station.¹⁹⁹ After it has been processed at the last station, the product 6-deoxyerythronolide is released from the last acyl carrier protein by an acyl-[acyl-carrier-protein] hydrolase, the last of the 22 enzymatic domains. When one of the domains at a particular station is inactivated or when one or more domains are experimentally added to a particular station, the product of the multienzyme complex changes at the position produced by that station to reflect its altered capacity. When the last station is deleted, a fatty acid lactone shorter by one C₃ unit is produced.²⁰⁰ The enzymatic reactions catalyzed by this large multienzyme complex are homologous to those catalyzed by fatty-acid synthase. Fatty-acid synthase, however, because each of its

successive steps passes through the complete sequence of enzymatic reactions to produce the alkane at each stage, uses only one station for all of the reactions rather than the six stations, one for each of its steps, used by erythronolide synthase.

Coenzymatic domains, such as the acyl carrier proteins carrying 4'-phosphopantetheine that are incorporated into fatty-acid synthase and erythronolide synthase, are domains to which coenzymes are covalently attached. The domains carrying acyl carrier proteins are domains because they are found as independent proteins in prokaryotes and plants; the domains carrying lipoic acid that are incorporated into 2-oxo-acid dehydrogenase complexes are domains because they can be detached.²⁰¹ Domains carrying biotin appear within the longer polypeptides of a number of different biotin-dependent carboxylases.²⁰²

A **functional domain** within a larger protein is a domain that is by itself responsible for a specific function. Enzymatic domains are functional domains, but there are also functional domains that are not enzymatic. Examples of functional domains would be the domains responsible for binding to specific segments of DNA (Figures 6-46, 6-50, and 6-53), each of which is a component of a larger protein responsible for controlling the expression of the gene adjacent to the segment of DNA recognized by the binding domain. Each of the other domains in the larger protein is responsible for a function essential to this control. For example, in each of the proteins that controls genes in response to steroid hormones such as estrogen, testosterone, progesterone, cortisone, and aldosterone, one of these other domains is responsible for binding the respective hormone.²⁰³ There are many examples of domains such as these that are responsible for binding a ligand and that are part of a larger protein. Examples are the two domains responsible for binding cyclic AMP in cyclic AMP-dependent protein kinase²⁰⁴ and the domain responsible for binding flavin mononucleotide and stabilizing its semiquinone radical in sulfite reductase.²⁰⁵ When the amino-terminal 240 aa of 3-phosphoshikimate 1-carboxyvinyltransferase from *E. coli*, which form a compact globular domain in the crystallographic molecular model of the intact protein (427 aa),²⁰⁶ was expressed separately, it folded to form a structure capable of binding shikimate 3-phosphate.²⁰⁷

The domains discussed so far are clearly capable of independent existence or are descended from ancestors that were. There are, however, domains in proteins that either cannot be detached or that are not identified with an independent function. These domains often were joined together so long ago that they have become completely dependent on each other both structurally and functionally. Nevertheless, it is possible to conclude that they once did have an independent existence because they recur in a number of extant proteins. Examples of such recurring domains would be domain 1, the antipar-

allel β barrel,²⁰⁸ and domain 2, the doubly wound parallel β sheet,²⁰⁹ in ferredoxin-NADP⁺ reductase (Figure 7-12), which are also found as domains in a number of different proteins. A **recurring domain** is a domain that is folded with a tertiary structure that can be superposed on the tertiary structures of other domains in other proteins of otherwise entirely different structure. A recurring domain is a compact structure used in more than one distinct situations. Because of its recurrence in different surroundings, there is little doubt that a domain of this type had at one time an independent existence.

Pyruvate kinase is one of the more informative examples of a protein built from recurring domains.²¹⁰ Domain 1 of the protein is an α -helically wound, parallel β barrel that is superposable on the entire folded polypeptide of triose-phosphate isomerase. Inserted into the loop between the third β strand and the third α helix of domain 1 is domain 2, which is a Greek key, antiparallel β barrel.²¹¹ Domain 3, which follows in the sequence of the polypeptide the complete elaboration of domain 1, can be superposed on half of the doubly wound, parallel β sheet found in L-lactate dehydrogenase. (Figure 7-11).²¹⁰ Each of these three structures is a recurring domain. In galactose oxidase from *Dactylium dendroides*, domain 2 is a β propeller (Figure 6-13) that is flanked by domain 1, an eight-stranded jelly roll, antiparallel β barrel,²¹¹ and domain 3, a bundle of seven antiparallel β strands that has the topological arrangement of an immunoglobulin domain.²¹² All three of these structures are also recurring domains.

Recurring domains occasionally appear to be associated with a particular role. For example, benzoate 4-monooxygenase, glucose oxidase, cholesterol oxidase, and glutathione-disulfide reductase contain a recurring domain about 160 aa in length.^{213,214} In all of these enzymes, the domain serves to bind tightly an integral flavin coenzyme, and it has been referred to as the "FAD-binding domain".²¹³

Some secondary structures, such as a β propeller (Figure 6-13)²¹² or a β helix, are self-contained and usually occur as **independent structural entities** in a protein. Because such secondary structures recur in many proteins, they could be considered recurring domains, and they usually do seem to be independent isolated units in a larger protein in which they occur.²¹⁵

An **internally repeating domain** is a member of a set of consecutive segments within the same polypeptide, each homologous in amino acid sequence to the other members of the set or each folded in a tertiary structure superposable on the tertiary structures of the other members of the set. An example of a set of such internally repeating domains are the 12 domains, four in each of the three detachable domains that compose immunoglobulin G (Figure 7-13). Each of these 12 internally repeating domains is a seven-stranded barrel of antiparallel β strands. Each is superposable on all the others and shares statistically significant similarities in

amino acid sequence with some of the others. The two identical long polypeptides in an immunoglobulin G, the heavy chains, each contain four of these domains; and the two identical short polypeptides, the light chains, each contain two. Polypeptides containing such internally repeating domains are quite common. About 10% of polypeptides 200 amino acids in length contain internally repeating domains but the frequency rises steadily to 80% for polypeptides 2000 amino acids in length.²¹⁶

Internally duplicated domains are internally repeating domains that occur only twice in the same polypeptide. Internally duplicated domains arise from the internal duplication of a gene encoding a smaller protein. An **internal duplication** is a gene duplication in which the duplicated genes end up immediately adjacent to each other so that when they are transcribed and translated, the duplicated amino acid sequences remain attached consecutively to each other in the same polypeptide. Because they are the products of internal duplication, the single, unrepeated ancestral amino acid sequence and tertiary structure of each of these duplicated domains must have existed on its own at some time in the past, before the duplication occurred. As with a gene duplication producing two separate proteins, an internal duplication arises in the genome of one individual and then spreads by genetic drift over the whole population. As with gene duplication in general, internal duplications arise often but only rarely spread over the whole population. Following the gene duplication and its spread and fixation by genetic drift, the two internally repeating domains begin to evolve separately.

The two halves of the doubly wound, parallel β sheet as it presently occurs in L-lactate dehydrogenase (Figure 7-11) can be superposed upon each other (Figure 7-15).⁸² It has been proposed that the complete doubly wound, parallel β sheet arose itself from a gene duplication in which the two segments of polypeptides encoded by the duplicated gene remained consecutively attached to each other and then began to evolve independently but within the same protein. That this did happen is supported by the fact that recurring domains are found in the crystallographic molecular models of pyruvate kinase²¹⁰ and phosphoglycerate kinase that superpose on only half of the doubly wound, parallel β sheet from L-lactate dehydrogenase.²¹⁰ The lineages leading to these two shorter domains presumably diverged before the gene duplication that produced the common ancestor of the larger.

The eight-stranded, α -helically wound parallel β barrel that forms the entire molecule of 1-(5-phosphoribosyl)-5-[(5-phosphoribosylamino)methylideneamino]imidazole-4-carboxamide isomerase from *Thermotoga maritima* has a fold typical of this structure, which is usually treated as a single domain (Problem 7-10B). Nevertheless, the amino-terminal half of its crystallographic molecular model can be superposed on the carboxy-terminal half with a root mean square deviation of

0.21 nm, and the amino acid sequences of the two halves can be aligned structurally with a percentage of identity of 23%.²¹⁷ A similar superposition and alignment can be performed with the two halves of the α -helically wound, parallel β barrel of imidazole glycerol phosphate synthase from the same bacterium.^{217,218} Unlike the two halves of the doubly wound, parallel β sheet (Figure 7-15), there are no examples of proteins in which half of an α -helically wound, parallel β barrel is found. Nevertheless, these superpositions and alignments suggest that all α -helically wound, parallel β barrels are also the product of an internal duplication.

The serine endopeptidases,²¹⁹ thiosulfate sulfurtransferase,²²⁰ carbamoyl-phosphate synthase from *E. coli*,²²¹ methionyl aminopeptidase from *E. coli*,²²² and diaminopimelate epimerase from *Haemophilus influenzae*²²³ are each an example of a protein **formed entirely**

Figure 7-15: One half of the doubly wound, parallel β sheet (Figure 7-11) found in the crystallographic molecular model of L-lactate dehydrogenase from *S. acanthus* (open lines), drawn as an α -carbon diagram, superposed on the other half of the same doubly wound, parallel β sheet (solid lines).⁸² Reprinted with permission from ref 82. Copyright 1974 *Nature*.

by one internal duplication. In UDP-glucose 6-dehydrogenase from *Streptococcus pyogenes*, however, the two domains of an internal duplication (123 and 93 aa) are separated from each other by another domain of 177 aa.²²⁴ Although the bifunctional enzyme phosphoribosylanthranilate isomerase/indole-3-glycerol-phosphate synthase has two consecutive enzymatic domains that are superposable,²²⁵ the two enzymes probably evolved separately from a common ancestor before being fused.

Aside from the alignments of the duplicated amino acid sequences or superpositions of the duplicated tertiary structures, there are other observations supporting the conclusion that duplicated domains at one time had independent existence. The internal duplication in mammalian hexokinase produced two independent enzymatic domains, each containing an active site and each superposable on the other and on the unduplicated enzyme from fungi.^{87,226} The two internally duplicated domains of ovotransferrin²²⁷ can be detached by digestion with endopeptidase, and the resulting amino-terminal domain can be crystallized and shown to have the same structure it had in the intact protein.²²⁸ The aspartic endopeptidase from retroviruses is formed from two identical polypeptides,²²⁹ but those from eukaryotes are formed from a single polypeptide containing an internal duplication of the structure assumed by each polypeptide in the viral protein.^{125,230} Each domain of the enzyme from eukaryotes is superposable on one of the folded viral polypeptides. The two halves of porcine aspartic endopeptidase were expressed separately and, when mixed together, folded to produce an enzymatically active protein formed, as is the retroviral enzyme, from two folded polypeptides²³¹ rather than two internal duplications.

Many proteins contain **more than two** internally repeating domains. Serum albumin^{232,233} is composed of three internally repeating domains; human interstitial retinol-binding protein, of four;²³⁴ gelsolin, of six;²³⁵ human placental ribonuclease inhibitor,²³⁶ hemocyanin from *Octopus dofleini*,²³⁷ and granulin,²³⁸ of seven; and the polymeric globin from *Artemia*, of nine.²³⁹ Such **gene multiplications** are usually not produced by several historically distinct duplications but arise when an initial gene duplication then catalyzes the further multiplication of the gene during successive rounds of recombination. Sometimes the same protein from different species has different numbers of internally repeating domains. Dihydrolipoyllysine-residue acetyltransferase from *E. coli* has three consecutive lipoamide domains; the enzyme from rat, two; and the enzyme from *S. cerevisiae*, one.²⁴⁰ An example of a very recently multiplied gene is the one encoding preproincretin from *Xenopus laevis* in which the identical sequence of 46 aa repeats five times²⁴¹ in the same polypeptide with the replacement of only one amino acid in only one of the repeats. In contrast to such proteins containing amino acid sequences

multiplied so recently that they can be readily aligned²⁴² are proteins in which the internally repeating domains diverged so long ago that their secondary structures, although obviously related, have rearranged significantly.²⁴³

Nebulin and spectrin are examples of proteins with even larger numbers of internally repeating domains. Nebulin is a long protein (6669 aa) composed almost entirely (the first 6480 aa) of 178 internally repeating domains each 30–32 aa long.²⁴⁴ Spectrin is a protein composed of 38 internally repeating domains consecutively occurring in its two unique folded polypeptides.^{245–247} The folded domains sit like beads on a wire to create a long, somewhat flexible protein (Figure 7–16A).^{245,248} Each domain of 106 aa²⁴⁶ is an antiparallel coiled coil of three α helices (Figure 7–16B).^{249–251} Spectrin offers an excellent example of the absence of a correlation between locations at which cleavages with endopeptidases occur upon the surface of a native protein and the boundaries between its domains. Of the 15 cleavages of native spectrin produced by trypsin,²⁵² only four occur that are even near the boundaries of the domains.²⁴⁵ This fact is not surprising, given that the junctions between the domains are continuous α helices (Figure 7–16B).

The internal repeats in a protein, if the multiplications of the gene that produced them have occurred recently enough, can be recognized on a **dot matrix** (Figure 7–2) in which the amino acid sequence of the entire protein is compared to itself. Such a dot matrix of a protein with internally repeating domains contains a set of lines parallel to the central diagonal of identity. The distance between the lines is equal to the length of the internally repeating domains, and the number of lines is one less than the number of domains. In the dot matrix for the self-comparison of the amino acid sequence of human intestinal retinol-binding protein,²³⁴ there are three lines parallel to the central diagonal and the distances between them are 302–310 aa, and in that for human placental ribonuclease inhibitor,²³⁶ there are six lines and the distances between them are 57 aa.

The β propeller (Figure 6–13) is a structure in which four antiparallel β strands form each blade and 6–8 blades form the intact unit. Each blade is superposable on each of the others²⁵³ so an argument might be made that each blade represents an internally repeating domain,^{254,255} but there are no examples of such a small structure having independent existence. There are a number of other repeating structures that are **too small to fold** on their own^{256–259} and consequently should not be considered to be domains. Often short repeating sequences such as those in dragline silk from spiders²⁶⁰ or antifreeze proteins from *Tenebrio molitor*²⁶¹ have been multiplied to produce a protein that is fibrous or that must conform to a repeating molecular structure such as a crystal of ice but that is not formed from a string of independent globular tertiary structures as is spectrin.

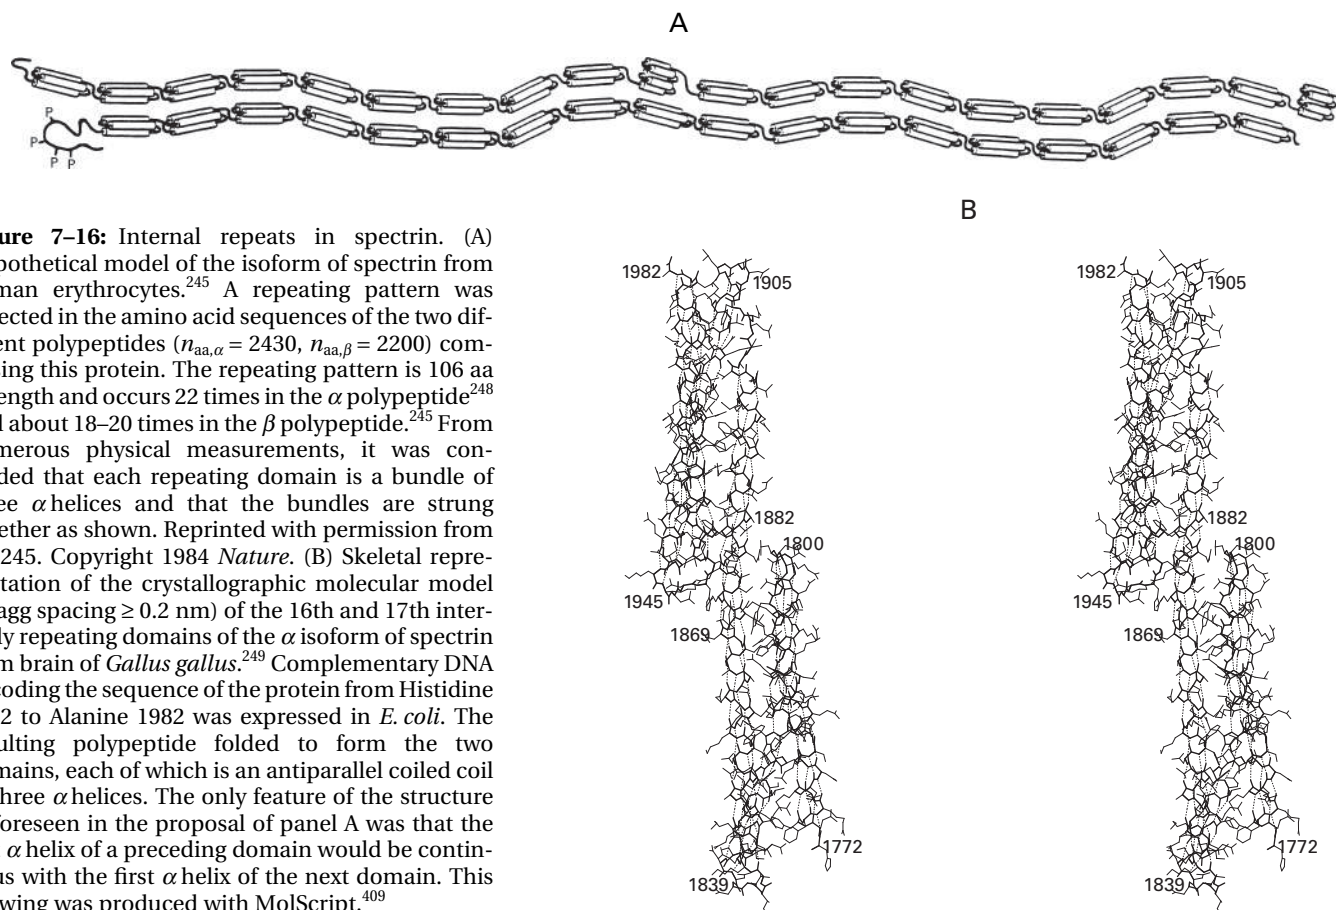

Figure 7-16: Internal repeats in spectrin. (A) Hypothetical model of the isoform of spectrin from human erythrocytes.²⁴⁵ A repeating pattern was detected in the amino acid sequences of the two different polypeptides ($n_{aa,\alpha} = 2430$, $n_{aa,\beta} = 2200$) composing this protein. The repeating pattern is 106 aa in length and occurs 22 times in the α polypeptide²⁴⁸ and about 18–20 times in the β polypeptide.²⁴⁵ From numerous physical measurements, it was concluded that each repeating domain is a bundle of three α helices and that the bundles are strung together as shown. Reprinted with permission from ref 245. Copyright 1984 *Nature*. (B) Skeletal representation of the crystallographic molecular model (Bragg spacing ≥ 0.2 nm) of the 16th and 17th internally repeating domains of the α isoform of spectrin from brain of *Gallus gallus*.²⁴⁹ Complementary DNA encoding the sequence of the protein from Histidine 1772 to Alanine 1982 was expressed in *E. coli*. The resulting polypeptide folded to form the two domains, each of which is an antiparallel coiled coil of three α helices. The only feature of the structure unforeseen in the proposal of panel A was that the last α helix of a preceding domain would be continuous with the first α helix of the next domain. This drawing was produced with MolScript.⁴⁰⁹

The proteins discussed so far are simple multiples of internally repeating domains, but other proteins have internally repeating domains attached to themselves and then to other domains. Sometimes one or the other of the odd domains appears to have evolved from the same common ancestor as the internally repeating domains but has undergone a few more additions, deletions, or rearrangements of its secondary structure,^{262,263} an observation suggesting that two gene duplications occurred at remarkably different times, but usually the odd domain or odd domains are entirely different. For example, pyruvate oxidase from *Lactobacillus plantarum* has two internally repeating domains, each 200 aa long, coupled to a recurring FAD-binding domain in the same polypeptide.²⁶⁴ The extracellular portion of mannose-6-phosphate receptor has 15 contiguous internally repeating domains coupled to a membrane-spanning segment and an intracellular domain.²⁶⁵

Titin is possibly the longest protein built from a single polypeptide. It is a protein greater than $1 \mu\text{m}$ in length that is found in vertebrate muscle.^{266,267} The amino terminus of its polypeptide is embedded in the Z disc, the carboxy terminus of its polypeptide is embedded in the M line, and its elasticity allows it to shorten and lengthen as the muscle contracts and relaxes.^{268,269} As does spectrin (Figure 7-16), titin achieves its remarkable length by using internal repeats. It contains 244

internally repeating domains, each about 100 aa long, that account for 90% of its amino acid sequence of 26,900 aa. Unlike spectrin, however, these internal repeats come in two types, immunoglobulin repeats²⁷⁰ and fibronectin type III repeats. Also, unlike the internally repeating domains of spectrin, these two types of internally repeating domains are widely recurring within a broad class of mosaic eukaryotic proteins that are cobbled together from a particular collection of promiscuous, modular domains. In the amino acid sequences of these proteins, segments have been observed that can be aligned with other segments within the same protein as well as segments in other proteins.²⁷¹ These recurring domains can appear many times in the same protein as internally repeating domains²⁷² or they can appear in combination with other different recurring domains. Because the proteins that contain them seem to have resulted from recent, remarkably active domain shuffling and because their amino acid sequences can usually be aligned readily with those of the other members of their type, these domains are usually considered to be members of a unique group and are referred to as modular domains.

A **modular domain** is a domain that recurs frequently within a group of **mosaic eukaryotic proteins** containing internal repeats of that domain, mixtures of other modular domains, or both internal repeats and

mixtures. The modular domains in such mosaic proteins are usually recognized by sequence alignment, a fact indicating that the proteins containing them have arisen from **recent genetic events**. The modular domains in these proteins can be readily assigned to one of the many types that have been observed. A few of these types are listed in Table 7–7.

A drawing of the crystallographic molecular model of a cohesin domain is presented in Figure 6–21. Although the mosaic proteins constructed from modular domains often contain only one or two types of domain with only a few internal repeats,^{306,317,318} some have four or more types, one or more of which can repeat a number of times (Table 7–8).

Several of the types of modular domains, for example, calcium-binding EF hand, leucine-rich repeats, EGF domains, and ankyrin repeats, are too short (Table 7–7) to fold on their own and are almost always repeated two or more times to produce a large enough structure to permit the polypeptide to fold. Together, in consecutive order, they form structures in which small compact units, each formed by one of the repeats and each of the same structure, are stuck together one against the next.^{319,320} It is the interfaces between the units that bury sufficient numbers of hydrogen-carbon bonds to make the structures stable. An example of this strategy is the β helix in the antifreeze protein from *T. molitor*, in which each turn is an internal repeat of only 12 aa.³²¹ Other short modular domains, clearly related by alignment of their sequences, assume different structures under different circumstances.^{322,323}

Examples of the group of proteins that are mosaics

Table 7–7: Examples of Types of Modular Domains Distributed among Mosaic Eukaryotic Proteins

type of domain	length ^a (aa)	structure ^b

Table 7–8: Extreme Examples of Proteins Assembled from Modular Domains^{306,317,318}

protein	order of modular domains ^a
factor XII	F2-EGF-F1-EGF-Kr-Endo ^b
thrombospondin I	Ths-CC-PcC-(Prop) ₃ -(EGF) ₃ -(EF) ₇ -Ths
collagen VI	(vWA) ₉ -Co-(vWA) ₂ -ST-F3-BPTI
aggrecan	(Li) ₂ -KS-Ch1-Ch2-EGF-Lec-Comp
perlecan	Per-(EGF) ₄ -Ig-(EGF) ₁₂ -Ig ₁₈ -[LaC-(EGF) ₂] ₂ -LaC
btK kinase	Plk-SH3-SH2-Kin
phospholipase C γ	Plk-PLC-PY-(SH2) ₂ -SH3-PLC
p120 GTPase activator	SH2-SH3-SH2-Plk-GAP

The order from amino terminus to carboxy terminus in which the modular domains are attached to each other. ^bModular domains (see Table 7–7): F2, fibronectin type II; F1, fibronectin type I; Kr, kringle; CC, coiled coil; PcC, carboxy-terminal procollagen; Prop, properdin; EF, calcium-binding EF hand; vWA, domain A of von Willebrand factor; ST, serine-threonine-enriched; F3, fibronectin type III; BPTI, bovine pancreatic trypsin inhibitor; Li, link protein; KS, keratan sulfate binding; Ch, chondroitin sulfate binding (types 1 and 2); Lec, lectin; Comp, complement control; Ig, immunoglobulin; LaC, carboxy-terminal laminin; Plk, pleckstrin; PY, phosphotyrosine-containing SH2-binding. Domains specific to the particular protein: Endo, endopeptidase; Ths, thrombospondin-specific; Co, (Gly-X-Y)_n repeat of collagen; Per, perlecan; Kin, kinase; PLC, phospholipase C; GAP, GTPase activator.

of modular domains are regulatory kinases and phosphatases, proteins of the extracellular matrix, and endopeptidases of the coagulation system. Within one of these proteins, the modular domains, which are widely recurring, are usually attached to one or more domains that are specific to the function of that protein (Table 7–8). Phosphoinositide phospholipase C δ 1 from *Rattus norvegicus* is a paradigm of such a mosaic protein. It contains, in order from the amino terminus, a pleckstrin domain, four consecutive EF hands, a catalytic domain responsible for the phospholipase activity, and a C2 modular domain (Figure 7–17).^{274,324,325}

Many of the types of modular domains, for example, the immunoglobulin, the EGF, the kringle, the fibronectin, and the hemopexin,^{271,306,316} are usually found on individual exons and are thought to have been distributed among their mosaics by exon shuffling. **Exon shuffling** is a genetic rearrangement in which an intact exon is coupled at one of its ends to the other end of another intact exon from elsewhere in the genome by a mistake in recombination that occurs at sites within the intron following the one exon and the intron preceding the other. The result of the shuffle is that the hybrid intron, containing the front end of one old intron and the back end of the other, now joins the two exons. This new intron is spliced away during the maturation of the messenger RNA so that in the protein the two amino acid sequences encoded by the exons are spliced together. Other types of modular domains, however, do not seem to be distributed by exon shuffling but by other types of genetic rearrangements.^{326–328}

In examining proteins formed from domains, **two periods of construction** can be discerned.²¹⁶ Modular domains and internally repeating domains, the amino

acid sequences of which can be readily aligned, are the products of recent genetic rearrangements. Proteins containing recurring domains and internally duplicated domains the amino acid sequences of which cannot be aligned and the tertiary structures of which have drifted apart significantly are the products of ancient genetic rearrangements by processes that assembled the proteins common to all existing organisms. Many of the recent rearrangements have been produced by exon shuffling, but whether or not any of the early rearrangements also were produced by exon shuffling is unknown.^{329–332}

When the tertiary structure of ferredoxin-NADP⁺ reductase is examined (Figure 7–12), it seems possible to divide it reasonably into two domains. It is now known that both of these are recurring domains, but it has been argued that, even if this were not known, a judicious decision that these were distinct domains could still have been made by inspection of the crystallographic molecular model alone. In this sense, these are two structural domains. A **structural domain** has been defined as a “section of peptide chain that can be enclosed in a compact volume ... by a closed surface ..., and is characterized by possession of two terminal points.”³³³ These two terminal points are the point at which the polypeptide enters the compact volume enclosed by the surface and the point at which it exits. For example, phosphoglycerate kinase is constructed from two structural domains, each formed from one continuous length of polypeptide possessing two terminal points and clearly capable of being enclosed by continuous surfaces surrounding compact volumes.¹⁴² This definition does not possess a requirement for evidence of the independent existence of the domain. It could be argued that evidence will eventually be gathered for the independent existence of each of the structural domains now designated.

The difficulty with the definition of structural domains is that it is **subjective**. Even though the closed surfaces chosen are the ones that seem to be reasonable, in most cases, other choices, which usually produce a greater number of smaller domains, could be made that would satisfy the same definition. In fact, when this basic definition was used to derive a set of objective rules to divide any given crystallographic molecular model into domains, the tertiary structures of the 22 proteins examined could be divided unambiguously into as few as two or as many as 10 structural domains. The number of domains so defined increased monotonically with the lengths of the respective polypeptides, which varied from 58 to 450 aa.³³⁴ The mean length of the polypeptide in these structural domains was about 50 aa, which seems too small to be an evolutionarily significant unit. Most of these irreducible units could be combined with one or more of their neighbors to produce larger structural domains. The relevance of these small segments either to the evolution of one of these proteins or to its structure is not apparent.

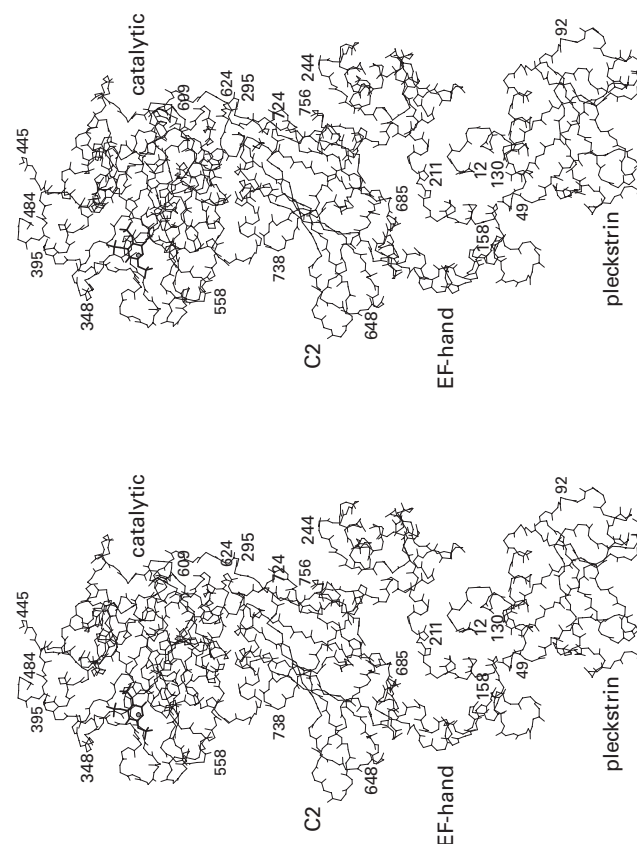

Figure 7–17: Crystallographic molecular model of phosphoinositide phospholipase C α 1 from *R. norvegicus*.^{274,324,325} The amino-terminal pleckstrin domain (Table 7–7) of the protein (Methionine 1 to Histidine 130) was expressed separately and crystallized. A skeletal representation of backbone of that crystallographic molecular model (Bragg spacing ≥ 0.19 nm) is at the bottom of the figure.³²⁵ The remainder of the protein (Glycine 133 to Aspartate 756) was also expressed separately and crystallized. A skeletal representation of that crystallographic molecular model (Bragg spacing ≥ 0.23 nm)³²⁴ is presented above that of the pleckstrin domain. There was no electron density for Glycine 133 through Aspartate 157 in the latter model. The representations of the two crystallographic molecular models are drawn at the same scale and arranged arbitrarily so that the carboxy-terminus of the pleckstrin domain is near the amino terminus of the rest of the molecule. The four EF hands (Table 7–7) comprise positions 133–175, 176–211, 212–245, and 246–282. None has a bound Ca²⁺ even though the cation was present during crystallization, so they do not assume the paradigmatic structure, but except for the first one, which is missing its first α helix, each has an α helix, a loop, and an α helix. The domain responsible for the phospholipase activity (catalytic) comprises Aspartate 299 through Alanine 606. It has a disordered segment (445–484) that produced no electron density, and the active site is occupied by a molecule of 1-D-*myo*-inositol-1,4,5-trisphosphate (thicker lines, upper left), a product of the enzymatic reaction, and a Ca²⁺ cation (gray circle). The C2 modular domain (Table 7–7) comprises Tryptophan 625 through Aspartate 756. This drawing was produced with MolScript.⁴⁰⁹

The intuitive impression persists, nevertheless, that the tertiary structures of most proteins, as revealed in their crystallographic molecular models, can be divided into two or more autonomous structural domains. It seems to be the case that anyone examining these structures would make the same decision, but there is no way to verify this surmise. Some examples of proteins that are thought to contain structural domains are DNA-directed DNA polymerase I,³³⁵ dihydrolipoyl dehydrogenase,³³⁶ and the hemagglutinin glycoprotein of influenza virus.³³⁷ An interesting example of a structural domain for which there is independent evidence of its existence occurs in catalase from *Penicillium vitale*. This protein has a structural domain formed from the carboxy-terminal 160 aa in its sequence (amino acids 510–670)³³⁸ that is missing entirely from bovine liver catalase,³³⁹ even though the two proteins are superposable throughout the other structural domain. Likewise, the carboxy-terminal structural domain found in the two structurally superposable proteins phosphoribosylamine–glycine ligase and biotin carboxylase is missing from the otherwise superposable proteins glutathione synthase and D-alanine–D-alanine ligase.⁹²

As the number of crystallographic molecular models has increased, more and more of the domains that were originally designated structural domains have been found to be recurring domains. It is possible that if the crystallographic molecular models of all of the proteins were known, all structural domains would turn out to be recurring domains, and this latter fact would provide the necessary evidence for their independent existence.

One indication that a structural domain does have independent existence is that its position relative to the rest of the protein shifts when crystallographic molecular models from different crystals of the same protein are compared. Lysozyme from bacteriophage T4 assumes five different structures in five different crystalline environments that differ from each other in the relative positions of its two structural domains.³⁴⁰ Such **independently shifting domains** that reorient within the same protein over milliseconds or seconds should be distinguished from domains that change their orientations over millennia as related proteins diverge from each other during evolution. As two proteins that are derived from a common ancestor diverge with time, structural domains often shift positions relative to each other even though the internal structures of the domains themselves remain superposable. Such **evolutionarily shifting domains** can be documented by superposing the crystallographic molecular models of related proteins. When the crystallographic molecular models of NADH peroxidase and glutathione reductase are compared, each of the four structural domains in these two related proteins superposes on its partner, but their relative positions in the two proteins are significantly shifted.³⁴¹ Significant shifts in the relative positions of the two inter-

nally repeating domains of aspartic endopeptidases have been documented by comparisons of crystallographic molecular models of six different members of the group,²³⁰ and the two structural domains in the related proteins ferredoxin–NADP⁺ reductase from *B. taurus* and thioredoxin–disulfide reductase from *E. coli*,³⁴² although separately superposable, differ in their relative positions by 66°.

One criterion that is often used as evidence for the independence of structural domains in a protein is that they unfold or fold independently. **Separately unfolding domains** are two or more regions of a protein that unfold independently of each other. Fibrinogen is a protein constructed from two copies of each of three polypeptides that are combined in such a way that the intact protein contains a central detachable domain, domain E, and two identical peripheral, detachable domains, domains D. The two domains D are attached to domain E by ropes constructed from three-stranded coiled coils of α helices,^{343–345} and the two domains D can be detached from domain E by cleaving disordered regions in the coiled coils with endopeptidases. When fibrinogen is submitted to differential scanning calorimetry,* two clearly separated transitions can be observed (Figure 7–18).³⁴⁶ These have been assigned to the melting of domains D and E, respectively.³⁴⁶

The melting, or unfolding, of the separately unfolding domains of fibrinogen is an irreversible process under the conditions chosen,³⁴⁶ but the unfolding and the refolding of a protein back to its native structure are often reversible processes, even in a calorimeter. Plasminogen is a protein composed of at least seven domains.³⁰⁰ These are five kringles that repeat consecutively within the entire sequence and two additional segments of polypeptide on each side of this pentuplication. Several of these domains or combinations of these domains can be detached and isolated separately. The reversible unfolding and refolding of five of these detached pieces could be followed by differential scanning calorimetry. These individual measurements could be combined to show that the rather complex, fully reversible calorimetric curve obtained with the intact protein was actually the sum of seven independent transitions.³⁴⁷ It is also possible to observe the independent

* A differential scanning calorimeter is used to measure the difference in the absorption of heat, as the temperature is raised, between a solution containing a protein and an identical solution lacking the protein. Two cells, sample and reference, contain precisely matched coils that introduce identical quantities of heat into each of them and establish a constant rate of temperature increase. The sample cell has an auxiliary coil that provides the additional heat necessary to keep its temperature exactly the same as that of the reference cell. The power supplied to the auxiliary heater is a measure of the excess heat absorbed by the sample, the endothermic heat flow. A protein unfolds, or melts, as the temperature rises, and this transition proceeds with the absorption of heat. This absorption of heat is a convenient way to follow the progress of the unfolding.

Figure 7-18: Thermal melting of domains D and E of bovine fibrinogen.³⁴⁶ (A) Native intact fibrinogen. A solution (26 μL) of native intact fibrinogen (88 mg mL^{-1}) was introduced into the sample chamber of the differential scanning calorimeter, and endothermic heat flow (microjoules second⁻¹) into the sample in excess of the flow into an identical solution lacking the protein was recorded as a function of temperature (degrees Celsius). (B) A solution (25 μL) of a 2:1 molar mixture of the chromatographically purified domains D and E that had been detached with an endopeptidase was used as the sample at a final concentration of 101 mg mL^{-1} . (C) A solution (22 μL) containing only detached and chromatographically purified domain E was used as the sample at a final concentration of 47 mg mL^{-1} . The scale of the two upper traces (microjoules second⁻¹) is 2.5 times that of the lower. Heating rate for all traces was 10 $^{\circ}\text{C min}^{-1}$. Adapted with permission from ref 346. Copyright 1974 National Academy of Sciences.

unfolding and refolding of separate domains in the same protein by perturbing the equilibrium between folded and unfolded forms of each domain through the addition of a denaturant such as urea³⁴⁸ or guanidinium chloride³⁴⁹ rather than with heat.

When there is no other independent evidence for the possibility that the structural domains in a particular protein at one time had an independent existence, attempts are often made to express one or more of these domains and demonstrate that they are able to fold inde-

pendently. An **independently folding domain** is a portion of a larger protein that is capable of folding by itself into a structure that is the same as the structure that portion assumes when it is within the larger protein. Experimentally, the portion of the protein thought to be an independently folding domain is detached either genetically or with an endopeptidase and shown to be able to fold properly on its own. If the fragment of the larger protein is an enzymatic domain, such as the bisphosphatase domain of 6-phosphofructo-2-kinase/fructose-2,6-bisphosphate 2-phosphatase,³⁵⁰ then its expression as an enzymatically active protein permits one to conclude that it has folded while being expressed to assume a structure that is the same as the structure it assumes in the intact protein.

The same conclusion can often be reached if the detached structural domain exhibits some **function** displayed by the intact protein. A genetically detached structural domain of aspartate transaminase folded independently to produce a globular structure capable of binding pyridoxal phosphate,³⁵¹ and a genetically detached internally repeating domain of human transferrin binds iron with high affinity.³⁵² When a structural domain located at the interface between the two identical subunits in glutathione reductase from *E. coli* was genetically detached, it folded and dimerized, presumably because the domain folded properly to create the face that participates in the dimerization of the native protein.¹⁶⁶ Unfortunately, the situation is often more ambiguous. For example, only when the two genetically detached structural domains accounting for the entire structure of CLC-0 chloride channel from *Torpedo californica* are coexpressed does the protein display function.³⁵³

In the absence of functional activity, a determination of its structure by nuclear magnetic resonance spectroscopy,^{354,355} or a crystallographic molecular model,³⁵⁶ how does one decide, even though it may display transitions characteristic of folding,^{348,357} whether or not the detached fragment is folding to assume the structure it had in the intact protein? A fragment of the polypeptide comprising thermolysin from *Bacillus thermoproteolyticus* can be produced by cleavage with cyanogen bromide and purified by molecular-exclusion chromatography in its unfolded state. This fragment contains the last 111 aa of the intact protein (sequence positions 206–316) and can be induced to refold. The solution that results contains a monomeric, compact, globular protein³⁵⁸ that has an α -helical content, determined spectroscopically, close to that predicted from the crystallographic molecular model of thermolysin.³⁵⁹ The protein in this solution melts, but at a temperature 20 $^{\circ}\text{C}$ below that at which native thermolysin, cut between amino acids 225 and 226, melts. The refolded protein unfolds in solutions of the denaturant guanidinium chloride, but at concentrations of guanidinium half those at which the nicked thermolysin unfolds. If the shorter polypeptide were folding

to assume the same structure it had in native thermolysin, that structure is now much less stable. But the results are also consistent with it assuming a completely different conformation and the protein displays no function that would indicate that it is properly folded.

A claim that an independently folding domain has been produced requires an unambiguous demonstration that the domain can refold into the **native conformation** it assumes in the parent protein. For example, both kringle 4 of plasminogen, detached by digestion with an endopeptidase,³⁶⁰ and kringle 2 of tissue plasminogen activator, detached genetically,³⁶¹ can be unfolded and refolded. The refolded detached domains bind lysine as they do when they are in their native conformation. The refolded kringle 2 also retains its affinity for plasminogen activator inhibitor 1. When kringle 4 is unfolded, its cystines reduced to cysteines, and then refolded, the fact that it has regained its native conformation is demonstrated by the ability of this refolded structure to enforce the formation of only the properly paired cystines upon its exposure to oxygen.³⁶⁰ In this case, the proper pairing of the cysteines, located at distant positions in the amino acid sequence, is the result of their proper juxtaposition in a properly folded polypeptide.

The **segments of polypeptide linking domains** together are of various types. Domains can be joined by flexible links such as those connecting the Fc and Fab domains of immunoglobulin G (Figure 7–13). The segments of polypeptide 35, 15, and 75 aa in length connecting the four enzymatic domains of the CAD multienzyme complex are rich in proline and glycine (30%) and the segments 27 and 24 aa in length connecting the three internally repeating lipoyl domains of dihydrolipoyllysine-residue acetyltransferase from *E. coli* are rich in proline and alanine (73%). All of these links should be **unstructured** and flexible. The amino acid segment –SKSSKEQKKQK– connecting the two functional domains of initiation factor IF3 from *E. coli* has been shown to be randomly disordered in the intact protein in solution,³⁶² and in the map of electron density for RNA recognition motifs from the Sex-lethal protein from *Drosophila melanogaster*, the segment connecting these modular domains is missing owing to its disorder.²⁸¹ It is such extended, disordered segments that are susceptible to endopeptidases when domains are detached by digestions. The long segment of 60 aa connecting the two modular SH2 domains in human protein-tyrosine kinase ZAP-70, however, forms a rigid, antiparallel, two-stranded coiled coil of α helices.²⁹⁵

Domains can also be joined by short **inflexible links**, such as the one in dihydrofolate reductase-thymidylate synthase (Figure 7–14), the interdomain α helix between two spectrin domains (Figure 7–16B), or the two connecting, internally repeating, modular EGF domains 3, 4, and 5 from murine laminin γ 1.²⁸⁶ In other instances, the segment connecting two domains may be structureless, but extensive **contacts between the**

domains cause them to be held tightly together (Figure 7–12). It is in proteins in which the domains were joined long ago that such contacts between domains are the most extensive. In the chaperone protein PapD from *E. coli*, however, it is the random meander of the link between the two domains that forms a hydrophobic core gluing together the two domains.⁹⁰

As a domain, by definition, is a structure that may be now or has been in the past an independent entity, the various categories (detachable, enzymatic, coenzymatic, functional, recurring, internally repeating, modular, structural, independently unfolding, and independently folding) are simply different ways of identifying members of a large group of **fundamental units of protein structure**. This group represents all of the smaller units from which the larger proteins that now exist were constructed, and the various domains that now exist in any one protein were at one time unique, unattached, stable, folded polypeptides that were the ancestors of those portions of the entire polypeptide now containing them. These primordial proteins were then internally multiplied or individually fused together during evolution by natural selection.

It is this role as a **fundamental unit of evolution** that lends luster to the title of domain and elicits the desire to grant it. But the term domain should remain an operational designation, closely tied to the particular evidence presented in each case. Problems can arise when it is applied indiscriminately. In particular, it often happens that when the term is used to describe a region of a protein for a very specific reason, all of the connotations associated with it have a way of attaching themselves to that region. For example, a structural domain subliminally gains the status of an independently folding domain, or an enzymatic domain is assumed to be also a detachable domain. Such confusion should be avoided.

Problem 7–8: There is a protein in vertebrate liver responsible for three enzymatic activities: phosphoribosylamine–glycine ligase, phosphoribosylglycinamide formyltransferase, and phosphoribosylformylglycinamide cyclo-ligase.³⁶³ It is composed of a single polypeptide 1010 aa in length. When the protein was digested with chymotrypsin, two products were produced that could be separated from each other. They were com-

posed of polypeptides 450 and 550 aa in length. The larger retained the phosphoribosylamine–glycine ligase activity; the smaller, the phosphoribosylglycinamide formyltransferase activity. The phosphoribosylformylglycinamidine cyclo-ligase activity was lost. In *E. coli*, the phosphoribosylformylglycinamidine cyclo-ligase reaction is catalyzed by a monofunctional protein composed of a polypeptide 330 aa in length. Discuss and explain these observations in terms of detachable domains and enzymatic domains.

Problem 7–10: Which of these three tertiary structures have structural domains? How many are there in each?^{365–367} These drawings were produced with MolScript.⁴⁰⁹

Molecular Taxonomy

The proteins observed today have evolved from a much smaller group of less elaborate, primordial proteins, just as the species of organisms observed today have evolved from a much smaller group of less elaborate primordial species. The **primordial proteins** are now represented by the domains of presently existing proteins. Establishing the evolutionary relationships among these species of domains, however, may be far more difficult than establishing the evolutionary relationships among the species of organisms. Unfortunately, there is no fossil record of proteins. It is also quite clear that the evolutionary divergence that produced most of the proteins that are universally distributed among present living organisms, for example, the metabolic enzymes, occurred before the divergence of the organisms themselves. This follows from the observation that the amino acid sequences of the proteins from all living organisms responsible for one particular biological function are usually able to be aligned or their crystallographic molecular models to be superposed, but proteins from

the same organism responsible for two different functions are usually difficult if not impossible to relate to each other. Thus the lineages of these universally distributed proteins have remained almost unbranched since the evolution of the earliest organisms, and the radiation producing these lineages must have occurred before that time. It is also clear, however, from examining amino acid sequences and crystallographic molecular models that more specialized proteins have been arising continuously throughout evolution and are still arising today. These **newer proteins** are usually members of classes peculiar to a particular kingdom or phylum of organisms, and one of the challenges is to identify their ancestral relationships to the more universally distributed proteins.

It is hoped that, as the number of tertiary structures elucidated by crystallography grows, an anatomical collection of the proteins large enough to form the basis for a comprehensive taxonomy can be assembled.²¹¹ When Linnaeus developed his taxonomic system of the organisms, it is possible that he was unaware of the reason for its existence. It was only when taxonomy was connected

to the theory of evolution through natural selection that an exercise in cataloguing became something more profound. At the present time, taxonomy in biology is one of the methods by which evolutionary relationships are established. The desire to establish the evolutionary history of the **speciation of proteins** has led, in an interesting inversion of history, to the formulation of a **taxonomic system of the proteins**.

The fundamental unit in a taxonomic system for proteins is the domain. The history of most of the proteins that now exist is that of the random association of domains, much as wildly different species are assembled into parasitic or symbiotic relationships or into ecosystems. Consequently, attempting to formulate a taxonomic system for proteins, just as assembling a taxonomic system for ecosystems, would be inappropriate. It is the domains that are the equivalent of species of organisms. An **individual domain** is a domain of a particular amino acid sequence in a particular isoform of a particular protein found in a particular species of organism, for example, the doubly wound, parallel β sheet in isoform A of L-lactate dehydrogenase from *S. acanthius* (Figure 7-11). A **species of domains** is a population containing all of the individual domains found in the same relative location in the same protein in all of its isoforms in all of the species of organisms in which it is found. A protein is regarded as the same protein as another protein if both of them perform the same function in their respective organisms and their two respective amino acid sequences can be significantly aligned over their entire length or their complete tertiary structures can be superposed. The doubly wound, parallel β sheets in all of the isoforms of L-lactate dehydrogenases from all of the species of organisms constitute a species of domains, as do all of the globins from all of the species of organisms in which they are found.

As in populations of organisms, individual domains of the same species can differ significantly. To add to the confusion, the names of the individual proteins composed from domains of the same species can often be different, for example, cathepsin K from mammals and papain from plants³⁶⁸ or ferredoxin-NADP⁺ reductase from mammals and thioredoxin-disulfide reductase from bacteria,³⁴² but an examination of their respective functions and an alignment of their respective amino acid sequences or a superposition of their respective crystallographic molecular models establishes they are individuals of the same species. Often the structures of individuals of the same species of domains, such as the single domains constituting the lysozymes from animals and bacteriophage⁸⁸ or the carbonate dehydratases II from animals and bacteria,³⁶⁹ have drifted apart significantly; but their functions identify them. It is the hundreds of thousands of different species of domains that are **hierarchically classified** in the taxonomic system. The sequence of the hierarchy for the taxonomic system of domains is species, family, superfamily, common fold, architecture. This can be compared

to the sequence of the hierarchy of the taxonomic system of the organisms, which is species, genus, family, order, class, phylum, kingdom.

The central concept upon which the present taxonomic systems³⁷⁰⁻³⁷³ for classifying domains are based is the common fold. Although the exact definitions differ among the systems, two or more species of domains share a **common fold** if they have the "same major secondary structures in the same arrangement with the same topological connections." Different species of domains with the same common fold can have "peripheral elements of secondary structure and turn regions that differ in size and conformation."³⁷¹ It is within the cores of their structures that the common fold exists, and loops connecting the elements of the common core can differ significantly in their length and structure. For example, the motor domains of kinesin and myosin share a common fold of an eight-stranded β sheet sandwiched between two sets of three α helices, but the loops connecting these elements of secondary structure differ dramatically in length. The short loop of five amino acids between β strand 6 and β strand 7 and the short loop of 11 amino acids between α helix 4 and α helix 5 in kinesin are 221 and 142 aa long, respectively, in myosin.³⁷⁴ Although such insertions have little influence on the selection of the common fold of a domain, they can have a significant effect on the function of the protein, for example, turning a sulfotransferase into a dehydratase.³⁷⁵

It has been estimated that there are fewer than 1000 common folds in existence,³⁷⁰ the estimate varies depending on the stringency with which a particular taxonomic system divides the species of domains into common folds. The number of common folds and the position of the concept of the common fold in the various hierarchies are both quite close to the number and position of the class in the taxonomic hierarchy of living organisms. *Homo sapiens* belongs to the class Mammalia. The level of the common fold³⁷¹ is also referred to as the topology level,³⁷² the level of the structure type,²¹¹ or the level of structurally unique domains³⁷³ in the different taxonomic systems.

Particular species of domains can be selected as representatives of their common fold (Figure 7-19).²¹¹ L-Lactate dehydrogenase domain 1 (Figure 7-19F) represents the common fold of doubly wound, parallel β sheets containing six β strands in the order 321456 (Figure 7-20).²¹¹ Five representatives from the large set of domains of this common fold³⁷⁶ are listed within the box in Figure 7-20. Domains of the same common fold are often found in proteins with significantly different functions. The catalytic domain of aspartate-tRNA ligase and the domain constituting an entire molecule of asparagine synthase are of the same common fold,³⁷⁷ as well as the domains constituting the entire molecules of tumor necrosis factor and the coat protein of satellite tobacco necrosis virus.³⁷⁸

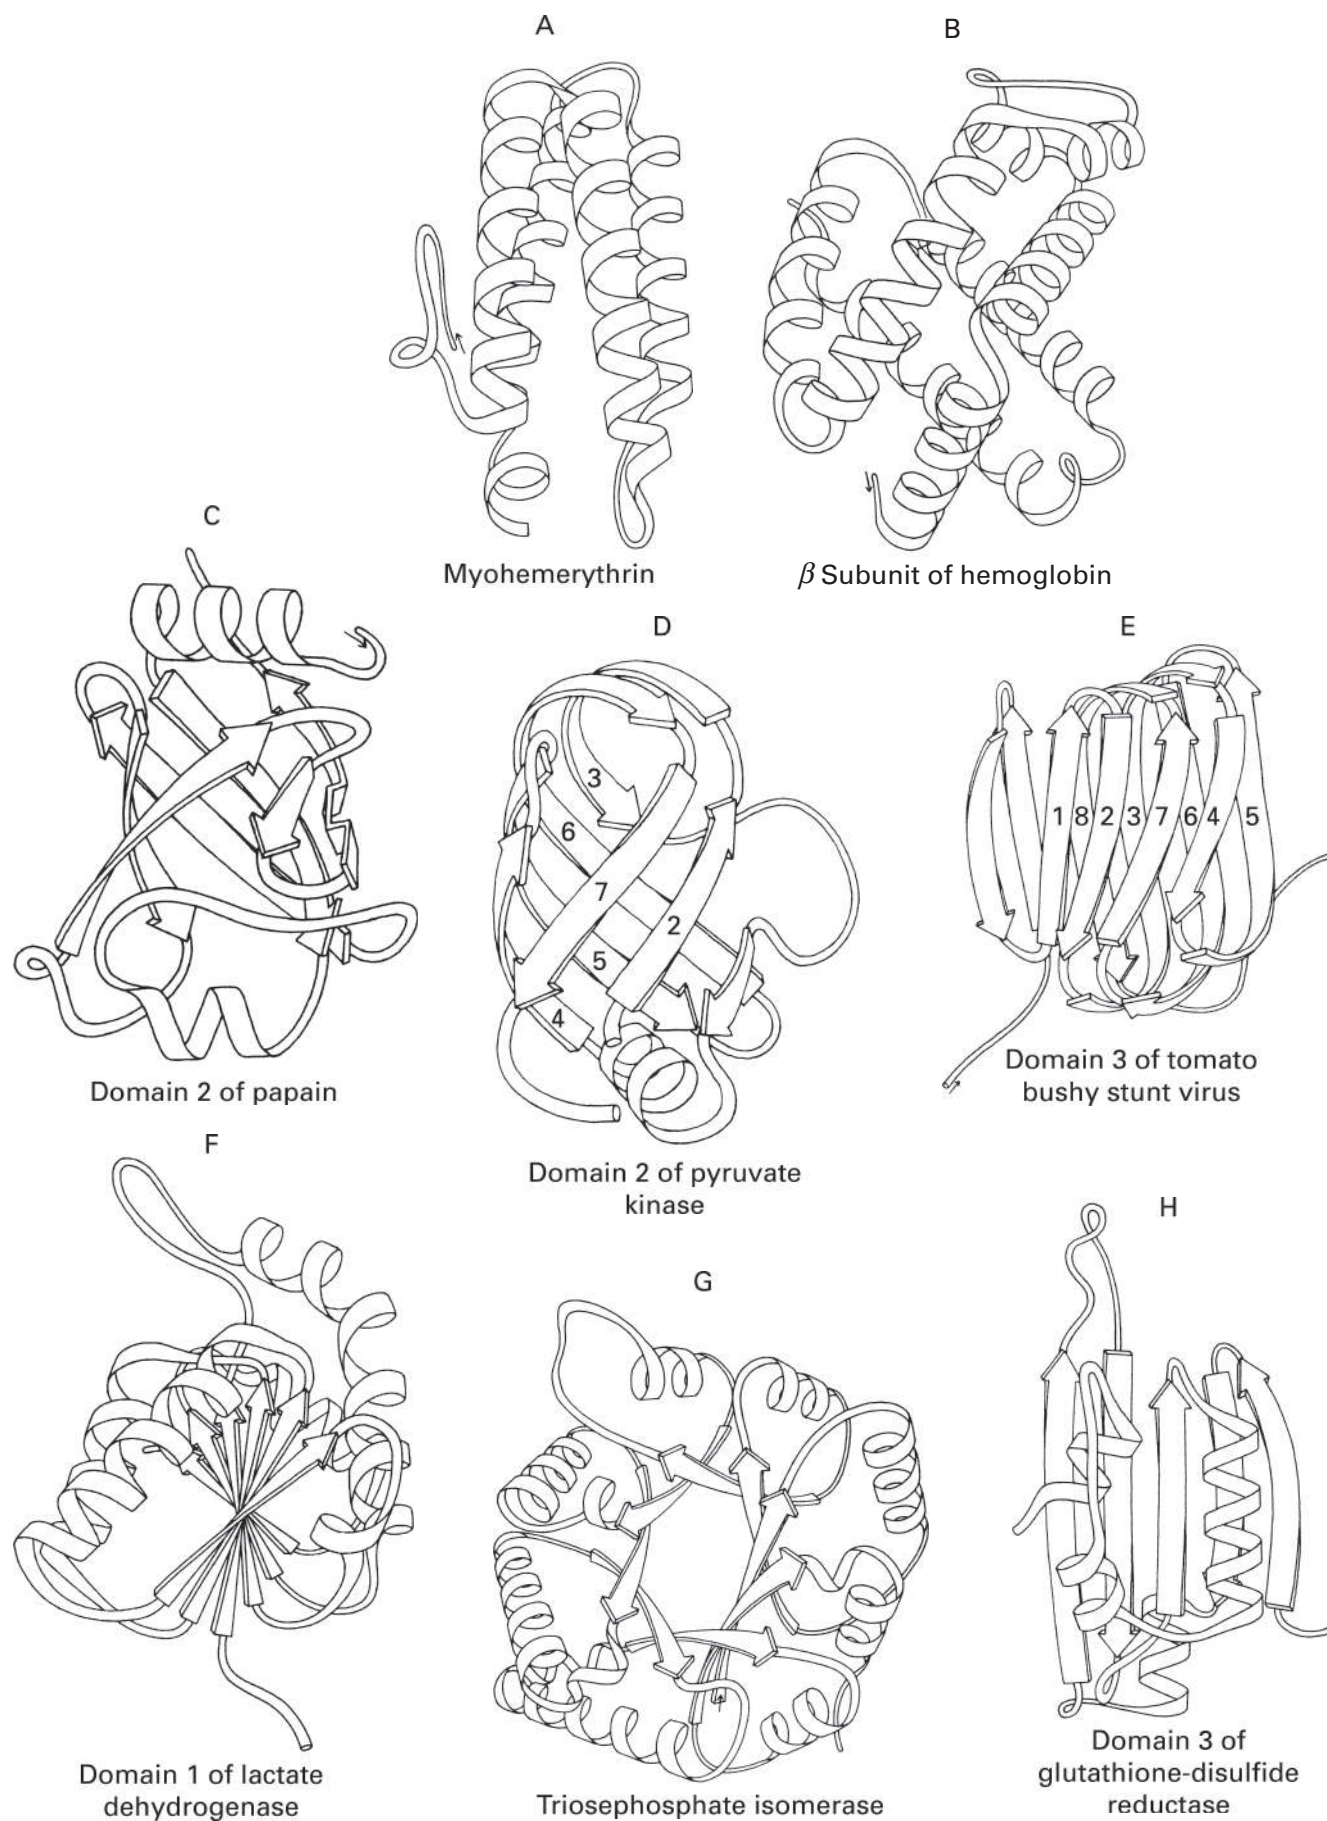

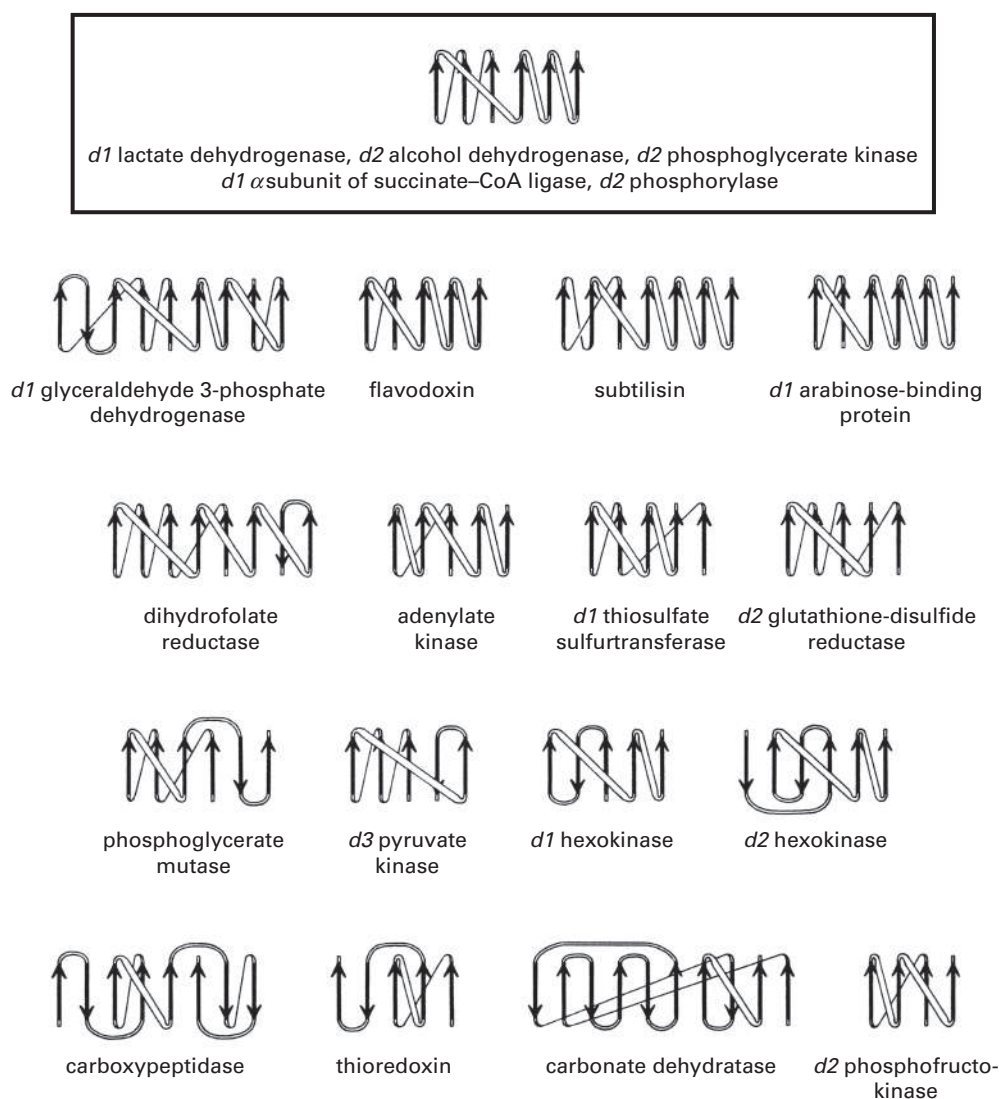

Figure 7-19: A menagerie of representative tertiary structures from eight common folds of domains.²¹¹ Each of these cartoons has been drawn from the respective crystallographic molecular model. The flat arrows represent strands of β structure; and the helical ribbons, α helices. (A) Myohemerythrin is an example of an up-down-up-down, antiparallel α -helical bundle. (B) The β subunit of hemoglobin is an example of a Greek key, antiparallel α -helical bundle. This can be seen if, from the amino terminus (indicated by the arrow), the first long, bent α helix, the second short α helix, and the next four long α helices are numbered 1 through 6, respectively, and it is assumed that α helix 1 has drifted 90° away from being parallel to α helix 6. (C) Domain 2 of papain is an example of an up-down-up-down β barrel if the last two short and bent β strands are ignored. (D) Domain 2 of pyruvate kinase is an example of a Greek key, antiparallel β barrel if the short strand of β structure, β strand 3, between β strands 2 and 4 is ignored. The six strands of the Greek key are numbered as in Figure 7-21. (E) Domain 3 from tomato bushy stunt virus is an example of a jelly roll, antiparallel β barrel if the first two, amino-terminal β strands are ignored. The eight strands of the jelly roll are numbered as in Figure 7-21. (F) Domain 1 of L-lactate dehydrogenase is an example of a doubly wound, parallel β sheet. (G) Triose-phosphate isomerase is an example of an α -helically wound, parallel β barrel. (H) Domain 3 of glutathione-disulfide reductase is an example of an open-faced β sandwich. Adapted with permission from ref 211. Copyright 1981 Academic Press.

Figure 7-20: Topological representations of several members of the architecture of doubly α -helically wound, parallel β sheets.²¹¹ The β sheets seen in each crystallographic molecular model were flattened upon a plane. The order in which the strands of the β sheet occurred in the amino acid sequence of the polypeptide was noted as well as whether the connecting loops, usually α helices, were above or below the plane. The dark arrows represent each β strand in the order in which they appear across the sheet. The open lines represent connections above the plane, and the thin lines represent connections below the plane. Within the box, the pattern of secondary structures displayed by domain 1 of L-lactate dehydrogenase (Figure 7-11), domain 2 of alcohol dehydrogenase, domain 2 of phosphoglycerate kinase, domain 1 of the α subunit of succinate-CoA ligase (ADP-forming), and domain 2 of phosphorylase (Figure 7-11A) represents the common fold to which these five domains belong. Reprinted with permission from ref 211. Copyright 1981 Academic Press.

The next higher level in the taxonomic hierarchy of domains is that of architecture.³⁷² A set of different common folds with the same **architecture** have the same clearly related spatial arrangement of secondary structures even though they differ in the number of individual elements of secondary structure or differ by one or more adjacent interchanges in the order in which those elements of secondary structure are juxtaposed or in both their number and their order. A collection of particular species of domains, each with a different common fold, can represent the architecture of doubly wound, parallel β sheets (Figure 7–20). This particular architecture,³⁷² however, has become so diverse^{379,380} that its systematic reorganization into several different architectures is probably required. A systematic census of the members of the architecture of open-faced β sheets (Figure 7–19H) has been taken.³⁸¹

Whether or not there is a higher level in the hierarchy than architecture is unresolved. For convenience, groupings have been used in which domains are sorted on the basis of whether they are formed entirely from α helices, formed from α helices alternating with β strands, formed from segregated α helices and β sheets, or formed entirely of β structure.³⁷² These groups may have no evolutionary significance. For example, α -helically wound, parallel β barrels (Figure 7–19G) would be in the alternating $\alpha\beta$ group, but glucan 1,4- α -glucosidase from *Aspergillus awamori* is an α -helically wound, parallel α barrel³⁸² that could be more closely related to α -helically wound, parallel β barrels than to any entirely α -helical domain. If so, this would demonstrate that β strands can become α helices, a possibility for which there is evidence on the much smaller scale of single elements of secondary structure.^{91,383} If such a transformation turns out to be common, higher groups based on topological arrangements rather than type of secondary structure might turn out to be more appropriate.

The level in the taxonomic hierarchy of domains above that of species is that of family. The central criterion on which the level of family is usually based in the classification of domains is that of the function and the structure of the protein containing the domain. A **family of domains** is a set containing all of the domains of the same common fold that are found at the same position in the complete set of those proteins that have coincident structures and that perform related functions. Two proteins have **coincident structures** when they are both composed of the same number of domains, and the domains found at the same respective positions in the two proteins have the same common fold. The crystallographic molecular models of proteins with coincident structures are superposable, domain by domain, over their entire length. Each of the consecutive folds can be, but is not necessarily, different. For example, the first and second domains in benzoylformate decarboxylase and the first and second domains in pyruvate decarboxylase all share the same common fold, but the third domains

from these two proteins with coincident structures share a different common fold.^{262,263}

Examples of domains in the same family illustrate the classification. The domains constituting the entire molecules of the hydrolases carboxymethylenebutenolidase, alkylhalidase, and carboxypeptidase D³⁸⁴ all belong to the same family. The single domains constituting the entire molecules of the mammalian endopeptidases factor D and trypsin are in the same family,³⁸⁵ as are those constituting the entire molecules of adenosine kinase and ribokinase.⁸⁹ Phosphoglycerate dehydrogenase, L-2-hydroxyisocaproate dehydrogenase, D-lactate dehydrogenase, erythronate-4-phosphate dehydrogenase, and glycerate dehydrogenase all have coincident structures and catalyze similar reactions.³⁸⁶ All of their domains 1 have one common fold and belong to one family, and all of their domains 2, which have a different common fold from that of the domains 1, belong to another family. The corresponding domains from cyclin-dependent protein kinase 2, MAP protein kinase ERK2, and cyclic-AMP dependent protein kinase are in the same respective families,^{387,388} as are the corresponding domains from aspartate-semialdehyde dehydrogenase and glyceraldehyde-3-phosphate dehydrogenase.¹²⁰

The **elaborations of the common fold** of the domains within the same family can be dramatic. For example, domains 1 of tyrosine phenol-lyase, cystathionine β -lyase, ornithine decarboxylase, aspartate transaminase, phosphoserine transaminase, and adenosylmethionine-8-amino-7-oxononate transaminase are members of the same family because they share the same common fold in which five β strands form the core, their pyridoxal phosphates are located in the same positions relative to the core, and the reactions they catalyze are of the same type. The elements of the common fold beyond the core, however, have drifted so far apart that they cannot be superposed, and there are a number of additional peripheral elements of secondary structure found in some species in the family but not in other species.³⁸⁹ This example illustrates the ambiguity of the upper limit for the level of family in the hierarchy.

Between the level of a family of domains, which is anchored in the coincident structures of the proteins containing the domains and their related functions, and the level of the common fold, which is anchored in the topological identity of their structures, is a region in the taxonomic hierarchy in which there are, at the moment, no consistent rules. This region is vaguely referred to as the level of the **superfamily**. Domains are grouped in a superfamily if the proteins that contain them have coincident structures but significantly different functions. For example, thiamine pyridinylase and maltose-binding protein have coincident structures but significantly different functions.⁹¹ Although all of the members of the enolase superfamily do share the function of abstracting a proton from a carbon α to a carboxylate, the superfamily has been divided into three families.^{118,390} Domains

are also grouped in a superfamily if the proteins that contain them have only partially coincident structures. The domains 2 and 3, respectively, from biotin carboxylase, phosphoribosylamine–glycine ligase, synapsin Ia, D-alanine–D-alanine ligase, and glutathione synthase have the same common folds, and all of the domains 1 have the same architecture,^{92,391} but the five proteins do not have coincident structures. Whether their domains 2 and 3 are of the same respective superfamilies or only of the same respective common folds is a question that illustrates the ambiguity of the upper limit of the level of superfamily in the hierarchy.

There are hundreds of common folds of domains, so a comprehensive discussion of even the architectures into which these common folds are arranged is not possible. There are some common folds and architectures, however, that have regular structural patterns that stand out. Both the **β helix** (Figure 6–12) and the **β propeller** (Figure 6–13) define architectures of domains. One architecture contains right-handed β helices; another, left-handed β helices.³⁹² Within the architecture of β propellers, the number of blades determines the common fold to which a particular member belongs.^{393,394}

A **parallel β barrel** (Figure 6–11) is usually wound completely by α helices (Problem 7–10B), as is the parallel β barrel constituting the entire folded polypeptide of triose-phosphate isomerase (Figure 7–19G). An α helix connects each stave of the barrel to the next. The number of staves in such a regularly α -helically wound, parallel β barrel determines the common fold to which it belongs. The common fold with the largest population is that in which the barrel has eight β strands. There are a large number of enzymes each of whose entire structure³⁹⁵ or the majority of each of whose structure³⁹⁰ is an α -helically wound, parallel β barrel of eight strands. There are often additional elements of secondary structure found in the loops connecting an α helix of the winding to a β strand in an α -helically wound, parallel β barrel,^{396,397} but these are found at the periphery of the structure and do not disrupt the common fold. α -Helically wound, parallel β barrels can stand alone or have other domains attached to them as in pyruvate kinase, phosphopyruvate hydratase,³⁹⁸ and the R1 protein of ribonucleoside-diphosphate reductase.³⁹⁷

In a number of the common folds of domains (Figure 7–19A–E), the structures observed seem to arise from a reasonable **topological operation** (Figure 7–21)²¹¹ that could explain their creation. Consider a polar curve that doubles back upon itself to form a hairpin. Twist the hairpin thus formed so that it folds into two turns of a right-handed superhelix (Figure 7–21A). Compress this superhelix until its neighboring segments both in front and behind come in contact and then incorporate the segments into the surface of a flattened cylinder (Figure 7–21B). This produces a flattened barrel with eight staves the polarities of which alternate as one proceeds around

the structure. This flattened cylinder can be rolled as the tread on a caterpillar tractor to produce eight different barrels that resemble each other but that vary in the juxtapositions of the staves across the center. The connections between the segments, which define the topological relations of the curve, remain unaltered during such rolling.

If the flattened cylinder in any of its guises is cut between the first and second segments in the hairpin (segments 1 and 2 in Figure 7–21) and spread upon a plane, a **jelly roll**²¹¹ (Figure 7–21C) is produced. Shorten the hairpin by removing the two most peripheral segments (cuts ① in Figure 7–21 to remove segments 1 and 8). A new flattened barrel is created (dotted lines in Figure 7–21B) with six staves that alternate in polarity. If this smaller flattened cylinder is cut between the first and last segments in the hairpin (segments 2 and 7 in Figure 7–21) and spread upon a plane, a **Greek key**²¹¹ (Figure 7–21D) is produced. Shorten the hairpin by removing the two most peripheral segments (cuts ② in Figure 7–21 to remove segments 2 and 7). A new flattened barrel is created with four staves that alternate in polarity. If this cylinder is cut between the first and last segments in the hairpin (segments 3 and 6 in Figure 7–21) and flattened upon a plane, an **up-down-up-down**²¹¹ pattern is produced.

The polar curve in the topological exercise can be substituted with a polypeptide either as a strand of β structure or in an α helix, and the staves of the flattened barrel will be either strands of β structure or α helices, respectively. If they are strands of β structure, they are gathered as systematically antiparallel (Figure 7–21B) pleated sheets (Figure 4–16C) into an **antiparallel β barrel** (Figures 7–12 and 7–13). The β jelly roll is represented by the cohesin domain (Figure 6–21)²⁸⁸ and domain 3 of the coat protein of tomato bushy stunt virus (Figure 7–19E). There are a large number of viral coat proteins each containing a domain of this class.³⁹⁹ There are elaborations on this topological arrangement; for example, each of the spermadhesins from seminal fluid is composed of a single domain that represents a class of domains in which two consecutive antiparallel β strands are added to a jelly roll (Figure 7–21C) at the amino-terminal end of the polypeptide (strands 0 and –1). These additional β strands are inserted into the barrel (Figure 7–21B) between staves 1 and 2.^{400,401}

The β Greek key is represented by domain 2 of pyruvate kinase (Figure 7–19D). There are also elaborations on this theme. The members of the class of immunoglobulin modular domains (Figure 7–13 and Table 7–7) are β Greek keys (Figure 7–21D) in which an antiparallel β strand is added at the carboxy-terminal end of the polypeptide (strand 8), but unlike the strand 8 in a jelly roll, which would be located between strands 2 and 3 of the barrel if strand 1 were deleted (Figure 7–21B), the strand 8 in the immunoglobulin class is found between strands 2 and 7 of the barrel.^{90,402–405} The class of

Figure 7-21: Topological explanation of how the patterns of the folded polypeptides defining six of the common folds of domains could have arisen by a common mechanism.²¹¹ (A) A long hairpin of β structure or α helix is twisted into a superhelical coil. (B) That superhelical coil is flattened into a barrel. (C) The order in which the strands occur around the flattened barrel (1, 8, 3, 6, 5, 4, 7, 2) is that of a jelly roll. (D) If strands 1 and 8 are cut away (cuts ①), or were never there to begin with, the order in which the strands occur around the smaller flattened barrel (2, 3, 6, 5, 4, 7) is that of a Greek key. (E) If strands 1 and 2 and strands 7 and 8 are cut away (cuts ②), or were never there to begin with, the order in which the strands occur around the smaller flattened barrel (6, 5, 4, 3) is up-down-up-down.

β up-down-up-down domains is represented by domain 2 of papain (Figure 7-19C).

Not all of the classes of domains in which the polypeptide forms an antiparallel β barrel have topological arrangements derived from a superhelical hairpin. For example, in the β barrel of licheninase, the structure is so far removed from a compressed superhelical hairpin that over all of the possible combinations of its 14 strands, there are only two turns of superhelical hairpin, one turn involving strands 9 through 12 and one turn involving strands 1 through 4.⁴⁰⁶

The antiparallel α Greek key is represented by the β subunit of hemoglobin in Figure 7-19B, but a much more regular representative of this class in which all six α -helical staves of the barrel are aligned more regularly is found in the caspase recruitment domain of the caspase activator Apaf1.⁴⁰⁷ The class of α up-down-up-down domains is cleanly represented by myohemerythrin (Figure 7-19A).

When these various representatives (Figure 7-19 A-E) are examined closely, it is obvious that if the topological scheme displayed in Figure 7-21 was the initial mechanism of folding, individual staves of the barrels have drifted significantly from their original positions (as do the helices in Figure 7-10), and more recent secondary structures have arisen at the ends of the barrels and in the loops connecting the staves.

There are two stereochemical properties producing alternative topological arrangements of the helical hairpin (Figure 7-21A) that generates the barrel (Figure 7-21B). Because the polypeptide is polar, amino terminus to carboxy terminus, there are two distinct **polarities to the hairpin**, the one shown by the arrowheads in Figure 7-21A and the one in which the polypeptide runs in the opposite direction. For example, in the α Greek keys of both the β subunit of hemoglobin and the caspase recruitment domain of the caspase activator Apaf-1, the polypeptide runs through the barrels with a

polarity opposite to that shown in Figure 7–21B. Because the barrel is generated by a helical conformation of the hairpin, there are two possible **twists to the helix**, the right-handed one shown in Figure 7–21A and the left-handed one. For example, the six-stranded β barrel forming the common fold in the family of domains containing growth hormones, interleukins, and granulocyte-colony-stimulating factor is a β Greek key in which the superhelix is left-handed.⁴⁰⁸ Because two polarities are possible and two twists are possible, there are four distinct geometries for the jelly roll, four for the Greek key, and two for the up-down-up-down conformation.

It is possible that the regular structures such as the β helix, the β propeller, the jelly roll, and the Greek key represent **evolutionarily efficient topological solutions** to the problem of folding a polypeptide. Within an architecture of domains or even among the members of the same common fold, a good deal of variation is observed; either individual elements of secondary structure in the common topological pattern do not superpose very well or extensive peripheral elements of secondary structure are found in one member of a class that are not found in others. If these variations represent the drift in the locations of the elements of secondary structure from those they had in the common ancestor or the insertion of elements following the divergence from a common ancestor, they reflect the degree to which these domains are evolutionarily related to each other, and the taxonomic system for domains parallels the taxonomic system for species. If many of the variations observed, however, state that the domains being compared differ so dramatically because they do not share a common ancestor, they reflect the fact that the structure is a particularly favorable solution to folding a polypeptide that has been exploited many times by convergent evolution and the taxonomic systems for domains overstate their phylogenetic information.

Chapter 8

Counting Polypeptides

Almost all of the proteins found in a living organism are multimeric proteins. A **multimeric protein** is a protein containing more than one folded polypeptide. Each of these folded polypeptides was originally synthesized by a ribosome from messenger RNA that encoded a sequence of amino acids of a precise, finite length. These polypeptides folded into defined conformations and were posttranslationally modified. Each of the folded, posttranslationally modified polypeptides in a multimeric protein is one of its **subunits**. Usually, only a specific and well-defined number of these subunits are gathered together to form the macromolecular complex that is the finished, existing molecule of the multimeric protein. An **oligomeric protein** is a multimeric protein with a fixed, invariant number of subunits. In a few instances, such as the proteins actin, keratin, and collagen, a large and undefined number of subunits combine to form a polymeric protein, which in theory could continue to polymerize indefinitely. A **polymeric protein** is a protein with many subunits, the number of which varies from molecule to molecule of that protein. Polymeric proteins are the exception; most proteins are oligomeric.

The **stoichiometry of the subunits** of a protein is the number of each type of folded, posttranslationally modified polypeptide that are combined to produce the specific structure. At this level of definition, each of the polypeptides is identified only by its length. The **length of a polypeptide** is the number of amino acids it contains, n_{aa} , an integer that is either dimensionless or has the units of amino acids (molecule of polypeptide)⁻¹ or moles of amino acids (mole of polypeptide)⁻¹. The length of a polypeptide is usually a precisely known quantity because its amino acid sequence is usually available and any posttranslational modifications have usually been defined.

A great deal of effort has been expended in discovering the stoichiometries of the subunits of proteins. The original approach to this information was to determine the molar mass of the intact protein, to separate the individual polypeptides composing the protein, to quantify the mass ratio among the various polypeptides, and to determine the molar mass of each of the separated polypeptides. The measurement of the molar masses of intact proteins was at one time a major area of biophysical research, but this pursuit presently attracts much less attention.

The individual subunits composing an intact native

protein are separated and catalogued analytically by electrophoresis on polyacrylamide gels cast in solutions of the detergent sodium dodecyl sulfate. The separation that is effected by these polyacrylamide gels relies on their ability to sieve the unfolded polypeptides. The constituent polypeptides of a protein are separated preparatively by chromatography that depends either on sieving or on ion exchange of the unfolded, dissociated polymers. The separated polypeptides are shown to be homogeneous and unique by peptide mapping.

The major weaknesses of the original approach to defining the stoichiometry of the subunits of a protein were the extreme care with which the initial measurements of the molar mass of the intact protein had to be performed and the unreliability of the assessments of the mass ratios among the constituent polypeptides and of their molar masses. The present approach to defining the stoichiometry of the subunits of a protein avoids these problems. The individual polypeptides composing a protein are still separated and catalogued by electrophoresis and shown to be unique and homogeneous by peptide mapping. The length of each of the constituent polypeptides is assessed either by the electrophoresis itself or, preferably, by sequencing the appropriate cDNA. Any glycosylation is quantified analytically. The number of each polypeptide composing the intact protein is determined by covalently cross-linking the protein to various degrees of completion and identifying the various intermediate covalent complexes and the limit complex.

The different subunits in an oligomeric protein are defined by their lengths and distinguished by assigning them consecutive letters of the Greek alphabet. For example, deoxyhemoglobin at its normal concentrations is constructed from two subunits, α and β , each present in two copies to produce the complex $(\alpha\beta)_2$. Nicotinic acetylcholine receptor has the composition $\alpha_2\beta\gamma\delta$; L-lactate dehydrogenase, $(\alpha_2)_2$; DNA-directed RNA polymerase from *Escherichia coli*, $\alpha_2\beta\gamma\delta$; and 2-dehydro-3-deoxy-phosphogluconate aldolase, α_3 . The grouping of subunits into subsets, for example, the groups of two subunits in L-lactate dehydrogenase, arises from the symmetries in which the subunits are arranged within the intact molecule of an oligomeric protein.

Some oligomeric proteins, when they are dissolved at certain concentrations, are mixtures of two different combinations of subunits in equilibrium with each other. For example, oxygenated hemoglobin is an equi-

librium mixture of $\alpha\beta$ dimers and $(\alpha\beta)_2$ tetramers. Most oligomeric proteins, however, have a particular composition of subunits that does not vary unless harsh conditions are applied. A solution of a pure oligomeric protein will usually be monodisperse. A monodisperse solution of a particular macromolecule is a solution in which every one of those macromolecules is of the same size and shape, and each is compact and unique and remains dissolved and unassociated with its neighbors.

When the map of electron density from a crystal of an oligomeric protein is examined, the complete molecule can be discerned. It is recognized as a large, independent feature in the map that is formed from several folded tubes of electron density. Although not always essential, it is reassuring to know before the map is examined how many subunits are combined to produce the protein that has been crystallized. This determination can be made by a combination of sequencing, molecular sieving, and cross-linking. It is now so routine to do this that few oligomeric proteins the subunit stoichiometry of which have not already been established are examined crystallographically.

Molar Mass^{1,2}

The only indubitably reliable method for determining the length and amino acid composition of a polypeptide, and consequently, its precise molar mass, is to **sequence** it correctly. At the moment, the sequences of a large array of readily available polypeptides are known, and they form a collection of standards each of the lengths of which, n_{aa} , is an exact quantity. It is often, but not always, the case that the amino acid sequence of a newly purified polypeptide is known from the nucleotide sequence of its cDNA before enough of it becomes available to study its physical properties in detail. This situation has inverted the classical strategy of physical measurements in which the molar mass of a protein was one of the ultimate discoveries rather than something precisely known from the beginning. Unfortunately, however, the extensive effort expended in determinations of molar mass, although expended decades ago, still influences the importance attached to molar mass.

The **molar mass** of a protein, M_{prot} , is the number of grams in a mole of that protein. The **molecular mass** of a protein is the mass of a single molecule of that protein expressed in relative units that are referred to as either atomic mass units (amu) or daltons (Da). Both an atomic mass unit and a dalton (1.6606×10^{-24} g) are $1/12$ the mass of carbon isotope 12. Because Avogadro's number is the number of carbon atoms of isotope 12 in 12 g of carbon atoms of isotope 12, the numerical values of molar mass and molecular mass for the same molecule are the same, but not the units attached to the numbers. Molar mass is the quantity that is determined by the measurements of physical behavior such as osmotic pressure, sedimenta-

tion equilibrium, and light scattering because the units on the final quantity are usually grams mole⁻¹.

Because both sedimentation equilibrium and light scattering are alternative measurements of osmotic pressure, all three techniques determine the same fundamental physical property of a protein in a solution, namely, its chemical potential. Osmotic pressure is a colligative property of the solution. A **colligative property** of a solute is a physical property that is a function only of the moles of independent particles of that solute in a standard volume of the solution. If the solution were monodisperse, if the only osmotically active particles present were individual molecules of the protein, and if the concentration of the protein in grams centimeter⁻³ were known precisely, the measured molar concentration could be used to calculate the molar mass of the protein.

Osmotic pressure is the pressure exerted by impermeant solutes when a solution containing those impermeant solutes is separated by a semipermeable membrane from another solution identical in every way to the first except that it lacks the impermeant solutes. A solute is **impermeant** to a particular barrier if it cannot pass through that barrier. A **semipermeable membrane** is a membrane through which all of the components of the two solutions can pass freely except the impermeant solutes. The chemical and physical properties of the membrane define which solutes are permeant and which are impermeant, which are osmotically silent and which are osmotically active, respectively. In the case of experimental measurements of the osmotic pressure of solutions of proteins, a membrane is chosen that is porous to the small molecules in the solution but the pores of which are too small to pass the molecules of protein. This is usually a sheet formed from a polymeric material that has spaces between the strands of polymer wide enough to pass small molecules and ions but too narrow to pass macromolecules.

Pressure is the force that results from the tendency of molecules to expand the confines in which they are contained and fill a larger volume. The pressure they exert is a direct measurement of the **chemical potential** of a population of molecules. When molecules such as impermeant solutes exert an osmotic pressure, they cannot expand their confines, as can gases, by entering the vacant space above the solution because they are held by intermolecular forces within a condensed phase. The volume of solution in which they are confined, however, can expand if solution from the other side passes across the semipermeable membrane into the solution containing the impermeant solutes. This is the liquid analogy to a balloon expanding to fill more space. Just as the balloon expands until the external pressure is equivalent to the internal pressure of the trapped gas, the solution containing the impermeant molecules expands until an external pressure equal to its osmotic pressure is applied to it. Operationally, the osmotic pressure of a

solution is the external pressure that must be applied to the solution containing the impermeant solute to prevent any expansion in its volume by the net movement of fluid through the semipermeable membrane. In an apparatus for measuring osmotic pressure, the difference in pressure between the chamber containing the protein and the chamber lacking the protein can be maintained and continuously monitored with a pressure transducer.³

It can be shown⁴ that the osmotic pressure exerted by a solution of impermeant solutes is formally equivalent to the pressure exerted on the walls of a container filled with gases that are impermeant to those walls. The molecules of the impermeant solute are formally equivalent to the molecules of the gas, and those of the solvent and permeant solutes are as physically silent as the vacuum in which the gas is suspended. The **ideal gas law** is

$$P = \frac{n_m RT}{V} \quad (8-1)$$

where P is the pressure (newtons centimeter⁻²) exerted by the gas, R is the gas constant (831.5 N cm K⁻¹ mol⁻¹), T is the temperature (kelvins), n_m is the number of moles of the gas, and V is the volume (centimeters³) in which it is confined. The pressure exerted by a real, nonideal gas, however, is

$$P = RT \left[\frac{n_m}{V} + B \left(\frac{n_m}{V} \right)^2 + C \left(\frac{n_m}{V} \right)^3 \dots \right] \quad (8-2)$$

where $n_m V^{-1}$ is the concentration (moles centimeter⁻³) of the gas and the coefficients B , C , and so forth are referred to, respectively, as the second virial coefficient, the third virial coefficient, and so forth. The **virial coefficients** provide the necessary corrections for the behavior of the nonideal gas due to the specific properties that make it nonideal, such as the finite dimensions of the molecules that fill, or exclude, some of the volume of the container, the intermolecular forces between the molecules of the gas, and the tendency of molecules of the gas to dimerize or polymerize. For all of the same reasons,⁴ the osmotic pressure Π (newtons centimeter⁻²), exerted by a nonideal, impermeant solute S is

$$\Pi = RT([S] + B[S]^2 + C[S]^3 \dots) \quad (8-3)$$

where $[S]$ is the molar concentration of the solute. If the impermeant solute S is protein i

$$\lim_{[\text{protein } i] \rightarrow 0} \Pi = RT[\text{protein } i] \quad (8-4)$$

Equation 8-4 states that, at low enough concentrations of protein, the osmotic pressure observed will be directly proportional to the molar concentration of the protein.

The molar concentration of the protein in the solution cannot be known if the molar mass of the protein is unknown, but the **concentration of the protein** in the solution must be known in some type of units. From the ultraviolet spectrum of the solution, the concentration (moles centimeter⁻³) of the tryptophan and tyrosine in the protein might be known.⁵ From a colorimetric assay, the concentration (moles centimeter⁻³) of peptide bonds in the solution might be known.⁶ From total amino acid analysis,⁷ the concentration (moles centimeter⁻³) of amino acids in the solution might be known. From a dry weight measurement of the protein, the grams of dry weight of protein in a milliliter of solution (grams centimeter⁻³) might be known. Regardless of the units, the value for the concentration of protein in the units of the quantity measured can be designated as C_{prot} (units centimeter⁻³). It follows that

$$W[\text{protein } i] = C_{\text{prot}} \quad (8-5)$$

where W is a constant of proportionality.

The units on W are moles of tryptophan and tyrosine (mole of protein)⁻¹, moles of peptide bonds (mole of protein)⁻¹, moles of amino acids (mole of protein)⁻¹, or grams of dry weight (mole of protein)⁻¹, respectively. It is only coincidental that the last is usually chosen. It is this exercise that defines what a colligative property is and illustrates that osmotic pressure does not measure molar mass directly. The final result can be always traced back to an independent measurement of the concentration of the protein. When Equation 8-5 is incorporated into Equation 8-4

$$\lim_{C_{\text{prot}} \rightarrow 0} \frac{\Pi}{C_{\text{prot}}} = \frac{RT}{W} \quad (8-6)$$

and the intercept of Π/C_{prot} as C_{prot} is decreased to 0 provides the value of W (Figure 8-1).^{8*} If the units of the concentration C_{prot} were grams of protein centimeter⁻³ and the only osmotically active species present were molecules of the protein of interest in a monodisperse solution, W would be the molar mass of the protein in grams mole⁻¹.

The complete equation describing the actual behavior of the osmotic pressure at low concentrations of protein is

$$\Pi = RT \left(\frac{C_{\text{prot}}}{W} + B C_{\text{prot}}^2 + C C_{\text{prot}}^3 \dots \right) \quad (8-7)$$

where B , C , ... are the virial coefficients expressed in appropriate units. In Figure 8-1, the chosen concentra-

* The units of concentration used by the authors for the data in Figures 8-1, 8-2, and 8-5 were grams centimeter⁻³. The established symbol for concentration in units of mass volume⁻¹ is γ .

tions of the protein, bovine serum albumin, are in the range where only the first virial coefficient, B , is significant, and the results are presented as if the equation were

$$\frac{\Pi}{C_{\text{prot}}} = RT \left(\frac{1}{W} + BC_{\text{prot}} \right) \quad (8-8)$$

It can be seen that when the charge on the protein was changed by changing the pH, the value of the second virial coefficient, B , and hence the slope of the line, changed in response to changes in the various parameters of the solution, but in agreement with Equation 8-6, the intercept seems to have remained the same.

The fact that the slopes of the two lines in Figure 8-1, and hence the two values of the second virial coefficient, are different arises from the **Donnan effect**. Because a molecule of protein bears a net charge at a given pH and because the two solutions on either side of the semipermeable membrane must be electroneutral, the concentrations of electrolytes cannot be the same in

Figure 8-1: Osmotic pressure of solutions of bovine serum albumin.⁸ The incremental osmotic pressure (Π/γ_{prot}), where the osmotic pressure Π is in newtons centimeter⁻² and the concentration of protein γ_{prot} is in grams of protein centimeter⁻³, is plotted as a function of γ_{prot} . The apparatus was at 25 °C, and within the apparatus the solution of protein was separated from the solution lacking the protein by a membrane of nitrocellulose polymer. The osmotic pressure of the solution was the external pressure that had to be applied to the solution of protein, in excess of the atmospheric pressure on the solution lacking the protein, to prevent its expansion. The excess pressure was measured with a toluene manometer, and millimeters of toluene was converted to newtons centimeter⁻². The concentration of protein, following the measurement, in each of the solutions containing protein was determined by a dry weight analysis that was corrected for the weight of other solutes present. The solutions contained 0.15 M NaCl as supporting electrolyte. The behaviors of the osmotic pressure at pH 7.0 (○) and pH 5.37 (●) are shown. Adapted with permission from ref 8. Copyright 1946 American Chemical Society.

the two solutions. Suppose that the only electrolyte in the solution is KCl, the solution in the compartment containing the protein is designated α , and the solution in the other compartment is designated β . To preserve electroneutrality

$$[K^+]_{\beta} = [Cl^-]_{\beta} \quad (8-9)$$

and

$$\bar{Z}_i [\text{protein } i] + [K^+]_{\alpha} = [Cl^-]_{\alpha} \quad (8-10)$$

where \bar{Z}_i is the mean net charge number on protein i . If activity coefficients are ignored for the moment,

$$\mu_{\text{KCl}} = \mu_{\text{KCl}}^{\circ} + RT \ln [K^+][Cl^-] \quad (8-11)$$

where μ_{KCl} is the chemical potential of the KCl. The chemical potential of the KCl must be the same on both sides of the membrane, and μ_{KCl}° , the standard chemical potential of KCl, is always the same, so

$$[K^+]_{\alpha} [Cl^-]_{\alpha} = [K^+]_{\beta} [Cl^-]_{\beta} \quad (8-12)$$

at equilibrium. Combining these equations

$$[K^+]_{\beta} = [K^+]_{\alpha} \left(1 + \frac{\bar{Z}_i [\text{protein } i]}{[K^+]_{\alpha}} \right)^{1/2} \quad (8-13)$$

$$[Cl^-]_{\beta} = [Cl^-]_{\alpha} \left(1 - \frac{\bar{Z}_i [\text{protein } i]}{[Cl^-]_{\alpha}} \right)^{1/2} \quad (8-14)$$

Equations 8-13 and 8-14 state that if the protein is positively charged, there will be more chloride and less potassium in compartment α than in compartment β , or that if the protein is negatively charged, there will be more potassium and less chloride in compartment α than in compartment β . These imbalances of molecular species will affect the osmotic pressure because the electrolytes cannot distribute freely across the semipermeable membrane and consequently they become osmotically active. Although there is no exact solution to these equations, at low concentrations of protein and at small values of \bar{Z}_i ⁹

$$\lim_{[\text{protein } i] \rightarrow 0} \Pi \cong RT [\text{protein } i] \left(1 + \frac{\bar{Z}_i^2 [\text{protein } i]}{4[KCl]} \right) \quad (8-15)$$

For molecules with large values of \bar{Z}_i , such as nucleic acids, this approximation fails badly.

From Equation 8-15 it can be seen that the Donnan effect is expressed in the second virial coefficient, B , as demonstrated in Figure 8-1; but when $[KCl] > 5\bar{Z}_i^2[\text{pro-}]$

tein i], the Donnan effect has less than a 5% effect on the osmotic pressure and as [protein i] approaches 0, the Donnan effect also approaches 0. For the measurements presented in Figures 8-2 and 8-5, but not those in Figure 8-1, the addition of 0.1 M KCl would satisfy this inequality.

Another way to consider the imbalances of counterions created by the Donnan effect is to assume that the charge on the impermeant protein creates an electrical potential and the permeant ions redistribute in response to this potential. This **Donnan potential** complicates measurements performed by sedimentation equilibrium and light scattering as well as osmotic pressure. In the absence of added electrolytes, gradients or discontinuities of electrical potential would form during all three of these procedures as the concentration of the protein varies within the chambers of the apparatuses. These gradients or discontinuities of electrical potential, because they arise from the Donnan effect, can be eliminated in the case of most proteins by adding a simple electrolyte such as KCl to the solution to a concentration of around 0.1 M. One way to understand the effect of adding salt is to imagine that the increase in ionic strength decreases significantly the thickness of the ionic double layer (Equations 1-71 and 1-77) so that it encloses the molecule of protein tightly, effectively neutralizes its charge, and turns it into an apparently neutral macromolecule. The added **electrolyte** also eliminates any local gradients of electrical potential caused either by separating two phases by a semipermeable membrane,¹ as in measurements of osmotic pressure, or by differential gravitational forces exerted on ions of unlike mass, as in sedimentation equilibrium.¹⁰ In addition to an electrolyte, a buffer may also be added to the solution to maintain the pH.

When a solution of protein is submitted to **sedimentation equilibrium**, it is placed in a chamber within the strong centrifugal field created by a spinning rotor, and its distribution through the chamber is allowed to reach equilibrium. Because the centrifugal force in this chamber in the rotor is a function only of the radial distance r from the center of rotation, the distribution of the protein at equilibrium is a function only of r . At equilibrium, the centrifugal force upon the protein at each point in the solution is equal but opposite in sign to the force of diffusion that arises from the gradient of its concentration. If negligible gradients of electrical potential form because sufficient electrolyte has been added to the solution, the protein will redistribute until the differential of the **chemical potential** it experiences at each position in the chamber balances the differential of the **centrifugal potential** that it experiences. For a protein, the equality produced by this balance can be expressed as

$$\left(\frac{d\Pi}{dC_{\text{prot}}} \right) \left(\frac{dC_{\text{prot}}}{dr} \right) = \omega^2 r C_{\text{prot}} \left(\frac{\partial \rho}{\partial C_{\text{prot}}} \right)_{T,P,\mu} \quad (8-16)$$

from which the exact relationship^{2,10,11} follows by rearrangement

$$\frac{d \ln C_{\text{prot}}}{dr^2} = \left(\frac{\omega^2}{2} \right) \left(\frac{\partial \rho}{\partial C_{\text{prot}}} \right)_{T,P,\mu} \left(\frac{d\Pi}{dC_{\text{prot}}} \right)^{-1} \quad (8-17)$$

where C_{prot} is the concentration of protein expressed in any units, r is the distance (centimeters) of any point in the chamber from the center of the rotor, ω is the angular velocity (radians second⁻¹) of the rotor, ρ is the density (grams centimeter⁻³) of the solution of protein, and $(\partial \rho / \partial C_{\text{prot}})_{T,P,\mu}$ is the change in density of the solution as a function only of the change in the concentration of protein. Because at sedimentation equilibrium the chemical potential through the entire solution must be the same, this change in the density of the solution is at constant chemical potential of solvent and all solutes other than the protein, as indicated by the subscript μ .

Because the derivative on the left in Equation 8-17 is that of the natural logarithm of the concentration of protein, it will have the same numerical value regardless of the units chosen to express the concentration of the protein, and the units of concentration cancel on the right. Because

$$\frac{d\Pi}{dC_{\text{prot}}} = RT \left(\frac{1}{W} + 2BC_{\text{prot}} + 3CC_{\text{prot}}^2 \dots \right) \quad (8-18)$$

and

$$\lim_{C_{\text{prot}} \rightarrow 0} \left(\frac{1}{W} + 2BC_{\text{prot}} + 3CC_{\text{prot}}^2 \dots \right) = \frac{1}{W} \quad (8-19)$$

Equation 8-17 can be combined with Equations 8-18 and 8-19 and rearranged to give^{2,10}

$$\lim_{C_{\text{prot}} \rightarrow 0} \frac{d \ln C_{\text{prot}}}{dr^2} = \frac{\omega^2}{2RT} \left(\frac{\partial \rho}{\partial C_{\text{prot}}} \right)_{T,P,\mu} W \quad (8-20)$$

As predicted by Equation 8-20, when a monodisperse solution of a particular protein is submitted to centrifugation and the distribution of that protein is allowed to reach equilibrium, the **gradient of concentration** that forms is such that a plot of $\ln C_{\text{prot}}$ against r^2 is a straight line (Figure 8-2).¹² From the slope of this plot and a value for $(\partial \rho / \partial C_{\text{prot}})_{T,P,\mu}$, the value of W can be calculated.

The independent measurement of the partial derivative $(\partial \rho / \partial C_{\text{prot}})_{T,P,\mu}$ in Equation 8-20 requires the tabula-

Figure 8-2: Sedimentation equilibrium of bovine serum albumin.¹² A solution of bovine serum albumin was placed in an optical cell in a rotor. The rotor was placed in an ultracentrifuge and spun at 24,630 rpm. The distribution of protein in the optical cell was followed by scanning the absorbance of the solution along the radial axis of the cell. After 18 h, the distribution of protein was no longer changing and equilibrium had been reached. The absorbance as a function of radial distance from the center of rotation of the rotor was measured at wavelengths of 280 nm (○) and 230 nm (△). Absorbance was converted to concentration of protein (γ_{prot} ; micrograms centimeter⁻³) and the logarithm to the base 10 of the concentration ($\log \gamma_{\text{prot}}$) was taken. Radial distance, r , was measured in centimeters and the respective values were squared (r^2). Adapted with permission from ref 12. Copyright 1966 American Chemical Society.

tion of the macroscopic density of a series of solutions containing increasing, precisely known concentrations of protein and brought to equilibrium, at the appropriate osmotic pressure, with a solution identical to the solution used to prepare the samples for centrifugation but lacking the protein. A procedure has been devised for measuring the required densities both at constant chemical potential of solvent and all diffusible solutes and at constant composition of the solution,^{13,14} and if this procedure is followed it permits the most accurate and reliable values for the molar mass of a protein to be calculated. Usually, however, the **approximation**

$$\left(\frac{\partial \rho}{\partial \gamma_{\text{prot}}} \right)_{T,P,\mu} \cong 1 - \bar{v}_{\text{prot}} \rho_{\text{sol}} \quad (8-21)$$

is made, where γ_{prot} is the concentration of protein in units of grams centimeter⁻³, \bar{v}_{prot} is the partial specific volume (centimeters³ gram⁻¹) of the protein in the particular solution chosen, and ρ_{sol} is the density (grams centimeter⁻³) of the solution in the absence of the protein. Unfortunately, because the decision to use this approximation was made for other reasons, many investigators are unaware that their use of the right-hand term in Equation 8-21 is only an approximation. This lack of

awareness can lead to some confusion.¹⁵ Furthermore, the approximation fails significantly under certain circumstances. For example, it is in error by 14% for DNA at 1 M sodium chloride and by 15% for protein in 4 M guanidinium chloride.¹⁶

The units on the term $(\partial \rho / \partial C_{\text{prot}})_{T,P,\mu}$, as is the case with the term Π / C_{prot} found in Equation 8-6, are determined by the units chosen for C_{prot} , the concentration of protein. By chance, it happens that if C_{prot} is expressed in units of grams centimeter⁻³ (γ_{prot}) and ρ is expressed in units of grams centimeter⁻³, $(\partial \rho / \partial \gamma_{\text{prot}})_{T,P,\mu}$ is dimensionless. Approximation 8-21, however, requires that C_{prot} be expressed in grams centimeter⁻³ and implicitly dictates a choice of these units for the entire equation. This assumption remains hidden in the definition of the partial specific volume

$$\bar{v}_{\text{prot}} \equiv \left(\frac{\partial V}{\partial m_{\text{prot}}} \right)_{T,P,m_j} \quad (8-22)$$

where m_{prot} is the mass (grams) of protein added to a solution, V is the resulting volume of the solution (centimeters³), and the subscript m_j states that the masses of all of the other components j in the solution must remain constant. The accuracy of this measurement is no greater than the accuracy with which the mass of the protein in grams can be known. Nor is this requirement avoided by the use of values of \bar{v}_{prot} calculated from the amino acid composition.¹⁷ In effect, this latter approximation simply relies on the care with which protein concentrations in grams centimeter⁻³ were determined in the earlier experiments validating such a calculation and demonstrating that it was reliable.¹⁸

Equation 8-20 requires an extrapolation to C_{prot} equal to 0. The purpose of the extrapolation is to eliminate the effect of the **virial coefficients** (Equation 8-19) on $d\Pi/dC_{\text{prot}}$. The same protein, bovine serum albumin, under similar conditions ($I_c = 0.1$ – 0.15 M), was used in the experiments described in Figures 8-1 and 8-2. From the values of the second virial coefficients, B , of Figure 8-1, it can be calculated that at the actual concentrations examined in Figure 8-2, the nonideality of the solution should only have affected the molar mass determined from the slope of the line by less than 0.1% of its value. Consequently, it is not surprising that the molar mass calculated¹² from Figure 8-2, 64,500 g mol⁻¹, agrees quite closely with the actual value of the molar mass of bovine serum albumin, 66,430 g mol⁻¹, a value that was subsequently established by its amino acid sequence.¹⁹ Uncoiled polypeptides or highly charged macromolecules such as DNA, however, have much larger virial coefficients, and sedimentation equilibrium of such species can be significantly affected by those virial coefficients.

At the present time, instruments that register the concentration of protein by its **absorbance** at 280 nm are

used to monitor its distribution over the cell within the rotor of the ultracentrifuge at sedimentation equilibrium.¹² Consequently, as the example of serum albumin in Figure 8–2 demonstrates, because the concentration of protein is so low, the virial coefficients can usually be ignored, but it is nevertheless prudent to perform measurements at several different concentrations of protein or several different angular velocities of the rotor or both to validate their insignificance.^{20,21}

If the virial coefficients can be disregarded so that the limit can be assumed, Equation 8–20 can be integrated, and because the concentration of protein (C_{prot}) is directly proportional to absorbance at 280 nm (A_{280})

$$A_{280} = A_{0,280} \exp \left[\frac{\omega^2 M_{\text{prot}}}{2RT} \left(\frac{\partial \rho}{\partial C_{\text{prot}}} \right)_{T,P,\mu} (r^2 - r_0^2) \right] \quad (8-23)$$

where $A_{0,280}$ is the absorbance the solution has at a reference position within the cell at which, by definition, $r = r_0$. This equation is then fit by nonlinear least squares to the distribution of absorbance as a function of radius (Figure 8–3).^{15,22,23} From the fit, a numerical value for the quantity $\omega^2 M_{\text{prot}} (\partial \rho / \partial C_{\text{prot}}) / 2RT$ is obtained. While ω^2 , R , and T are known precisely, M_{prot} and $(\partial \rho / \partial C_{\text{prot}})_{T,P,\mu}$ or its surrogate \bar{v}_{prot} (Equation 8–21) may or may not be.

Usually, independent measurements of either $(\partial \rho / \partial C_{\text{prot}})_{T,P,\mu}$ or \bar{v}_{prot} are made because the reason for the experiment is to determine M_{prot} . In the case of the p51 subunit of RNA-directed DNA polymerase from human immunodeficiency virus 1 (Figure 8–3), however, which is a monomer containing a single subunit, its molar mass M_{prot} (49,660 g mol^{–1}) was already known precisely from its amino acid sequence, and the purpose of the measurement of sedimentation equilibrium was to estimate $(\partial \rho / \partial \gamma_{\text{prot}})_{T,P,\mu}$ (0.225), a quantity that was needed for the later experiments reported. It is also possible to use the sedimentation equilibrium of a protein of known molar mass at different concentrations of another solute to determine a value for the preferential hydration of the protein, $(\partial m_{\text{H}_2\text{O}} / \partial m_{\text{prot}})_{T,P,\mu}$ in the presence of that solute.²⁴

From the molar mass of a subunit of a protein, which has been determined precisely by sequencing its constituent polypeptide or polypeptides, and the molar mass of the intact protein, which has been estimated by sedimentation equilibrium, the **number of subunits** in an intact protein can be assessed. For example, by sedimentation equilibrium, the molar mass of the UvsY recombination protein from bacteriophage T4 has been estimated to be 98.6 ± 3.9 kg mol^{–1}²⁵ and the molar mass of each of its identical constituent polypeptides is 15.84 kg mol^{–1}. The molar mass of carbon-monoxide dehydrogenase from *Moorella thermoacetica* was estimated to be 300 ± 30 kg mol^{–1} by sedimentation equilibrium;²⁶ the molar masses of its constituent polypeptides,

Figure 8–3: Sedimentation equilibrium of a recombinant form of the p51 subunit ($M = 49,660$ g mol^{–1}, $n_{\text{aa}} = 426$) of RNA-directed DNA polymerase from human immunodeficiency virus 1.¹⁵ The optical cell in the rotor was loaded with a solution of the protein with an initial absorbance at 280 nm of 0.29. Centrifugation was performed for 74 h at 12,000 rpm to reach equilibrium. The distribution of absorbance at 280 nm over the cell is plotted in the lower panel as a function of radius (centimeters) from the center of rotation. The line drawn through the points is a nonlinear least-squares fit of Equation 8–23 to the data, using as the reference position r_0 the point of highest measured absorbance, $A_{0,280}$, at the bottom of the optical cell (to the right of the graph). The upper panel is the deviation of the experimental absorbance (ΔAbs) for each point from the value of the fit at that point. The deviations are distributed at random around a value of 0.

α and β , are 81.73 and 72.92 kg mol^{–1} respectively; and the measured mass ratio of the two polypeptides in the intact protein is 1.18 g g^{–1}.

There is some confusion between the use in the present instance of a centrifugal field to create a gradient of the molar concentration of a protein and its use to measure the sedimentation coefficient, a hydrodynamic property of an individual molecule of the protein. Because the centrifugal potential at each point in the chamber can be calculated directly, at equilibrium the chemical potential of the solute, and hence its molar concentration at each point, can also be calculated. In contrast to this measurement at equilibrium, a measurement of a hydrodynamic property of a molecule of protein is, as the name implies, a kinetic measurement. In such a kinetic measurement, the rate of movement of the

molecule of protein under an applied force is measured. Free electrophoretic mobility is an example of such a hydrodynamic property. The confusion arises because, in addition to its use in sedimentation equilibrium, centrifugal force can be used to move a molecule of protein through a solution. This use of centrifugal force is unrelated to the use of centrifugal force to create a gradient of concentration. The confusion also arises because the same instrument, an analytical ultracentrifuge, is used to make each of the measurements, even though they are unrelated to each other.

The distribution of concentration as a function of radius at sedimentation equilibrium is often used to obtain a value for the **dissociation constant between two oligomeric states** of a protein that are in equilibrium with each other. For example, the protein could be an equilibrium mixture of a monomer and a dimer

for which there is a dissociation constant

$$K_{d,\alpha_2} = \frac{[\alpha]^2}{[\alpha_2]} \quad (8-25)$$

To estimate the numerical value of this dissociation constant, the mass-average molar masses can be calculated at selected radii from the respective slopes of the distribution of concentration at those radii at sedimentation equilibrium (Equation 8-20), and a plot of molar mass against concentration of protein can be fit by an equation incorporating the equilibrium between monomer and dimer.²²

Usually, however, a value for the dissociation constant is extracted directly from the distribution of the concentration of protein as a function of radius at sedimentation equilibrium. The purpose of creating the centrifugal field is to form predictably a continuous gradient in the molar concentration of the protein. If the protein is involved in an equilibrium between two forms that have different stoichiometries of subunits, the ratio between the molar concentrations of the two forms at a particular position in the sample will be a function of the total concentration of protein, $[\text{protein}]_{\text{TOT}}$, at that position. For example, in the case of an equilibrium between monomer and dimer

$$\frac{[\alpha_2]}{[\alpha]} = \left(\frac{1}{4} - \frac{2[\text{protein}]_{\text{TOT}}}{K_{d,\alpha_2}} \right)^{1/2} - \frac{1}{2} \quad (8-26)$$

Because the molar concentration of particles of protein at any position in the sample is $[\alpha] + [\alpha_2]$, the equilibrium between monomer and dimer affects the chemical potential of the protein and hence the balance between chemical potential and centrifugal potential. The result

of this effect is that the distribution of the concentration of protein as a function of radius is perturbed by the equilibrium between the two forms of the protein.

The distribution of the concentration of protein in the chamber as a function of the radial distance from the center of rotation can be fit by numerical analysis with an equation incorporating both the centrifugal potential and the perturbation caused by the equilibrium between the two forms of the protein¹⁵ to obtain simultaneously estimates of both the molar masses of the two forms and the numerical value of the equilibrium constant. For example, the distribution of the concentration of the p66 subunit of RNA-directed DNA polymerase from human immunodeficiency virus 1 at sedimentation equilibrium is consistent with the existence in the solution of an uncomplicated equilibrium between a monomer and a dimer of the subunit with a dissociation constant of 2×10^{-5} M,¹⁵ that of the subunit of chaperonin GroES is consistent with an uncomplicated equilibrium between monomer and heptamer of the subunit with a dissociation constant of 1×10^{-38} M^{6,27} and that of the subunit of CTP synthase from *E. coli* is consistent with an equilibrium among monomer, dimer, and tetramer of the subunit.²⁸ The dissociation constant ($3 \mu\text{M}$) for the equilibrium between monomers and dimers of DNA helicase II measured by sedimentation equilibrium²⁹ agreed with that ($1.4 \mu\text{M}$) estimated by counting monomers and dimers directly in an atomic force microscope.³⁰

The perturbations of the distributions of concentration at sedimentation equilibrium caused by such equilibria are slight, so a detailed analysis of the deviations of the data from the curve that has been fit to them must be made to insure that those deviations are at random (Figure 8-3) rather than systematic. Better yet, the measurements should be performed at several different concentrations of protein or several different rotor speeds or both to demonstrate that the same value of the measured dissociation constant is consistent with each of the distributions of protein observed under these different conditions.^{31,32}

Sedimentation equilibrium can also be used to rule out the existence of an equilibrium among oligomers and demonstrate that there is only one form of the protein present in the solution³³ or that there are two forms of the protein present with different stoichiometries of subunits that are not in equilibrium with each other and that are distributing independently of each other.³⁴ Again, in order to bolster the conclusion that no equilibration among oligomers is occurring, it should be demonstrated that the calculated molar mass or masses are affected neither by changing the concentration of the protein added to the cell nor by changing the speed of the rotor.^{20,21}

Light scattering is a property of any fluid. It arises because a fluid is a collection of molecules undergoing random movements rather than a rigid solid or a uniform continuum of electrons. Scattered light emerges from a

fluid at all angles to the incident direction of a beam of light passing through the fluid. The source of this scattered light is the electrons in the fluid that oscillate in response to the alternating electric field of the light and in turn emit light. The magnitude of the susceptibility of electrons in a molecule to this phenomenon arises from their respective polarizabilities, which are reflected in the refractive index of the molecule. The scattered light is emitted in directions other than that of the incident light.

The **emission of scattered light** from a solution arises from regional fluctuations in polarizability on a scale smaller than the wavelength of the light. If a fluid were a uniform, unfluctuating distribution of electrons, the scattered light from its constituent electrons would always be canceled by interference and hence no emission would result. The fluctuations producing the net scattering are related to local fluctuations in the concentrations of the components of the solution and hence to the chemical potential of those components. The majority of the electrons in a solution of protein are on molecules of water. Fluctuations in the local concentrations of water are the major contributors to the light scattered from the solution in the absence of the protein. When protein is present, the scattering arising from the molecules of protein in the solution is in addition to this background scattering.

The scattering of a beam of collimated, unpolarized light is measured by placing a detector at an angle θ to the beam of unscattered light passing through the sample (Figure 8-4) and at a distance r (centimeters) from the sample. The **incremental scattering**, i_θ , is the difference in intensity between light scattered by a unit volume of the solution of protein [photons second⁻¹

(centimeter³ of solution)⁻¹] and that scattered by an identical solution (also in photons second⁻¹ centimeter⁻³) not containing protein, and it is reported relative to the intensity of the incident light, I_0 (photons second⁻¹), of which it is a very small fraction. It can be shown^{1,35,36} that

$$\lim_{\theta \rightarrow 0} \frac{r^2 i_\theta}{I_0 (1 + \cos^2 \theta)} = RTKC_{\text{prot}} \left(\frac{\partial \tilde{n}}{\partial C_{\text{prot}}} \right)_{T,P,\mu}^2 \left(\frac{d\Pi}{dC_{\text{prot}}} \right)^{-1} \quad (8-27)$$

where \tilde{n} is the refractive index (dimensionless) of the solution of protein and the optical constant K (moles centimeter⁻⁴) is defined by

$$K \equiv \frac{2\pi^2 \tilde{n}_0^2}{\lambda_0^4 N_A} \quad (8-28)$$

where \tilde{n}_0 is the refractive index of the solution in the absence of the protein, λ_0 is the wavelength (centimeters) of the light in a vacuum, and N_A is Avogadro's number ($6.022 \times 10^{23} \text{ mol}^{-1}$). It should be noted that the units on C_{prot} , the concentration of protein, cancel in Equation 8-27. This cancellation again illustrates that the concentration of protein can be expressed in any units. Equation 8-27 also illustrates that light scattering is a measurement of the partial derivative of the chemical potential and hence the osmotic pressure of the solution of protein. The limit in Equation 8-27 is taken to eliminate any optical interference that might arise if the dimensions of the protein are close to the magnitude of the wavelength of the light.

The partial derivative $(\partial \tilde{n} / \partial C_{\text{prot}})_{T,P,\mu}$ is the change in the refractive index of the solution as only the concentration of protein is increased, at constant chemical potential of the other solutes such as electrolytes and buffers. Each of the solutions of protein used to make the determination of $(\partial \tilde{n} / \partial C_{\text{prot}})_{T,P,\mu}$ as well as the solution used in the determination of the light scattering itself, should be equilibrated by dialysis at the appropriate osmotic pressure against a solution identical except for the protein to obtain a constant chemical potential of the other solutes throughout. A procedure for measuring the required refractive indices at constant chemical potentials of diffusible components has been devised.^{2,37}

At the present time, the light source usually used for measurements of light scattering is a laser; and, if it is not already polarized, the light is passed through a polarizer. The intensity of the scattered light from a source of **polarized light** has a different angular dependence than that from a source of unpolarized light. The oscillating electric vector of the polarized light defines the z axis of a coordinate system with the sample at the origin (Figure 8-4). As defined, the x,y plane is normal to the oscillating electric vector. If ϕ is the angle between the z axis and the ray of scattered light entering the detector, then

Figure 8-4: Angular dependence of scattered light. The angular dependence of scattered light is related to a coordinate system in which the x axis is along the beam of incident light, the z axis is parallel to the electric vector of the light from a polarized source, and the origin is the center of the sample. The angle θ is the angle ABC where A is a point on the x axis beyond the sample, AB is along the x axis, B is the origin, and C is the position of the detector. The angle ϕ is the angle DBC where D is any point on the z axis, B is the origin, and C is the position of the detector. The distance r is the distance from the origin to the detector.

$$\lim_{\theta \rightarrow 0} \frac{r^2 i_\theta}{I_0 (2 \sin^2 \phi)} = RTKC_{\text{prot}} \left(\frac{\partial \tilde{n}}{\partial C_{\text{prot}}} \right)_{T,P,\mu}^2 \left(\frac{d\Pi}{dC_{\text{prot}}} \right)^{-1} \quad (8-29)$$

where θ is still the angle between the beam of unscattered light emerging from the sample and the ray of scattered light entering the detector. If the detector is confined to the x,y plane (Figure 8-4), the angle ϕ is always 90° and $\sin^2 \phi = 1$. In this configuration, to perform the necessary extrapolation to $\theta = 0$, the angle θ can be varied over all values without changing the angle ϕ . When unpolarized light is used, $\cos^2 \theta$ changes continuously as the limit of $\theta \rightarrow 0$ is taken, and this complicates the extrapolation.

It is convenient to define a quantity, R_θ , known as **Rayleigh's ratio** (centimeters⁻¹), to eliminate the dimensions of the apparatus from the calculation. For unpolarized light

$$R_\theta \equiv \frac{r^2 i_\theta}{I_0 (1 + \cos^2 \theta)} \quad (8-30)$$

and for polarized light when $\phi = 90^\circ$

$$R_\theta \equiv \frac{r^2 i_\theta}{2I_0} \quad (8-31)$$

When Equation 8-27 or 8-29 is combined with Equation 8-30 or 8-31, respectively, as well as Equations 8-18 and 8-19

$$\lim_{\substack{\theta \rightarrow 0 \\ C_{\text{prot}} \rightarrow 0}} R_\theta = KC_{\text{prot}} \left(\frac{\partial \tilde{n}}{\partial C_{\text{prot}}} \right)_{T,P,\mu}^2 W \quad (8-32)$$

The double limit in Equation 8-32 is often taken by a procedure known as the Zimm plot,³⁸ but with proteins of normal dimensions, the variation of R_θ with θ is small and inconsequential, and the extrapolation to $\theta = 0$ is a minor correction and often ignored. The extrapolation to $C_{\text{prot}} = 0$ is always required because the virial coefficients (Equation 8-7) can be appreciable (Figure 8-5).³⁹ To perform this extrapolation, a rearrangement of Equations 8-29 and 8-32, incorporating the virial coefficients explicitly, is performed:

$$\lim_{\theta \rightarrow 0} \frac{C_{\text{prot}}}{R_\theta} = \frac{1}{K} \left(\frac{\partial \tilde{n}}{\partial C_{\text{prot}}} \right)_{T,P,\mu}^{-2} \left(\frac{1}{W} + 2BC_{\text{prot}} + 3CC_{\text{prot}}^2 \dots \right) \quad (8-33)$$
